* Values are cu ft in 24 hours at a base pressure of 14.65 psia; base and flowing temperature, 60°F. The volumes obtained from these tables apply only to Orifice Well Testers manufactured by American Meter Company. For other testers, use the tables recommended by the manufacturer. The rates given in the tables for water are based on the following equation:

$$q = C\sqrt{p}$$

where

q = rate in cubic feet in 24 hours,
 C = rate for 1 in. given in the tables, and
 p = pressure in inches of water.

The rates given in the tables for mercury are based on the following equation which was determined from a series of 100 tests covering the limits of the tables:

$$q = C\sqrt{p_m(29.32 + 0.3p_m)} + \gamma_g$$

where

q = rate in thousands of cubic feet in 24 hours,
 C = 7.464 for ¾-in. orifice,
 = 13.61 for 1-in. orifice,
 = 23.10 for 1¼-in. orifice,
 p_m = pressure in inches of mercury,
 29.32 = assumed atmospheric pressure in inches of mercury
 = 14.4 psi,
 0.3 = factor determined by tests, and
 γ_g = specific gravity of gas.

*Values are thousands of cu ft in 24 hours at a base pressure of 14.65 psia; base and flowing temperature, 60°F.

The orifice used differs from that in the orifice meter. This one is thicker and has a rounded edge. This edge is placed toward the flow, for experience has shown that a sharp-edged orifice does not give reproducible results under critical-flow conditions. In fact, sharp-edged orifices do not conform to existing theories and correlations.

The general equation for a critical-flow prover is

$$q_g = \frac{Cp}{(\gamma_g T)^{0.5}}, \quad \dots \dots \dots (9)$$

where

p = pressure on prover, psia,

C = orifice coefficient for prover,

q_g = rate of flow, thousands of standard cu ft/24 hr, measured at 14.4 psia and 60°F,

γ_g = specific gravity of gas (air=1.00), and

T = absolute temperature, °R.

The critical-flow prover is one of the basic devices used for determining the gas-flow rate in the open-flow testing of gas wells. Values of the coefficient C may be found in Table 13.3.*

Pitot Tube. The pitot tube is another measuring device used extensively for testing flow rates during tests. It works by measuring the difference between the impact pressure at the tip and the static pressure in the flowing stream. This impact pressure results from conversion of the kinetic energy of the flowing gas to pressure. If the conversion efficiency is relatively constant, a conversion between pressure and flow rate is possible. The pitot tube is normally made of 1/8-in.-ID pipe and is inserted in the center of a nipple at least eight diameters long.

Table 13.4 gives the flow rate in thousands of cubic feet per day for a pitot tube inserted in different-diameter nipples.

A pitot tube is used largely for temporary flow measurement since it is small and easy to handle. Very few permanent installations are made, for it produces low-pressure differentials, is difficult to calibrate, and often clogs.

A pitot tube measures a point velocity, i.e., the velocity at only one point across the cross section of the pipe. Inasmuch as the velocity varies throughout this cross section, the problem of proper location presents itself. In the absence of unknown disturbing elements such as pipe burrs or undue roughness, the velocity at the center is theoretically 20% greater than the mean velocity. For approximate measurement, the standard tables use this factor to convert readings taken at the center of the pipe to a volume flow rate. For exact work, the mean velocity would be found by taking a series of experimental velocity measurements across the pipe diameter.

A similar method is used for large gas-flow rates and/or where debris produced with the gas makes other methods unfeasible. This consists simply of measuring

the static pressure through a side opening four diameters from the end of a nipple at least eight diameters long. Values for this system are also shown in Table 13.4. This is the least desirable of the methods discussed because of the potential error involved.

Further data on the use of these four devices for the measurement of gas flow may be found in U.S. Bureau of Mines Monograph 7.

Other Meters That Use Velocity. *Rotameter.* This is a variable-orifice meter useful for the indication of flow rates in operations (Fig. 13.5). It is economical in sizes up to 10 cm [4 in.], at moderate pressures. It can transmit electrical or pneumatic signals. Its rangeability is about 10:1.

Eccentric Orifices. These are used for many two-phase streams including those containing solids (Fig. 13.6). Substantial straight-line pipe sections are required both upstream and downstream.

Segmental Orifices. These possess the same basic applicability as the eccentric orifices with an additional advantage that they do not dam solids on the upstream side of the plate (Fig. 13.7). These are used primarily for large line sizes and low fluid viscosities.

Centrifugal (Elbow) Meters. This is used for large pipe sizes primarily. It is based on the centrifugal force induced as the fluid changes direction (Fig. 13.8). This centrifugal force is a function of velocity, R and D , as well as fluid properties. A common pipe elbow is generally used. If very accurate results are desired, calibration is necessary. Its rangeability is about 3:1.

Turbine Meters. The turbine meter has a wide range of applicability except for high-viscosity fluids. Rangeability is about 20:1. Turbine meters come in various configurations, but they all transmit a signal based on rotation speed, which in turn is a function of flow rate and fluid properties (Fig. 13.9). It is difficult to generalize about this type of meter because some have

*A set of constants in SI metric units has not been officially adopted at this time. Therefore the constants in customary units are used (Table 13.3) and final results are converted to SI metric units. The readers are advised, however, to refer to the official standards in their area for the appropriate tables and equations presented in this chapter.

Fig. 13.7—A segmental orifice.

proven very good and some very bad in a given application. For this reason, the choice should be based on experience with a given model in a given service.

Bearings can be troublesome. Ball bearings may be susceptible to damage by abrasive solids; sleeve bearings tend to be more trouble-free but rangeability may be reduced.

When properly selected, turbine meters are very acceptable. Their acceptability for custody transfer has been slow in some areas because of lack of proven experience compared with the orifice meter. Liquid turbine meters have been accepted more readily than those for gas service because they could be tested more readily.

Repeatability is often $\pm 0.05\%$ on test and accuracy is within $\pm 1\%$. Like all meters, these values are a function of meter condition.

The axial flow turbine meter has proved useful for high gas-flow rates. Its rangeability is up to 100:1 and it has a linear response to flow rate. A summary of performance of these meters is found in Refs. 5 and 6.

Vortex Shedding Meter. This is a newer meter for measuring all fluids that do not have too high a viscosity (Fig. 13.10). It has no moving parts, wide rangeability, and is linear over wide ranges of flow.

Fig. 13.11 shows the principle involved when a fluid flows around a blunt object. The flow is unable to follow the surface of the object and sheds from it at some point to form a continuous series of eddy currents. The frequency of shedding is proportional to flow velocity and inversely proportional to the diameter of the object. This shedding may be sensed by thermistors or by what is called a "shuttle ball" contained in the fixed flow element. Movement of this ball is detected by a magnetic sensor. This ball-type is suitable for low-density, clean liquids.

Sonic Meters. Sonic meters offer many potential advantages if they can be made so that they remain stable electronically and overcome drift tendencies. They possess no moving parts and have linearity.

They contain three components: a transducer assembly, transmitter, and a receiver. The transducer assembly shown in Fig. 13.12 contains two transducers that alternately transmit sonic pulses diagonally across the pipe. The difference in transit times is proportional to flow velocity.

Regulation

Principles of Control

The regulation of pressure and temperature flow or level is an integral part of the regulation of gas and liquid streams. A means is necessary to sense the value of the controlled variables and then cause the movement of a valve to maintain the value desired. The communication link between sensing element and valve may use gas (pneumatic), liquid (hydraulic), electricity, and electronics. More than one may be used in a given system by employing a *transducer*, a device for converting signals.

Historically, most of the systems used pneumatic controls, so they will be used to illustrate the principles involved. However, the use of electrical and electronic controls is increasing rapidly. When a control system is chosen, these also should receive serious consideration.

Many of the routine problems encountered with lease equipment stem from failure or misapplication of controls. This has become even more pronounced in recent years as this equipment has become more complex.

Oilfield instrumentation is less complex than that in plants and refineries but imposes severe service conditions. In such service, the instruments often have only wet supply gas and rare adjustment by expert servicemen and are exposed to the elements, yet must give continuous and trouble-free service. Even with these severe conditions, it must be concluded that many troubles stem from improper application rather than inadequacy of the controls themselves, although many types are not suitable for oil-field use.

Definitions

To choose controls properly, it is necessary to know not only the requirements of the process but also the corresponding characteristics of the controls available. No understanding of controls may be complete without a familiarity with applicable definitions.

Pneumatic controls are those actuated by air or gas (the most common type used in the field).

Diaphragm motor valve is the term applied to a complete valve that uses pressure to open and close it.

Topworks (motor) is that portion of the motor valve that contains the mechanism to open and close the valve.

Inner-valve assembly (trim) includes the stem and seat within the valve body that actually controls the flow of fluid.

Fluid is any liquid or gas being controlled.

Proportional control describes the system whereby the valve opening is proportional to the degree of change in the controlled variable.

Snap action is a mode of control whereby the valve is either wide open or closed (on/off control).

Fig. 13.8—A centrifugal (elbow) meter.

Fig. 13.9—A turbine meter.

Fig. 13.10—Karman vortex trail.

Fig. 13.11—Vortex flow pattern.

Fig. 13.12—A sonic flowmeter.

Reset is an addition to a proportional-control system to enable the instrument to hold itself at the control point as the process load varies.

Derivative response is a further addition that provides corrective action based on the time rate of change of the deviation from the control point.

Self-operated controller is a valve that is actuated directly by the controlled variable.

Pilot is a relay that transforms the controlled variable into an equivalent signal to the control valve, such signal controlling the action of that valve.

Supply gas is that gas necessary in a pneumatic pilot to operate it.

Controlled variable is the pressure, liquid level, temperature, or flow rate being controlled.

Measuring means is the means used to detect any change in the controlled variable.

Sensitivity is the ability to detect small deviations in the controlled variable.

Reproducibility is the ability of an instrument to repeat and measure consistently the values of a static condition over a period of time.

Static error is the difference between the absolute value of the controlled variable and the measured value.

Lag is the period of time by which the measured value follows the change in the absolute value of the controlled variable.

Static conditions occur when all changes in the controlled variable are instantaneous.

Dynamic conditions occur when the controlled variable is continually changing.

Normally closed valve is a valve that is held closed by a spring or some similar device and is opened by the action of pilot and/or the controlled variable.

Normally open valve is the reverse of the above; one that is closed by the action of the pilot and/or the controlled variable.

Drift includes reproducibility and the inability to repeat a measurement because of changes in the measured variable.

Process Characteristics

Because the purpose of an automatic controller is to regulate a process, it is fundamental that the properties and characteristics of a process be understood. A process is defined as the collective functions performed in and by equipment in which a variable is controlled. As an example, a field heater that heats well effluent by circulating hot water is a unit of equipment in which the process of heating the wellstream is accomplished. The process consists of a controlled variable (the temperature) and a controlled medium (the wellstream). Other controlled variables could be rate of flow, liquid level, or pressure. A control agent (circulating water) is the medium for effecting the temperature change, and thus regulation of the control agent regulates the controlled variable. The total requirements of the process for the control agent at any one time are defined as the process load. If the rate of flow of the wellstream increases, then more or hotter water is required to maintain the same temperature, and a change in process load has taken place. By the same token, a drop in inlet temperature at the original rate of flow would also constitute a process-load change.

The properties of an entire process include its potential, capacitance, resistance, and dead time. Capacitance, not to be confused with capacity, is the change in the quantity of energy or material per unit change in some variable, usually the controlled variable.

Resistance, or opposition to the flow of energy or material, is another process characteristic. The most familiar concept of resistance is in electricity when it is expressed as the ohm.

Potential is most generally recognized in the concept of electricity where it is expressed as a volt. Table 13.5 summarizes the characteristics of a process.

Dead time is the time lag that occurs when energy is being transferred at a constant rate of flow through a given distance. It is equal to the time it takes the energy to move the distance. The dead time is a characteristic of the process, and it is not to be confused with the time lag inherent in the automatic controller itself.

The purpose of the automatic controller is to prevent deviation of a process from a desired standard. This may be accomplished by various modes of control action, each of which incorporates a distinct limit, range, and speed of correction.

TABLE 13.5—PROCESS CHARACTERISTICS

Process Characteristic	Thermal	Pressure	Liquid Level	Electrical
Capacity	Btu	cu ft	cu ft	Coulomb
Potential	degree	psi	ft	volt
Capacitance	Btu/degree	cu ft/psi	cu ft/ft	Farad
Resistance	degree	psi	ft	ohm
	Btu/sec	cu ft/sec	cu ft/sec	

Fig. 13.13—Liquid-level control using displacement-type float.

Proportional Control. The modes used depend on the frequency and magnitude of the process load changes, the degree of control needed, and the dynamic lag inherent in the process and controls used.

Proportional control is the basic action that is employed in all controllers not using snap (on/off) action. Because it is defined as control action in which a continuous linear relation exists between the value of the controlled variable and the position of the valve, the following equation may be written.

$$\frac{dp}{dr} = S \frac{dy}{dr}, \dots\dots\dots (10)$$

where

dy/dr = rate of change of the controlled variable with time (level, pressure, etc.),

dp/dr = rate of change of pilot output pressure or current signal with time, and

S = characteristic constant of the pilot relating output to input.

This characteristic is represented by the sensitivity usually expressed as a percentage. The proportional band or range, expressed as a percentage, relates the percentage of the full range of the measuring means that the controlled variable has to traverse to stroke the valve fully. This is illustrated in Fig. 13.13.

This figure represents a typical level-control application using a displacement-type controller—i.e., one that does not float on top of the liquid but depends on the varying buoyancy of the liquid as the level changes. Consequently, the control range is represented by the distance between Points A and B, because below A or above B a change in level has no effect on the buoyancy of the float.

Therefore, at 100% proportional control the level would have to move from A to B or vice versa, to stroke the valve fully from full open to closed. At 25%, a level change of $0.25 \times \text{distance AB}$ would fully stroke the valve, etc. The same principles apply with all other modes of control, including gas regulation.

Example Problem 2. A backpressure controller with a range of 0 to 100 psig is set at 50% proportional control,

Fig. 13.14—Characteristics of proportional control.

using a normally open valve. If the valve is open at 100 psig, (a) at what pressure will it be fully closed? (b) what is the opening at 75 psig?

Solution. The control range is 100 psig, which at 50% proportional control means that a $0.50 \times 100 = 50$ psig change will fully stroke the valve; therefore it is fully closed at 50 psig. At 75 psig it would be half open.

The amount of fluid that a valve will pass at a given position depends on the size and characteristic of the inner-valve assembly. Ideally, the amount of fluid passed under given conditions, with a given valve, should be directly proportional to the valve opening. Often it is not, however; so that the type of inner valve has a definite effect on the proper proportional setting. Also ideally, the diameter of the inner valve should be such that the range of anticipated process loads may be handled when the valve is between 25 and 75% open. In the final analysis, the choice of the proportional band to use in a given installation must be governed by experience and adjustment on the job.

This is illustrated in Fig. 13.14. The slope of the lines depends on the proportional band used, each line representing a valve of given size. Under these conditions, each valve may operate only along a single line, in accordance with Eq. 1.

If the instrument was set to control at 60% of the range, Valve A would be 50% open; Valve B, 25% open; and Valve C, 75% open.

Suppose, however, that an instrument set to operate along Line A is in gas-regulation service and the flow rate increases such that a valve opening of 75% is needed to maintain the pressure. According to Line A, the only way the proportional controller can provide this opening is for the pressure to be at 70% of the range, or 10% above the set point. This 10% is called offset.

Consequently, with proportional control alone a change in process load brings a change in the valve position and some change in the liquid level. The proper proportional setting is therefore one which makes the lines in Fig. 13.14 as perpendicular as possible.

Zero per cent proportional control represents a special case. It is the upper limit of a range where the pressure is controlled by the valve alternately opening and closing. This is normally called snap action or on-off control. At a given snap setting, the valve will stay closed until the liquid level reaches a certain point between A and B and

Fig. 13.15—On/off action of a controller.

Fig. 13.16—Proportional action of a controller.

Fig. 13.17—Valve action for reset and proportional controllers (at left); valve action for combined proportional/reset controller (at right).

Fig. 13.18—Typical control curves when using a proportional/reset controller.

then remain full open until the liquid level drops to the control point. Where rapid process load changes are encountered, such as surging flow through separators, snap action is normally recommended.

Reset. The "offset" obtained with proportional control is sometimes too great to be tolerated and it is necessary to add other modes of control. One such addition is known as *reset*.

Figs. 13.15 and 13.16 show on/off action and proportional action, respectively. In the latter, it is seen that the amount of valve movement is proportional to the deviation of the measured variable. By contrast, the amount of correction applied with reset action depends on both the magnitude and duration of the deviation away from the control point. The prime purpose of reset is therefore to prevent "offset" and keep the controlled variable at the control point even as the process load changes.

The differential equation of a controller with proportional plus reset action is

$$\frac{dp}{dt} = S \frac{dy}{dt} + SR(y - y_o), \dots\dots\dots (11)$$

where dp/dt , S , and dy/dt have been previously defined, R = controller reset constant, and $y - y_o$ = duration of the controlled variable from the control point.

In this type of controller, the two corrections occur simultaneously as shown in Fig. 13.17 (this figure also shows whether the actions took place separately).

Fig. 13.18 shows typical curves in a process being controlled by this combination action. When a change in process load takes place the valve returns the measurement to the control point with a minimum of cycling. The original motion of the valve corresponding to the measurement change is caused by proportional action, but the change of the valve to its new position is due entirely to reset. In other words, the valve has moved to a new position to maintain the controlled condition. With only proportional control both the valve and controller would have changed.

Derivative Response. Proportional control plus reset does not provide correction that is rapid enough for certain processes. Derivative response may therefore be added to anticipate a change in process load and transmit a corrective signal to minimize the lag. This action corrects on the basis of the rate of change of the deviation from the desired standard. This term stems from the fact that the first derivative of the change from the desired standard is incorporated into the control mechanism. The equation for an instrument with proportional plus reset plus derivative response is therefore

$$\frac{dp}{dt} = SR(y - y_o) + S \frac{dy}{dt} + SF_{ia} \frac{d^2y}{dt^2}, \dots\dots\dots (12)$$

where F_{ia} is an instrument-adjustment factor. The action of a controller with this response is shown in Fig. 13.19.

The general applications of the various combinations of control action may be summarized as follows:

Proportional. Where process time lag is small in comparison with the apparatus capacity such as tank heating or large surge vessels, or where "offset" may be tolerated.

Proportional Plus Reset. Where it is necessary to use a narrow band to prevent "hunting" or overcontrol, and as the frequency and magnitude of the process load changes become greater.

Proportional Plus Derivative Response. In processes involving long time lags and large capacities when small and frequent load changes occur. Does not provide compensation for process load changes.

Proportional Plus Reset Plus Derivative Response. Where long time lags and large capacities are combined with large and sudden load changes.

Because the addition of reset and derivative response increases the investment cost, they should not be used unless their action is needed for proper control.

Liquid-Level Control

The control of liquid level is an integral part of gas processing. It furthermore affords a means of illustrating the general problem of instrumentation and gas regulation. In view of the widespread applications and the variety of conditions encountered, it is not surprising that a number of mechanisms are used. These may be conveniently subdivided as: (1) mechanically operated valve actuated by a float; (2) pilot-operated valve actuated by a float; (3) diaphragm motor valve actuated by (a) displacement-type controller and (b) "floatless" level controller; and (4) external devices, including inverted bucket traps, float traps, etc.

Either snap action or proportional control is normally employed on most lease equipment. Most applications do not justify the cost of reset and/or derivative response since small changes in level with flow rate and time lag are usually not critical problems.

Separator controls, in fact, are usually set on snap action because this enables the controller to handle a surging condition better. The degree of snap action will depend on the conditions encountered. However, it should be set so that not over 25% of the vessel's liquid capacity is filled, above the control point, before the valve opens. The inner-valve size should be determined on the basis of 110% of the maximum flow to be encountered. This means that during a surging condition the valve can handle the volume and prevent the separator from filling up.

Some uncertainty always exists, of course, when one tries to estimate future flow rates. On low-pressure separators, sizing is not a serious problem because of the low-pressure drop across the valve. On high-pressure gas-condensate separators, however, where the liquid flow rate is low, too large an inner valve on snap action can blow all the liquid out of the separator and allow gas to enter the stock tank before the valve can close. The author observed one such installation when 1,000-psig gas hit a 100-bbl tank, knocked the cover off the vent valve, sprayed oil over the countryside, and lifted the tank off the ground.

The manufacturers of control valves furnish sizing curves, and these should be consulted. In using these, it should be remembered that critical-flow conditions occur when the upstream pressure is approximately twice the valves' downstream pressure. Consequently, only twice the downstream absolute pressure should be used with these sizing curves if the actual pressure ratio exceeds 2.

When handling very small volumes of liquid, the use of such curves often indicates the use of so-called "metering trim." Its use is not recommended in field applications, for the small quantities of solid materials often present may clog the valve. For this reason, nothing smaller than $\frac{3}{16}$ -in. needle trim is usually recommended in field service.

Float-operated mechanical oil valves are satisfactory at pressures up to 125 psig. Such valves are directly actuated by movement of the float on top of the liquid,

Fig. 13.19—Typical control curves for proportional, reset and derivative-action controllers.

through an adjustable linkage. At higher pressure, the leverage supplied by the float is insufficient to provide satisfactory valve action because of the pressure acting on the valve seat. On separators with greater than 125-psig working pressure, the use of a pilot-operated valve is advisable. Whenever applicable this type of control is very dependable and simple to adjust and repair.

Float-actuated pilot-operated valves are particularly applicable at pressure to 1,000 psig on vertical vessels. Such control has been "standard" on separators for years because the pilot is rugged and simple and will operate satisfactorily with the "wet" supply gas from the separator overhead.

This overhead gas contains entrained liquid so that a drip pot ahead of the pilot is advisable. With high-pressure separators, the expansion of gas from separator to instrument pressure may cause sufficient temperature drop to condense some water. This in turn presents hydrate or freezing problems, particularly in cold weather. A variety of solutions have been used, including tracing with warm separator gas, use of dehydrator pots, running such gas through a heater or treater if available, and insulation of the lines.

Displacement-type liquid-level controls use the buoyant effect of liquid on the float. The average float movement does not exceed $\frac{3}{16}$ in. As the level varies on the float, the weight changes correspondingly and this change in torque is transmitted to the pilot, which, in turn, controls the valve movement. This type of control is applicable in all pressure ranges but is used primarily at high pressures and/or in horizontal vessels. Because of the small movement and small float diameter, the vessel opening may be decreased. This advantage becomes pronounced at high pressure or on small-diameter horizontal vessels.

The pilots on such controls are more sensitive than those discussed above, which allows one to control the level more closely. Most such pilots also allow the valve action to be changed from snap to varying degrees of proportional control by a simple adjustment.

They are necessarily more complex and expensive. Consequently, their use must be justified by process requirements. The instrument gas requirements are also more critical, because as little as one drop of water may plug the small orifice in some pilots.

Floatless level controls are a relatively new development. With these, the pilot is actuated by the varying liquid head in the vessel. As the liquid rises in the separator, it overcomes the pilot spring and forces the pilot assembly upward, closing the upper seat and opening the lower separator seat, which vents the diaphragm pressure to atmosphere. The separator fluid pressure then opens the valve. When the valve is throttling, the nonbleed three-way valve action of the pilot plug against its seat adjusts the motor-valve diaphragm pressure. This type of control has the obvious advantage of eliminating large vessel openings and offering application on very small vessels.

External devices such as float cages and traps find application particularly on vessels with small and/or infrequent liquid loads. Some types of float cages offer no particular economic advantage at high pressure. They are most commonly used on low-pressure plant suction and instrument systems. Inverted bucket traps have been successfully used on small glycol absorbers for economic reasons but regular level controls certainly offer advantages.

At high pressures, a choke nipple downstream from the control valve is advisable, for it (1) provides a factor of safety if the valve "cuts out" or fails to close for any reason; (2) reduces the pressure differential across the valve, which improves the valve action and enables it to shut off tighter; and (3) prevents damage to low-pressure equipment downstream if the instrument supply gas fails on a normally open valve.

The control range with a float-operated controller is limited by the flange diameter and the float-arm length. With a displacement element, control is possible only throughout the float length, for a change in level above or below the float does not affect the buoyancy. Therefore, the desired change in level should not exceed the float length.

The choice of a liquid-level control is somewhat arbitrary, but it is good policy to choose the simplest control that will meet process requirements. Average lease-operating conditions impose severe service on the control, and the ability to make repairs with field personnel will generally reduce downtime.

Types of Regulators

The regulation of backpressure and pressure reduction in a system may be conveniently divided into three categories when considering the type of system needed. The low-pressure range is usually 0 to 125 psig; the intermediate pressure 125 to 500 psig; and the high pressure greater than 500 psig. The use of these ranges is primarily for convenience since some types of valves can operate satisfactorily in all of them.

All pressure regulators are similar in principle, the specification of type being dependent on the process requirements, pressure drop, variation in flow rate, limitations of the loading device, and the maximum pressure. In either of these services, pressure is regulated by the control of flow rate.

This flow is controlled through movement of the regulator inner valve, which is held either open or closed by some means of preloading. The amount of preloading and the size of the diaphragm used, if any, are such that the inner valve will move to the opposite extreme of

travel shortly after the diaphragm pressure passes the desired working pressure. The control pressure, therefore, is varied by changing the amount of preload, thus upsetting the equilibrium between it and the diaphragm pressure. With most valves, increasing preload increases pressure.

The preloading may be accomplished through the use of spring compression, dead weight, or fluid pressure. Valves a and b in Fig. 13.20 are examples of weight-loaded and spring-loaded valves, respectively. Valve c is a spring-loaded valve incorporating a pilot.

In backpressure service, the preloading normally closes the valve, while in pressure reduction the valve is normally open. With the former, the upstream pressure is introduced under the diaphragm and works against the loading device to position the valve properly. In pressure-reduction service, the downstream pressure is introduced under the diaphragm and tends to close the valve until the inner valve is properly positioned. Many valves may be changed from one service to the other by simply reversing the valve body and the stem, while still others have provision for reversing the diaphragm action.

Some applications require that a certain differential pressure be maintained across the valve regardless of how much the upstream or downstream pressures vary. The chief application of this is with positive-displacement pumps where the maximum pressure ratio is controlled by a valve located on a bypass.

In this service, the valve is normally closed with the downstream (higher) pressure under the diaphragm and the upstream (lower) pressure on top of the diaphragm. The desired differential is then established with the loading device.

Each of the types of preloading has its distinct applications and limitations. The weight-loaded regulator is very sensitive within its pressure range if the flow rate does not vary widely. This is true primarily because the inner valve may move through a greater change of position than with a spring-loaded valve. The greater sensitivity is particularly pronounced when the diaphragm is in direct communication with the valve body, which eliminates friction in the stuffing box.

Very few weight-loaded regulators are recommended above 50 psig because at greater pressures heavy weights are necessary. As a result, a small change in controlled pressure is only a small portion of the loading weight, and there is less subsequent movement of the inner valve, which in turn renders control more difficult.

A spring-loaded regulator is generally slightly less sensitive than a comparable weight-loaded regulator under constant-flow conditions. In low-pressure service, (particularly between 0 and 20 psig) it is an ideal type of loading, for the springs used tend to compress in direct proportion to the load, with constant load increase being required for each increment of compression. Consequently, spring loading is excellent in low-pressure systems and where the diaphragm is loaded with a pilot. Because each compression increment is a valve-travel increment, the valve travel is always in proportion to the relationship of the controlled pressure to the preloading. At high pressure, this characteristic does not exist because of the heavy springs required. Therefore, non-pilot-operated spring-loaded regulators are not normally

Fig. 13.20—(a) Weight-loaded backpressure regulator. (b) Pressure-reducing valve. (c) Backpressure valve with self-contained pilot.

recommended above 125 psig because of this loss in sensitivity and their closer approach to the price of pilot-loaded regulators.

With either a direct-acting weight or spring-loaded regulator, a change in the uncontrolled pressure will cause a corresponding change in the controlled pressure if the pressure drop is low. This is true especially if the pressure drop is less than 25% of the inlet pressure. Therefore, when accurate control is necessary under these circumstances, pressure-loaded or pilot-operated valves are recommended.

Both the regulation of flow and tight shut-off should not normally be attempted with the same valve unless absolutely necessary. If this is required by operating conditions, a single-seated valve should be used. Double-seated valves are seldom operated under the actual conditions at which they were manufactured and tested.

Consequently, as temperature changes the distance between the two seats, only one of the two will seal off tight.

Single-ported valves will seal off tight but the unbalancing force on the inner valve increases with the square of diameter. Because the diaphragm/spring combination must overcome this force and still control travel, it is logical that the inner-valve size is limited by practical diaphragm size. As a general rule of thumb, direct-acting spring- and weight-loaded regulators up to 2-in. diameter may be used with single-port construction.

Pilot-loaded valves, either pressure-balanced or spring-loaded, offer particular advantage at higher pressure since the pilot presents a means of increasing the control-valve travel with a given change in controlled pressure. This enables one to use a more accurately sized valve. The resultant smaller valve gives better shutoff and closer control because the full range of travel may be utilized.

Low-Pressure Service. It is in this pressure range that weight- and spring-loaded regulators find particular application on the lease. One of the most common applica-

tions is in back-pressure service on low-pressure separators operating at less than 40 psig. All the valves shown in Fig. 13.20 are applicable. One modification of a diaphragm-type weight-loaded valve is used where the weight simply acts to counteract the unbalanced force acting under the inner valve. The choice of this valve is predicated primarily from cost considerations since it is the cheapest of the valves. No diaphragm is used.

The simple weight-loaded valve has the advantage of being cheap and simple. Its primary disadvantage stems not from its operation but from the circumstances surrounding its use. The weights become loose and shift, are lost, or are hindered in movement by outside obstructions. It is not too uncommon to see rocks and other miscellaneous objects used as substitutes for, or additions to, the proper weights. Consequently, these regulators serve as a proper but not necessarily completely satisfactory backpressure control.

Not too many spring-loaded regulators are used on separators because of their higher price, although they are generally satisfactory below 40 psig. The best regulator in this range is Valve c, Fig. 13.20. It gives fine control throughout the range with widely fluctuating flow rates and uncontrolled pressures. Where fine control is necessary, particularly above 40 psig, the extra investment is normally justifiable.

Because of the almost infinite number of different field conditions that arise, the above considerations can at best serve only as a general guide. Unfortunately, the actual choice of type must often stem largely from past experience.

High-Pressure Service. At pressures above 125 psig, it is usually difficult to justify anything other than a pilot-operated diaphragm motor valve for pressure control. Non-pilot-loaded valves are sometimes applicable but usually only in those circumstances where pronounced load changes are not encountered. At these higher pressures, the cost differential also becomes less, which further encourages the use of pilot-operated controls.

Fig. 13.21—Proportional pilot for pneumatic service.

Most pilots now in use in the oil field are pneumatic in nature and use natural gas as the actuating fluid. Any natural gas that is free of fluids and at a pressure greater than 15 psig is suitable in this service.

Fig. 13.21 is a schematic view of a pressure pilot that will give both proportional and on/off control. As the controlled pressure varies, the bourdon tube will change shape and, in turn, raise or lower the curved bar.

The supply pressure is held constant between 15 and 20 psig by the pressure regulator. The vent nozzle is so sized that when wide open (curved bar away from it) it will pass more gas than the orifice. Consequently, the pressure on the valve diaphragm and the valve position depends on the opening of the vent, which in turn depends on the position of the curved bar, as fixed by the bourdon tube. If the vent is wide open, the pressure on the diaphragm is zero, while if it is fully closed, the diaphragm pressure equals the controlled supply pressure.

It is necessary that both the vent and orifice be very small to minimize the amount of gas vented. If the curved bar had a fixed pivot rather than a bellows, only on/off (snap) action would be possible because of these small openings. From a purely mechanical standpoint, any small movement of the curved bar would in effect make the vent wide open.

The bellows is used to impart a rotating motion to the curved bar around the end of the vent. When the bar begins to rise off the vent, the bellows contracts, which tends to keep part of the vent opening covered. As a result, more vertical movement of the bar is necessary to open (or close) the valve fully. All points in between then represent some degree of proportional control.

The vertical distance that the bourdon tube has to lift the bar to stroke the valve completely increases as the lever arm decreases. This then allows for adjustment of the proportional band.

If the vent is close to the left end of the curved bar, the movement of the bellows imparts little rotation to the bar and on-off action results.

Most pressure pilots have the bar marked to show various percentages of proportional control. The percentage shown indicates that the controlled variable must vary through that percentage of the instrument's range to open or close the valve fully.

Example Problem 3. If a pressure pilot has a bourdon tube with a range of 0 to 200 psig and it is set on 50% proportional control, how much must the pressure vary to make the valve be fully stroked?

Solution. It must vary $(0.50)(200 - 0) = 100$ psig to stroke the valve fully.

From the discussion above it therefore follows that the closer the vent is to the bellows, the higher the percentage of proportional control obtained.

Most pressure pilots are slightly more complex than the schematic presentation in Fig. 13.21, to improve the mechanical action and the sensitivity. However, the basic mechanism and principle of operation shown is common to all pneumatic pilots.

In most applications, the valve is spring-loaded, but there are some applications where a large quantity of high-pressure gas must be controlled with a low-pressure drop. Such an application is encountered with the switching valves of a dry-desiccant dehydrator. A large inner-valve assembly is required, which increases the unbalanced forces on the diaphragm, which in turn necessitates a heavy spring. In such cases, the use of a pressure-loaded balanced diaphragm valve is indicated. With this type, greater valve travel may be obtained, with less change of controlled pressure than with any other type. With a constant loading pressure, on a larger balanced diaphragm, the available force to travel the valve with incremental change of control pressure is greater than with a spring-loaded valve because of spring characteristics. However, spring loading is simpler wherever applicable.

The greater the pressure drop across a valve, the greater the unbalanced force that exists. Where this pressure drop is greater than several hundred psi, it is good practice to install a choke nipple downstream from the valve. This choke nipple should preferably be about 10 to 25% larger than the inner valve so that the latter is the controlling element. The nipple serves two purposes:

Fig. 13.22—Typical pressure control for a high-pressure well.

Fig. 13.23—Small high-pressure spring-loaded pressure regulator.

(1) it reduces the pressure drop across the valve and increases sensitivity; and (2) it acts as a secondary control in the event the valve fails to close or cuts out.

The pilot shown in Fig. 13.21 may be modified to give what is known as high-low shut-off. A pilot so modified will cause the valve to close if the controlled pressure becomes higher (or lower) than the preset condition. This modification has particular application in high-pressure wells to (1) shut in the well in the event a line break is encountered; and (2) prevent overpressuring of a separator or other piece of equipment downstream from a choke or valve.

In some instances, it is desirable to use an automatic rather than a manual adjustable positive choke. A regular diaphragm-motor-valve topworks may then be combined with the choke body to give a control valve and choke combined. Although it costs more, there is some advantage to using the positive choke as a rough control with a separate valve at the wellhead for safety. Fig. 13.22 illustrates such a scheme where several wells are being flowed to a central low-temperature separation unit, the pressure drop being taken at the unit. The valve at the well protects against line break while the back-pressure valve at the separator holds the separation pressure constant regardless of how the sales line pressure varies. The two control valves fix the pressure drop across the choke, with the flow rate being determined by the choke setting.

Where very high formation pressures are encountered, one or more "storm chokes" in the well proper make a desirable installation.

Fig. 13.23 shows a spring-loaded valve for pressure-reduction service. This is a popular valve for pressure regulation in services where the rate of flow is not large. The pivot point on the arm is so located that it ratios the force on the inner valve down to where the spring can control properly.

Fig. 13.24 shows a double-port diaphragm motor valve that would be controlled by a separate pilot, such as that shown in Fig. 13.21. Fig. 13.25 shows several of the different types of inner valves that might be used in the double-port valve shown. The shape used depends on the service and the type of control desired. The same

Fig. 13.24—Typical spring-loaded motor valve.

general shapes of inner valves are also available in single-port valves.

Control of Field Compressors

Most of the controls on a field booster compressor are designed to protect the equipment and facilitate operation with minimum attention; it is theoretically possible to operate the system with little more than manual control. The exact scheme used will of course vary with the application, but that shown in Fig. 13.26 is typical of small-lease operations where low-pressure gas is compressed in one stage.

No control and cooling system is shown for the engine since this will depend on the engine manufacturer. On most small portable units, the engine is self-contained

Fig. 13.25—Several types of inner valves used in double-port valves.

with its own radiator and pump. If two-, or more, stage compression is used, the controls shown for the inlet scrubber would be duplicated for each interstage scrubber. A provision would also have to be made for interstage gas cooling.

The backpressure controller shown on the vent is to prevent overpressuring of the separator in case the compressor plant is down. The other backpressure valve on the suction line is to prevent the plant from lowering the separator pressure by drawing off gas faster than it is produced. It should be set several pounds lower than the valve on the vent line.

The meter run is shown at the plant, although it could be conveniently located at the separator. A check valve (Location 12) is included to prevent the backflow that may result when multiple units feed the same compressor.

A butterfly valve (Location 14) is an optional but desirable item to control the compressor suction pressure. All compressors are rated using a given suction and discharge pressure, and this valve simply prevents the former from getting too low and overloading the unit. This valve is particularly desirable if the deliverability of gas to the plant is widely variant.

The inlet scrubber is primarily a protective device to keep liquid out of the cylinders and should not be used as a primary oil and gas separator. This vessel serves simply as a liquid sump and a convenient device on which to hang certain necessary controls. As a convenient rule of thumb, this vessel should have a cross-sectional area of at least 100 sq in./MMcf/D of gas processed. The minimum size is normally 12 in. A float-operated trap (Location 6) is very satisfactory for controlling the liquid level.

Switches (Locations 1, 2, 7, and 8), constitute the basic safety shutdown system. These switches are normally open, but if the condition at any one goes beyond set limits, it closes, grounding out the engine magneto, which in turn stops the engine. All are simple and inexpensive and afford positive protection. A horn and/or remote indicator may be incorporated that is actuated at any time the compressor stops.

Switches at Locations 1 and 8 are high- and low-pressure shutdown, respectively. They serve to keep these pressures within the limits set up for the compressor. The switch at Location 2 is a high-temperature shutdown that is actuated by the hot water leaving the cylinder jacket. It shuts down the unit when any failure occurs in the cooling system.

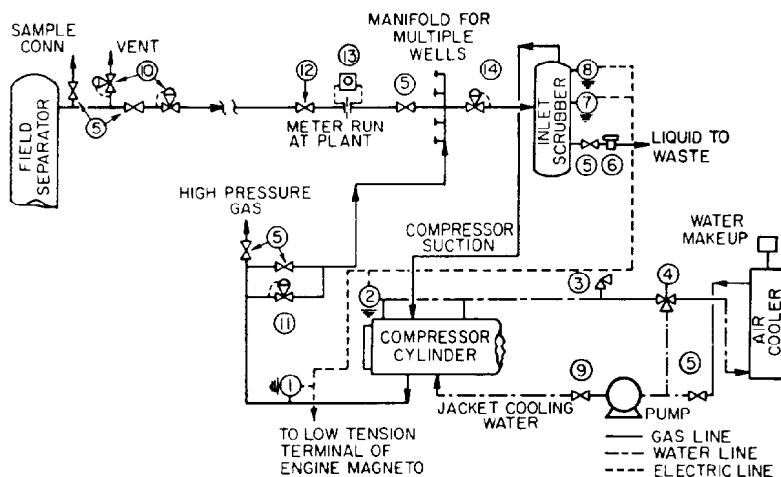

Fig. 13.26—Typical control system for field compression of natural gas. (1) High-pressure shutdown switch. (2) Water-temperature safety switch. (3) Low-pressure liquid-relief valve. (4) Water-temperature bypass control. (5) Plug valve. (6) Trap-type level control. (7) High-level shutdown. (8) Low-pressure shutdown switch. (9) Globe valve. (10) Low-pressure backpressure controllers. (11) Relief valve. (12) Check valve. (13) Orifice meter. (14) Low-pressure pilot-controlled butterfly valve.

The switch at Location 8 is a high-level shutdown that operates when the liquid level becomes too high in the scrubber because of either failure of the valve at Location 6 or an excess quantity of liquid entering the plant.

The bypass valve at Location 5 is desirable because it provides a means of taking the load off the compressor, particularly during start-up. During normal start-up, this valve would be open and gradually closed once the compressor and engine reached running speed.

The bypass relief valve (Location 11) is an optional and, to a certain extent, a luxury item because it duplicates the protection offered by the switch at Location 1. It provides relief in the event the outlet or bypass plug valves are inadvertently closed, without shutting down the compressor. If used, it would normally be set to open 5 to 10 psig before the high-pressure switch closes.

The water-temperature bypass control (Location 4) serves to control the jacket water temperature by governing the amount of water to the cooler. In its simplest and cheapest form, it consists of an automobile-radiator-type thermostat in a three-way cast-iron valve body. It is substantially the same device used on most oil-field engines. A conventional temperature control would of course be satisfactory but its cost cannot be justified unless it is a large installation or is used where the complexity of the system does not lend itself to this type of control. In some cases where several services are handled by the same cooler, it is often more satisfactory to control the temperature by varying the speed or pitch of the fan.

Although no scale trap is shown, it is normally a good policy to have one to prevent accumulation and possible system damage. Some provision for water make-up is necessary; so a small surge tank on top of the cooler should be provided for this purpose. Drains should be provided so that the system may be completely drained.

The pop-off valve (Location 3) is primarily to prevent overpressure of the system, particularly the radiator. A simple brass valve 1/2 in. in size is normally sufficient.

On large systems, a standpipe may be used ahead of the pump suction to handle surges and serve as a water reservoir.

Nomenclature

- A_2 = area of orifice plate opening
- b = values for Reynolds number factor, Tables 13.1g and 13.1h
- C = orifice coefficient for prover
- C' = orifice constant
- d_i = internal diameter of pipe
- d_o = orifice-opening diameter
- F_a = thermal expansion factor
- F_b = basic orifice factor
- F_d = ratio of orifice opening diameter to internal pipe diameter
- F_g = specific-gravity factor
- F_{ia} = instrument-adjustment factor

- F_L = gauge location factor
- F_m = manometer factor
- F_{pb} = pressure-base factor
- F_{pc} = supercompressibility factor
- F_r = Reynolds-number factor
- F_{tb} = temperature-base factor
- F_{tf} = flowing-temperature factor
- g = force-mass conversion factor
- h_w = differential water head across orifice
- K_o = efficiency factor, which includes approach factor
- p = pressure
- p_{fm} = flowing mean pressure
- p_m = pressure in inches of mercury
- q_g = gas-flow rate
- Q = heat gained or lost by system
- R = controller reset constant
- S = characteristic constant of the pilot relating output to input
- t = time
- T = absolute temperature
- U = internal energy, which includes all energy such as heat, electrical, chemical, and surface
- v = velocity in conduit
- V = volume
- W = work done by system
- X = 0, datum defined in Fig. 13.1
- X_1, X_2 = potential energy above the datum plane defined in Fig. 13.1
- Y = expansion factor
- Z = height above an arbitrary datum plane
- γ_g = specific gravity of gas (air=1.0)

Subscripts

- f = flowing conditions
- g = gas
- o = orifice
- s_c = base or standard conditions

Chapter 14

Lease-Operated Hydrocarbon Recovery Systems

Robert N. Maddox, Oklahoma State U.*

Introduction

In lease production of natural gas, the marketing specifications as prescribed by the gas sales contract must be considered when selecting the system for processing wellhead gas for liquid recovery. Natural gas at the wellhead can contain liquefied hydrocarbons, free water, water vapor, acid gases, and other undesirable components. To make wellhead gas merchantable, these components must be reduced to a composition that will satisfy the marketing specifications. The first part of this chapter is devoted to the removal of liquefiable hydrocarbons from natural gas. The latter part of the chapter describes techniques for removal of some of the other components.

The removal of liquefiable hydrocarbons, which are called "condensate," is necessary for efficient transmission of natural gas in pipelines. If hydrocarbons condense in the pipeline, additional horsepower is required to overcome the increased pressure drop. Where the heating value of the natural gas is specified by the gas sales contract, there must be control of the condensate removal to satisfy this limitation. A final consideration for removal of condensate is that additional revenue is derived over that from sale of natural gas. In many instances this additional revenue will readily pay out the cost of process equipment required to produce gas of merchantable quality.

Low-Temperature Separation (LTS) Systems

Theoretical Considerations

Before various methods for removing condensate from natural gas are discussed, some of the physical phenomena involved in the formation of condensate are examined.

Retrograde Condensation. Retrograde condensation is a phenomenon that occurs at the high temperatures and

pressures frequently encountered in condensate hydrocarbon reservoirs. In the retrograde condensation region, as shown in Fig. 14.1, condensate forms at constant temperature with a reduction in pressure or at constant pressure with an increase in temperature, both of which are contrary to the normal expectations for condensation. If fluid in the reservoir existed at Point A, condensation would occur as the pressure in the reservoir declined from A to B. Less frequently encountered is the case shown by Line C-D. Here the fluid is in the single-phase region at Point C. As the temperature is increased at constant pressure from C to D, condensation occurs.

Retrograde condensation also can occur at lower temperatures and pressures than those encountered in the reservoir. This phenomenon¹ can occur at normal processing conditions for lease-operated equipment. Gas removed from a separator at typical high-pressure separator conditions (100°F and 1,000 psia) will undergo an increase in dewpoint temperature as the pressure is lowered. In many cases this "bulge" in the dewpoint line at lower pressures can amount to as much as 20°F or more, enough to cause troublesome condensation in lines thought to be at constant temperature as relatively small pressure drops occur.

Fig. 14.2 shows the calculated dewpoint curve for the off-gas from a separator operating at 120°F and 1,000 psia. The maximum dewpoint temperature is 136°F and occurs at about 500 psia. Also shown in Fig. 14.2 are constant mol% liquid lines. Over nominal line pressure drops very little liquid will form but that formed will be primarily the heaviest components in the gas stream.

Cooling. A second phenomenon to consider in condensate removal from natural gas is the cooling that can occur when the pressure on the gas is decreased. This temperature decrease can have one of two causes. When natural gas expands from a high pressure to a lower pressure without heat transfer or work being done (a constant-

*The author of the chapter on this topic in the 1962 edition was Edwin C. Young.

Fig. 14.1—Pressure-temperature diagram for typical natural gas and showing retrograde behavior.

Fig. 14.2—Retrograde condensation of separator off-gas.

enthalpy expansion), there is an accompanying temperature drop or refrigeration effect normally referred to as the Joule-Thomson effect. If, however, the expansion occurs through a turbine then work is removed from the gas during the expansion and cooling occurs also. Advantage can be taken of the available pressure drop to lower the separation temperature of the hydrocarbon mixture and cause more liquid to form from the natural gas. Cooling from turbine expansion must be modeled along the lines of compression calculations and is not easily correlated. Cooling available from constant-enthalpy expansion can be estimated by charts such as Fig. 14.3. One must be cautious in using charts like Fig. 14.3 because they are composition-dependent and cooling depends on gas composition and amount of liquid formed as well as the initial and final pressures.

Hydrate Formation. A third phenomenon that must be considered is the possible formation of hydrates when

water is present in the natural gas stream. Hydrates are materials that have fixed chemical compositions but exist without chemical bonds and are called "clathrates." They form a solid similar to snow at temperatures above 32°F (the freezing point of water) when the gas is under pressure. They appear to be hydrates of a mixture of the component gases and not a mixture of the hydrates of the individual gases. The hydrates form at a temperature that is characteristic of a given gas mixture rather than at the hydrate temperature for the individual components in the mixture. The hydrates normally include several water molecules for each hydrocarbon molecule so that the presence of liquid water is generally considered necessary for the formation of hydrates in sufficient quantity to cause plugging of a line, valve, etc. Turbulence accelerates the formation of hydrates and for this reason they frequently occur downstream from valves, regulators, chokes, orifice plates, sharp bends, etc. Fig. 14.4 can be used to estimate hydrate-forming conditions for different natural

Fig. 14.3—Temperature drop associated with a given pressure drop.

gases. Caution also must be used in Fig. 14.4 because, as shown by the different hydrate-forming lines for 0.6-gravity gases, there can be considerable difference in the hydrate temperature of gases of the same gravity.

If the composition of the gas is known, a composition-dependent calculation of the hydrate temperature, either by hand³ or by computer,¹ will give a much better estimate of the hydrate temperature than will Fig. 14.4.

A necessary condition for hydrate formation is the presence of liquid water. Prediction of the temperature where free water will occur will help identify the first point at which hydrates might form. The chart shown in Fig. 14.5 gives the water vapor content of sweet [no hydrogen sulfide (H_2S) or CO_2] natural gas as a function of temperature and pressure. As the temperature decreases at a given pressure the water content required for saturation also decreases. This will result in condensation of liquid water for a saturated gas stream as it is cooled. As an example, suppose a well is flowing 1 MMscf/D of natural gas at 1,000 psia saturated with water vapor but containing no liquid water at 110°F. The gas is cooled to 60°F because of ground and atmospheric cooling. At 1,000 psia and 110°F, the gas contains 80 lbm water vapor/MMscf and at 60°F it contains only 18 lbm/MMscf. One day of gas production will result in the formation of 62 lbm of free water because of the cooling. Referring to Fig. 14.4, if the gas flowing has a specific gravity greater than 0.6, hydrates are likely to form in the flow line at some point of turbulence.

Constant-Enthalpy Expansion Systems

The constant-enthalpy expansion systems use the refrigeration effect that results from a pressure drop taken on a high-pressure wellstream. This expansion occurs across a choke and the resulting refrigeration effect is dependent on the temperature on the upstream side of the choke, the pressure differential across the choke, and the amount of liquid formed. For obtaining the maximum removal of liquefiable hydrocarbons from the gas stream for a given pressure differential and sales-gas pressure, the lowest possible temperature within reasonable limits should be attained in the separator. This in turn means the lowest possible temperature upstream of the choke. Two basic methods commonly used to accomplish condensate removal are low-temperature separation with or without hydrate inhibitors. Each method is discussed in the following sections.

Low-Temperature Separation Without Hydrate Inhibitor.

The basic unit for low-temperature separation without hydrate inhibitor includes essentially a choke, separator, and heat-exchange coils. Assuming that the inlet wellstream contains a minimum amount of free water and is of sufficient temperature to prevent formation of hydrates upstream of the choke, the operation is as follows. The wellstream enters the unit shown in Fig. 14.6 through the heat-exchange coil, where it is cooled through heat exchange with the liquid external to the coil. The wellstream then passes through an adjustable choke used to control the flow rate through the system and establish a means for introducing the necessary pressure drop. The turbulence and temperature drop created by the expansion across the choke cause the formation of hydrates and the

Fig. 14.4—Approximate hydrate-forming conditions for natural gas mixtures.

condensation of the liquefiable hydrocarbons. The hydrates and condensate are separated from the gas by means of centrifugal force, normally generated by locating the choke tangential to the shell of the separator, and by gravity. The hydrates and condensate collect in the bottom of the separator where they absorb heat from the inlet coil, causing the hydrates to be melted. The liquid level is maintained by a level controller such that the coils are always submerged in the liquid.

Two possible operating problems might occur in this simple system. Either the wellstream could be near the hydrate temperature on entering the coil and further cooling would create hydrates upstream of the choke, or there is an insufficient amount of the liquid bottoms causing hydrates to build up inside the separator. In either case the system will malfunction. To use low-temperature separation successfully, the pressure of the gas upstream of the choke must be approximately twice the pressure in the low-temperature separator. Certainly, the higher the pressure upstream of the choke the lower the temperature that can be achieved in the low-temperature separator.

The common solution to this problem is to install an indirect heater upstream of the low-temperature separator. The indirect heater temperature would be maintained at a level to ensure wellstream gas temperatures above the hydrate temperature. Heat transfer is accomplished

Fig. 14.5—Water dewpoint of natural gas.

by flowing the wellstream through the coils in the indirect heater. The gas temperature is controlled by a thermostat located in the outlet end of the coil. A second thermostat can be located in the liquid section of the low-temperature separator to override the heater controls in the event the liquid temperature is too low.

For the simple system outlined here, the prime concern was to keep the temperature high enough upstream of the choke to ensure continuous operation. One of the necessary elements for hydrate formation, as pointed out previously, is the presence of free liquid water. In cases where free water and liquid hydrocarbons are present in the wellstream, and where these liquids are formed because of the chilling effect in the coil, a high-pressure separator can be placed between the coil and the choke. The liquids separated in this vessel are dumped at a relatively warm temperature into the bottom of the low-temperature separator and combined with the liquids in the separator. This reduces the amount of free water and liquid hydrocarbons passing through the choke and allows more net cooling to occur. Since the sensible heat transfer to these liquids can be used for cooling the gas and condensing additional hydrocarbon vapor, it also reduces the amount of hydrates formed by minimizing the amount of free water passing through the choke.

A further refinement to this system is possible for increasing the condensate removed from the wellstream. This includes the addition of a heat exchanger located between the inlet high-pressure liquid separator and the choke. The high-pressure wellstream flows through the tube side of this heat exchanger, and cold sales gas off the top of the low-temperature separator flows through the shell side. The amount of sales gas flowing on the shell side is controlled by a three-way bypass valve actuated by a temperature controller upstream of the choke. In this manner the upstream temperature at the choke can be maintained at a minimum value but still above hydrate

Fig. 14.6—Typical low-temperature separator.

temperature. From the analysis given, the lower this inlet temperature, the lower will be the temperature in the separator and the greater will be the amount of condensate removed.

The complete system is shown in Fig. 14.7. The wellstream flows through the coil in the low-temperature separator where it is slightly chilled, then to the inlet high-pressure liquid separator where free liquids are separated from the gas. The gas then flows through the gas-to-gas heat exchanger, through the choke, and into the low-temperature separator. The cold gas flows from the separator, through the gas-to-gas heat exchanger, and into the sales-gas line. The liquids from the bottom of the low-temperature separator are dumped to some form of stabilization before going into storage.

Fig. 14.7—Typical LTS system with inlet separator and intermediate heat exchanger.

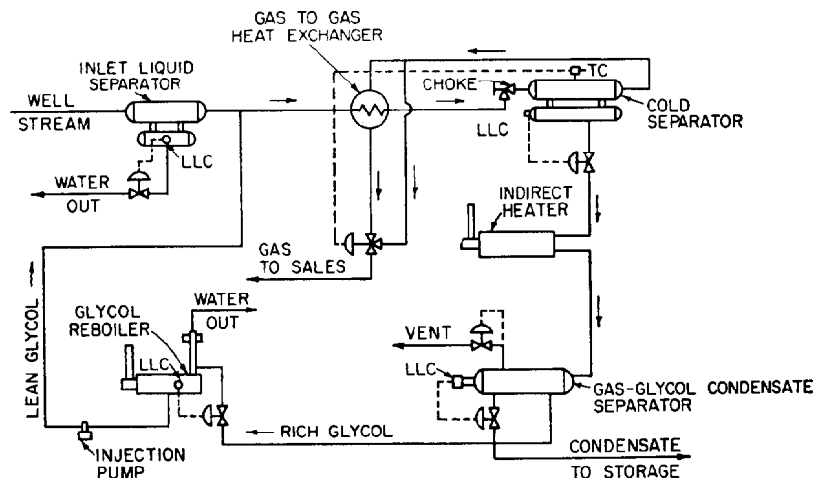

Fig. 14.8—Schematic flow diagram of a glycol injection LTS system.

In summary, the following considerations are necessary for operation of low-temperature separation systems without hydrate inhibitors. The controlled temperature of the high-pressure stream must be kept slightly above the hydrate temperature to prevent freezing upstream of the choke. The hydrate temperature can be determined by reference to the hydrate curve for natural gas (Fig. 14.4). The temperature of the low-temperature separator can be estimated from pressure-temperature drop curves for natural gas in Fig. 14.3. Allowances must be made for the liquid content, which will slightly reduce the temperature drop if the liquid hydrocarbons are not separated in a high-pressure separator upstream of the choke.

On wellstreams with low flowing temperatures a heater may have to be installed upstream of the low-temperature unit. In such cases the temperature is controlled with the heater and the gas-to-gas heat exchanger may not be required. If a well makes little free water and/or no waxy distillates or free condensate, the inlet high-pressure liquid separator can be eliminated.

This type of system is economically feasible from a liquid-recovery standpoint for gas streams with liquid content of a few barrels up to about 100 bbl/MMscf gas. The optimal recovery pressure will vary with different wellstreams but may be as low as 350 psig.

A rough rule of thumb is that 0.05 bbl additional liquid can be recovered per MMscf of gas for each degree lowering of the temperature. Below 20°F the increase in recovery becomes lower, and in some cases only slight additional recovery of net stock-tank liquid can be realized by lower temperatures.

Low-Temperature Separation With Hydrate Inhibitor.

The formation of hydrates can be prevented by changing the character of the water in such a way that it will not hydrate with the natural gas. This is accomplished through the use of a substance known as a "hydrate inhibitor." The most commonly used hydrate inhibitors are glycols and alcohols. Either will function satisfactorily. The system with a hydrate inhibitor is similar to the one in Fig. 14.7 except that the inhibitor is injected between the inlet high-pressure separator and the regenerative heat ex-

changer. The inhibitor mixes with free water formed on cooling and prevents hydrate formation. The advantages and disadvantages of alcohols and glycols as inhibitors are discussed by Campbell,² as is the required amount of either material necessary for preventing hydrate formation. Further discussion here centers on the use of glycol as a hydrate inhibitor. A typical system using glycol is shown in Fig. 14.8.

The presence of the inlet high-pressure liquid separator is very important in this system. The produced water must be removed in this inlet separator to prevent contamination of the glycol and to keep the regeneration equipment from having to handle this extra vaporization load. The contamination occurs as (1) excessive dilution of the glycol, which reduces its inhibiting qualities; (2) as salt water, which is detrimental to the regeneration system; and (3) as solids, which can cause foaming and other problems in the separation and regeneration systems. If the wellstream contains waxy heavy ends these must be removed and kept out of the low-temperature separator where they could build up and cause the system to malfunction.

Glycol, which has been processed through the regeneration system to remove the water picked up in the system, is pumped from a storage tank to an injection point downstream of the inlet separator. The glycol rate is controlled by setting the speed of the pump. The rate is established by calculating the amount of water to be inhibited while going from the saturated condition downstream of the inlet separator to a saturated condition in the low-temperature separator. The glycol concentration, resulting from dilution with this water to be picked up, must be maintained sufficiently above the freezing point of the solution to prevent freeze-up in the low-temperature separator or the regenerative heat exchanger. There are published curves³ that can be used to calculate the necessary quantity of glycol.

The inhibited wellstream passes through the regenerative heat exchanger, to the choke, and into the low-temperature separator. The cold sales gas off the separator passes through the shell side of the heat exchanger. A three-way valve is used to control the amount of heat

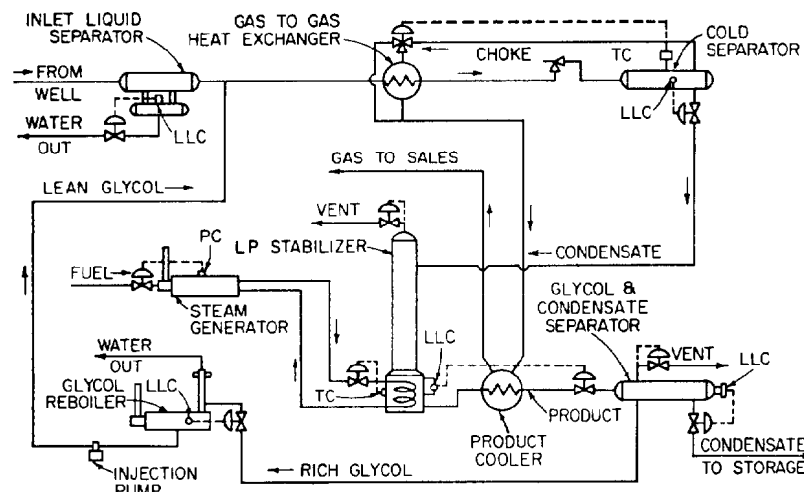

Fig. 14.9—Schematic flow diagram of a glycol injection LTS system with low-temperature stabilization.

transferred from the wellstream to the sales gas to maintain a specified temperature in the low-temperature separator. This valve is actuated by a temperature controller located in the low-temperature separator. Since the inhibited wellstream can be cooled below hydrate temperature ahead of the choke, lower temperatures are possible in this system than with the uninhibited system. This allows more liquefiable hydrocarbons to be condensed out of the wellstream and separated along with the rich glycol.

The liquids from the low-temperature separator contain condensate and rich glycol. The step of separating these liquids is difficult because of the low temperature and high viscosity. One method of handling this separation is to pass the liquids through a heater, as shown in Fig. 14.8, to bring the temperature to a level where separation can be achieved. However, this decreases the potential liquids recovery because of the warming up of the liquid hydrocarbons. Since condensates from glycol injection systems are commonly stabilized to give better stock tank recovery, in some cases the glycol hydrocarbon mixture passes through the stabilizer before separation. A flowsheet for this process is shown in Fig. 14.9.

If the gas being processed contains aromatic hydrocarbons, these will dissolve preferentially in the glycol. They may then cause degradation and decomposition problems in the glycol regeneration system.

The glycol from the injection system is rich in water and must be reconcentrated before it can be recirculated. This is accomplished in the glycol reboiler as shown in Figs. 14.8 and 14.9. The rich glycol is fed into a still column where it contacts the steam rising from the reboiler. This serves to preheat the glycol, strip out any dissolved gases, and condense any glycol that may be entrained in the steam vapors. With diethylene glycol the reboiler is operated at around 240 to 250°F to provide outlet glycol concentrations of about 80 to 85 wt%. The glycol-condensate separator is usually designed to act as a surge to take up the slack in the event that glycol might be temporarily accumulated elsewhere in the system.

Glycols are expensive, so the system must be designed and operated to keep losses at a minimum. Losses occur because of the slight solubility of glycols in condensate

and the vaporization of glycols in the regeneration system. Proper equipment design and sizing for separation in the low-temperature separator and the glycol-condensate separator can keep mechanical losses to a minimum. In considering the type of glycol best suited for an injection system, both the solubility and the vaporization characteristics must be considered. Ethylene glycol has the least solubility in condensates but the highest vaporization losses. The vaporization can be reduced through a more elaborate regeneration system but at a higher initial equipment cost. Triethylene glycol has the least vaporization loss but is the most soluble. Diethylene glycol is usually considered a good compromise. In a typical condensate, 70 to 80 wt% diethylene glycol solution is about 0.4 wt% soluble. More concentrated solutions are more soluble but these are seldom encountered in glycol injection systems. Aromatic hydrocarbons tend to increase the solubility of the glycol in the condensate and higher losses can be expected when they are present. In installations where extreme care is exercised to eliminate glycol losses of a mechanical nature, such as leakage past the pump packing and unnecessary spillage, glycol losses have been found to be approximately 0.2 gal/MMscf of gas processed.

Hydrocarbons separated in the inlet high-pressure liquid separator can be recombined in the low-temperature separator provided they are not of a waxy base. The solution gas flashed in discharging from the high-pressure separator can be recombined with the sales gas and the liquids recombined with the condensate prior to stabilization. Waxy-based hydrocarbon liquids are best discharged directly to the stabilizer, where the temperatures are higher and they are more easily handled.

The low-temperature separation system with hydrate inhibitor eliminates the formation of hydrates and allows the gas to be cooled below the hydrate temperature before expansion. This results in an increase in the amount of condensate removed from the wellstream. The operating costs are higher than for the system using expansion without inhibitor, but the increased recovery will normally more than offset this. Glycol injection can be used more effectively on wellstreams where the pressure drop is low-

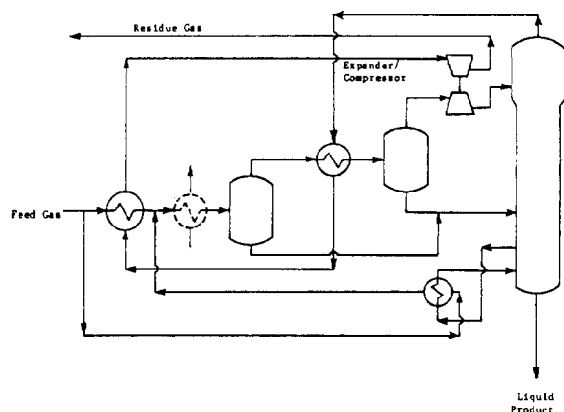

Fig. 14.10—Process flow for expansion process.

er than can the straight expansion system. Approximately 1,000 psi of pressure drop should be available for operation of an LTS system while a glycol injection system can function well with pressure drops as low as 500 psi.

Turbine Expansion Systems

The turbine expansion low-temperature liquid recovery system differs from the choke or valve expansion in that the turbine turns a shaft from which work is extracted. A typical turbo-expander process is shown in Fig. 14.10. The gas enters through an inlet separator with any liquid separated at this point being introduced to a low point in the stabilizer tower. The gas then goes through heat exchange with the cold gas leaving the stabilizer. Another separator is installed if sufficient liquid is formed in the gas-to-gas exchanger with the liquid being introduced at an intermediate point in the stabilizer. The cold gas then flows to the expander where the pressure is reduced and low temperature achieved. The gas and liquid mixture

leaves the expander and flows to the separator that normally is on top of the stabilizer column. Sales gas flows back through the exchanger and may be compressed in the direct-connected centrifugal compressor before being put into the sales gas line. Since extremely low temperatures are reached in a typical turbo-expander plant, dehydration normally is a first step though some plants do use alcohol injection. The gas frequently is expanded below sales gas pressure and then recompressed to make use of the work that must be extracted from the shaft of the turbine. The stabilizer is either a demethanizer or deethanizer with the mixed hydrocarbon product being sold.

A fairly recent development in gas processing, the turbo-expander process is one of great simplicity and ease of operation. The favorable operating characteristics allow the plant to run unattended through long periods and its simplicity and relatively low investment cost make it an attractive option.

Mechanical Refrigeration Systems

Because mechanical refrigeration systems frequently chill to as low as 0°F, they involve essentially the same problems encountered in the low-temperature systems where the temperature is obtained by pressure expansion. The systems really are quite similar. The only essential difference is that the choke in the low-temperature separator systems is replaced by a chiller in the mechanical refrigeration systems.

Although glycol-injection systems are used extensively, there are many installations where inlet dehydration is used to lower the water dewpoint of the gas below the operating temperature in the chiller. There is merit to this system since the glycol does not come in contact with the condensate and glycol losses are, therefore, much smaller. Some of the other operating problems such as separation of glycol and condensate also are eliminated. The dehydrator, if it exists in the flowsheet, would ordinarily be placed between the inlet liquid separator and the chiller. The dehydrator could either be a liquid or granular desiccant type.

4. All cases shown can be handled by one compressor body except ammonia at 0°F and colder (95°F condensing) and 20°F and colder (125°F condensing).
5. One ton of refrigeration = 12,000 Btu-hr.

In a refrigeration process, low temperature is achieved by cooling the gas using a refrigerant at low pressure. The heat in the incoming stream vaporizes the refrigerant at low pressure. The refrigerant must then have its pressure increased so that it can be liquefied. The pressure may be raised in two ways—compression or by absorbing the refrigerant in a liquid, which is then pumped to high pressure with the refrigerant being stripped and subsequently condensed. Compression refrigeration systems are more common, but either should work satisfactorily.

Compression Refrigeration Systems

A typical compression refrigeration system is shown in

Fig. 14.11. The inlet gas stream flowing through the chiller causes the refrigerant to boil. The cold refrigerant vapors flow out of the chiller and to the compressor. Only one chiller is shown in Fig. 14.11. However, frequently in larger systems two or even three chillers may be used with each operating at a different pressure. The chiller pressures are fixed at interstage compression pressures for the compressor.

After compression, the refrigerant vapors are liquefied by cooling with either water or air. The liquid refrigerant is stored in the receiver until required in the chiller. A number of different materials may be used as refrigerants. Tables 14.1 and 14.2³ compare properties of a number of commonly used refrigerants.

The refrigeration load on the chiller for a given gas flow rate is a function of the wellstream analysis, pressure, and the inlet temperature to the chiller. The two factors involved in this cooling load are the sensible heat required to reduce the wellstream from flowing temperature to chiller temperature and the latent heat required to condense the liquefiable hydrocarbons. Obviously, the richer the wellstream the greater the refrigeration load required. The chiller and refrigeration system must be designed to meet the requirements of each individual installation. These requirements are based on the wellstream analysis, pressure, and temperature.

For economical operation the system must be designed to use as much of the cooling as possible. This is done by taking advantage of heat exchange between cold and hot streams wherever possible.

Selective Adsorption Systems

On lean wellstreams where economic justification and payout of the equipment necessary for hydrocarbon removal by refrigeration are not possible, a selective adsorption system should be considered. This type of system frequently will be competitive in hydrocarbon recovery with mechanical refrigeration for lean gas streams.

The selective adsorption system consists basically of two or more adsorption towers filled with a solid material capable of adsorbing hydrocarbons. The towers are controlled on a time cycle to be adsorbing, regenerating, and/or cooling. Alternatively, the bed is used to adsorb the desired quantity of hydrocarbon from the gas stream. When the bed becomes saturated with hydrocarbons, the gas stream is switched to another bed. The saturated bed then is regenerated by passing hot gas through the bed. The hot gas vaporizes and drives off the adsorbed hydrocarbons. During the regeneration cycle, the bed and some of the parts of the adsorber become heated and must be cooled before the bed can again be used on an adsorbing cycle.

The approach used in hydrocarbon adsorption is the same as is widely used in dry-desiccant dehydrators. The basic difference is in the time allowed for the adsorption cycle. Dehydrators normally operate on a 6-hour or longer cycle. Hydrocarbon recovery units operate on a much shorter time cycle and for this reason are frequently called "short-" or "quick-cycle" units.

When a multicomponent mixture like natural gas is adsorbed, the lighter components saturate the bed first. They then are displaced gradually by the heavier hydrocarbons and, eventually, the hydrocarbons would be displaced by

water present in the gas. The secret to operating a hydrocarbon recovery unit is determining the point where the largest percentage of desired liquefiable hydrocarbons has been adsorbed. The cycle time normally has to be a compromise since it is done on a time basis.

Fig. 14.12 shows a typical installation for a selective adsorption system. The wellstream flows into an inlet-liquid separator to remove any free liquids and thus cut down on possible adsorbent contamination. The gas then flows through a pressure-reducing valve, used to control the flow of gas through the regeneration and cooling cycles, and into a manifold for switching to the tower on stream by the time-cycle controller. As the gas passes through the bed, the heavier hydrocarbons and water vapor are adsorbed. Stripped dry gas leaves the tower and flows through the gas-to-gas heat exchanger into the sales-gas line.

The tower being regenerated has been saturated through previous contact with the main gas stream. Gas for regeneration is taken off the main gas line upstream of the pressure-reducing valve, and the flow rate through the regeneration system is controlled by the pressure drop across this valve. The regeneration gas flows through the heater where it is heated and then to the tower being

regenerated. The heavier hydrocarbons and water vapor that were adsorbed are driven off by the hot gases. The gas and vaporized fluids pass through an air-cooled heat exchanger where the temperature is lowered, condensing some of the liquid. Additional cooling is obtained in the main gas-to-gas heat exchanger with further condensation. The regeneration gas and condensates are passed through the regeneration-system separator where the condensates are removed from the gas. The gas off the separator flows back into the main gas stream downstream of the pressure-reducing valve. The condensates are separated, the water is dumped, and the hydrocarbon liquid typically flows to a stabilizer.

The system just described is commonly called an "open regeneration system." This means that the regeneration gas flows continuously out and into the main gas stream on either side of the pressure-reducing valve. This requires that a pressure drop be taken in the main gas stream. In applications where pressure drops cannot be tolerated, a closed regeneration system can be used. Such a system can be seen in Fig. 14.13.

A blower is used to recirculate the regeneration gas through the regeneration heating and cooling cycles. The blower picks up gas downstream from the regeneration-

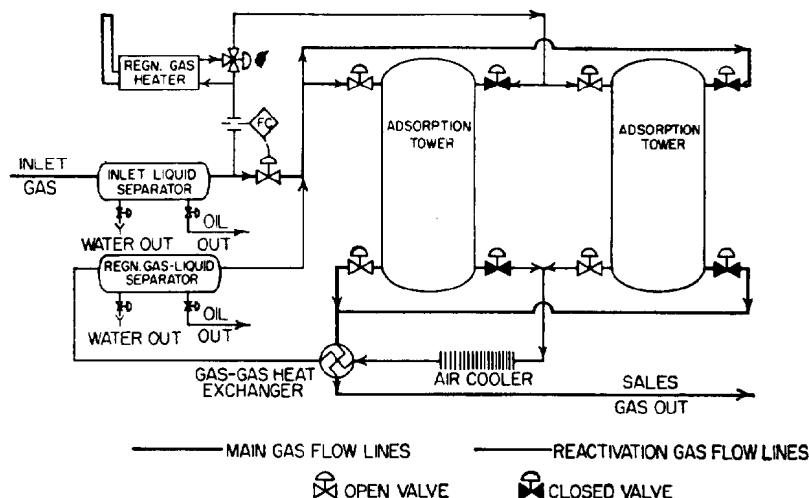

Fig. 14.12—Typical two-tower open-cycle selective hydrocarbon-adsorption system.

liquid separator and boosts the pressure sufficiently to produce the required circulation rate of the regeneration gas. Although the system shown in Fig. 14.13 is for a three-tower system, the blower will work equally well on the two-tower system shown in Fig. 14.12. The blower discharge would connect into the meter run going to the regeneration gas heater. The pressure-reducing valve and extra piping shown in Fig. 14.13 are included to ensure continuous operation while the blower is shut in for maintenance. Under these circumstances the unit operates as an open-cycle system. To compensate for varying pressures in the reactivation-gas system caused by temperature changes, equalizer lines are connected into the system with check valves. In the event that gas is required in the system, dry gas is taken from the sales-gas end of the system. If the reverse is the case, then gas within the regeneration system is discharged ahead of the adsorber so that

wet gas can be processed before entering the sales-gas line.

One advantage of the closed system is that the regeneration gas never becomes a factor in the drying cycle. Essentially the same gas is used over and over again. This results in slightly higher recoveries with an additional operating expense that requires an economic study for justification. The inclusion of the blower in the system adds considerably to the maintenance expense and operating problems encountered over the open system. The main advantage of the closed system is that the pressure drop on the main gas stream can be held to a minimum.

The size of the adsorption beds is a function of the amount of liquid to be removed. This quantity of liquid may be obtained from a small volume of rich gas or a large volume of lean gas. The diameter of the tower is established from the allowable velocity of the gas through

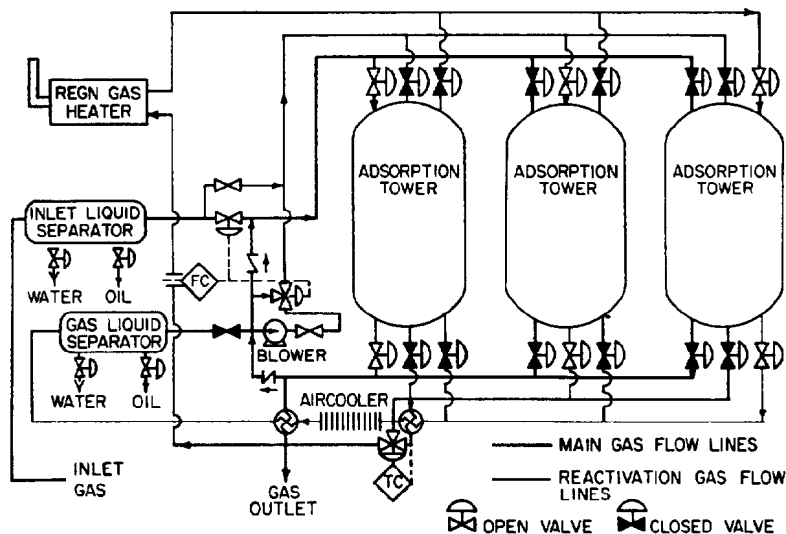

Fig. 14.13—Typical three-tower closed-cycle selective hydrocarbon-adsorption system.

the bed. At low pressures this diameter can become quite large if a given capacity must be satisfied. The depth of the bed is determined by the amount of adsorbent required, the allowable pressure drop, or the minimum bed depth. The length of the time cycle affects the size of the bed for a given amount of liquid removed. The amount of adsorbent decreases with decreasing time, but the heating and cooling requirements increase as the cycle is shortened. The heat required is a function only of the pounds of liquids to be removed and the materials to be heated such as the adsorbent and portions of the towers. The heating and cooling rates are thus inversely proportional to the time of the cycle.

For a given wellstream, the design of the equipment and the operation and control are most important in effecting liquid removal. The time cycle is important and is good only for a range of variation in the wellstream analysis. If the wellstream becomes richer, the cycle may be too long and all liquids are not removed. If the wellstream becomes leaner, the cycle is too short and the adsorbent is not used to the maximum capacity.

The quality of process cooling can also affect the process efficiency. If sufficient cooling is not accomplished, condensation of the liquefiable hydrocarbons will not be complete. In the open cycle this means that the regeneration gas will carry these vapors back into the bed to be adsorbed again. This could result in a considerable amount of recycling of hydrocarbon vapors.

The nonhydrocarbons present in the natural gas will have some effect on the process. This is especially true of the water vapors that eventually replace the hydrocarbons adsorbed in the bed and allow them to be expelled. The short-cycle unit is an excellent dehydrator as well as a hydrocarbon-removal unit. Presence of H_2S has little effect on the process unless oxygen is present. In this event, the oxygen causes free sulfur to form which will tend to foul the desiccant. CO_2 , nitrogen, and other gases occasionally found in natural gas do not affect the process significantly.

When selecting a short-cycle unit, the following can be used as a guide. When the butanes and heavier hydrocarbons to be adsorbed amount to 10 bbl/MMscf of gas or less, then the application of this type of system is normally feasible. Between 10 and 15 bbl/MMscf the choice must be made between the quick-cycle and the refrigeration system. Only through an economic analysis of both these systems can the proper choice be made. On wellstreams in excess of 15 bbl/MMscf the refrigeration system is more feasible. The normal application for the quick-cycle unit is downstream of low-temperature separation systems in which the reservoir pressure has decreased to the extent that the refrigeration from expansion cannot effectively remove the liquefiable hydrocarbons.

Hydrocarbon Stabilization

The previous discussion covers the processes by which a maximum removal of liquefiable hydrocarbons from the gaseous phase of the well stream is accomplished to satisfy gas pipeline specifications and derive additional revenue from the liquid hydrocarbons. Unless the liquid hydrocarbons are handled properly after separation from the main gas stream, the maximum revenue will not be derived. The maximum is obtained by retaining the maximum volume of separated hydrocarbon liquids in atmospheric

Fig. 14.14—Vapor pressure-temperature curves for motor and natural gasolines.

storage and salvaging or recovering the maximum amount of light vapors that flash from the separated liquids.

If a liquid is to be stored at atmospheric pressure without vaporization losses, it must have a vapor pressure no greater than the existing atmospheric pressure at the maximum temperature it will reach in the storage tank. The vapor pressure exerted by the liquid is called its "true vapor pressure." Measuring the true vapor pressure of a liquid is difficult. For this reason a standard vapor pressure, called the "Reid vapor pressure" (RVP) is much more frequently determined for the liquid. The RVP is determined by using a standard ASTM technique in a 100°F controlled-temperature bath. By sampling the liquid hydrocarbon product, the actual RVP of the liquid being produced can be determined.

Fig. 14.14 shows a correlation for approximating the true vapor pressure of a liquid for which the RVP has been determined. Because vapor pressure is composition-dependent, Fig. 14.14 should be considered an approximation only. If the maximum storage temperature were expected to be 60°F, Fig. 14.14 shows that approximately a 29-psi RVP product could be stored. If the maximum storage temperature were 100°F, the maximum RVP for the product would be approximately 14 psi.

When the hydrocarbon liquids are dumped from the high-pressure separator, the liquids are at their boiling point for the pressures involved. Each reduction in pressure causes some vapors to be boiled off. If the liquids were dumped directly to a storage tank, violent boiling would take place, resulting in a loss of not only the lighter vapors but also some of the heavier ends. By taking

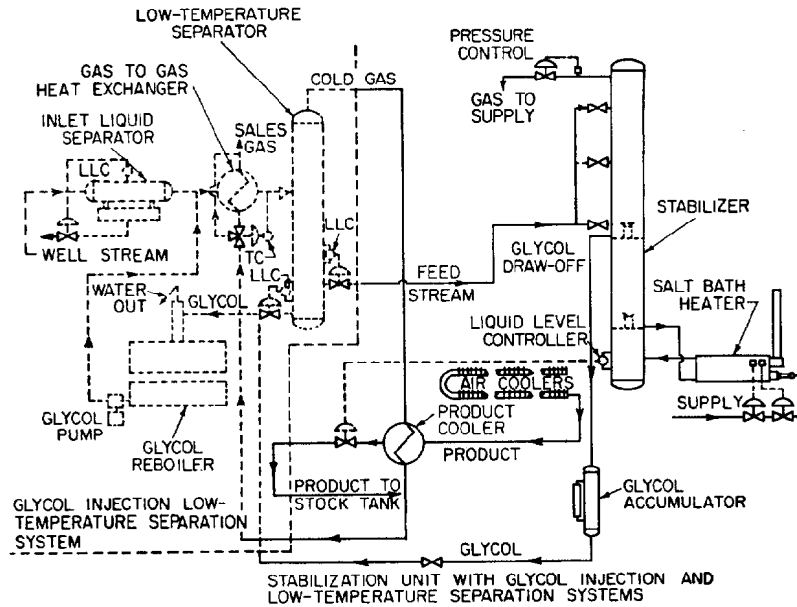

Fig. 14.16—Stabilization unit with glycol-injection LTS system.

the column to reflux itself. This eliminates the relatively expensive reflux system required on stabilizers where the feed is at higher temperatures. The elimination of reflux condenser, reflux control, and reflux pump greatly simplifies the operation of a stabilizer on an oilfield lease where operational supervision is limited. In most cases sufficient refrigeration is available in the system to chill the liquid from the heated-liquid-type low-temperature separation system. The simplified stabilizer can then be used with the heated-liquid system as well as with the glycol-injection low-temperature system.

By this method, the separator liquid is separated into its heavier components, which will remain liquid at atmospheric pressure and temperatures, and its lighter components, which will become a gas at atmospheric conditions. A minimum of liquid components is lost with the lighter components in this method of separation.

For selective adsorption units the liquefied hydrocarbons are recovered on a batch basis. This means that the liquids build up fast over a short period of time and no more are produced until the cycle switches. This means that an accumulator must be used between the separator and the stabilizer so that a more continuous flow of liquids can be provided to effect efficient stabilizer operation.

In stage separation all the increased volume of normally liquid hydrocarbons is not reflected in the stock tanks because a larger amount of it is carried out as a vapor during the separation of the lighter components. By the use of stabilization, almost all the increased volume of normally liquid components in the low-temperature separator is retained in the stock tanks under stable conditions. In addition to producing a larger stock-tank volume of liquid from a given volume of low-temperature separator liquid, the stabilizer produces all the lighter normally gaseous components overhead at one point in the system at relatively high pressure. Gas at this pressure can be compressed back to gas-transmission line pressure at a much reduced compression cost as compared with the low-

pressure vapors from the same system using stage separation. The vapors from the stabilizer are also lean in heavy hydrocarbon components and therefore more desirable in a gas-transmission line than the hydrocarbon-liquid-laden vapors from stage separation.

When the overhead vapors from a stabilizer are compressed into the sales-gas line and the stabilized liquid is stored in a vapor-tight tank, every pound of the produced well fluid, with the exception of that used for fuel gas in lease heaters (if any) and the stabilizer reboiler, can be marketed.

Fig. 14.17—Stabilizer operating conditions. Initial settings for determining the point of maximum recovery.

Fig. 14.18—Equilibrium flash separation.

To evaluate the requirements of the lease from an equipment standpoint, the operator must understand the principles of material balance and equilibrium as they apply to multicomponent light hydrocarbon mixtures. Before undertaking such an evaluation, the complete properties of the wellstream must be known. This includes a component-by-component analysis, the temperature, pressure, and the quantities of gas and liquid that can be marketed. These quantities are essential if a payout for the equipment is to be estimated. If sufficient information is available, liquid recoveries can be calculated by using the procedure outlined next.

In making hydrocarbon liquid recovery calculations, compositions and flow rate normally must be expressed in terms of the number of molecular weight equivalent of the material present (moles). The feed to the recovery unit, F , is the sum of the liquid, L , and the vapor or gas, V , as given by

$$F = L + V. \quad (1)$$

Individual component compositions are expressed in mole fractions. The mole fraction of any component in a stream is the moles of that component divided by the total number of moles for all components in the stream. The mole fraction of any component in a liquid stream is denoted x_i ; in the vapor phase y_i ; and in the feed or wellstream z_i . A material balance for any component on the same basis as Eq. 1 can be written

$$z_i F = x_i L + y_i V \quad (2)$$

or

$$f_i = l_i + v_i. \quad (3)$$

By definition the vapor/liquid equilibrium (VLE) constant, K_i , for a given component is the ratio of the mole

fraction of that component in the vapor, y_i , to the mole fraction in the liquid, x_i , that would be in equilibrium with that vapor at the temperature and pressure as given by

$$K_i = \frac{y_i}{x_i} = \frac{v_i/V}{l_i/L} \quad (4)$$

The value of K_i for a given component in a stream is a function of the temperature, pressure, and composition of the stream. In light hydrocarbon systems containing essentially only the paraffin hydrocarbons, the composition dependency of the VLE constant is slight. For this reason many calculations only approximate the composition dependency of K_i .

By definition the summation of the mole fractions in any stream is equal to unity and shown by $\Sigma x_i = 1$, $\Sigma y_i = 1$, and $\Sigma z_i = 1$.

The operating equations used for equilibrium flash calculations are derived by assuming that the separator operates with the vapor and liquid leaving the separator in equilibrium as shown in Fig. 14.18.

Combining Eqs. 3 and 4 and eliminating v_i leads to

$$l_i = \frac{f_i}{1 + \frac{K_i V}{L}} \quad (5)$$

If l_i had been eliminated we would get

$$v_i = \frac{K_i f_i}{K_i + L/V} \quad (6)$$

In either case $L = \Sigma l_i$, $V = \Sigma v_i$.

Eqs. 5 and 6 apply at any point in the process step where the liquid and vapor are in equilibrium. In normal lease processing, there will be many instances where the vapor and liquid are separated. Eqs. 5 and 6 can be used to predict the amount and composition of vapor and liquid present. Solution of either Eq. 5 or 6 is by trial and error because both equations involve V and L , the total vapor and liquid rates leaving the separator. To use the equations, the recommended procedure is to solve for the stream that is expected to be present in smallest amount. A value for that stream is assumed and the appropriate equation used to solve for the moles of the individual components in that stream. These are summed to give the total-stream flow rate. If the value calculated differs from the value assumed, the next assumption should be even further in the direction of the difference.

Keep in mind that the terms involved in Eqs. 5 and 6 are molar flows and not the normal units used to describe liquid and vapor flow rates.

If a digital computer program is available it can readily be used for solution of Eqs. 5 and/or 6. In most instances the computer program will incorporate an appropriate equation of state (EOS) to evaluate equilibrium constants. The user of such a program should be aware that the results will differ for different EOS's. Also, two programs written by different people using the same EOS may give significantly different quantities of liquid and vapor for the same separator at the same temperature and pressure

conditions. In addition, the manner in which the undefined components (C_6+ or C_7+ fractions) are characterized also will have an impact on the calculated liquid present.¹

To determine the volume of gas at any point in the process, the number of moles of gas present may be multiplied by 379.5 to determine the number of standard cubic feet. If the actual volume of the gas under the temperature and pressure are required the procedure followed in determining the gas volume in Chap. 20 must be used. To estimate the liquid production, the number of gallons per mole for each component should be determined from a standard reference such as the GPSA's *Engineering Data Book*.³ These densities in gallons per mole should be multiplied by the number of moles of each component and the results summed to give the total volume of liquid formed.

For the case of hydrocarbon recoveries from a stabilizer or from short-cycle adsorption units, no attempt is made to present the methods of calculations here. They are beyond the scope of this treatment but should be checked carefully for reasonableness and apparent accuracy.

Gas-Treating Systems for Removal of Water Vapor, CO_2 , and H_2S

Natural gas can contain any number of nonhydrocarbon impurities in the formation or at wellhead conditions. Some of these are detrimental to efficient pipeline operation, whereas others have no effect on operation but do affect the heat content or Btu rating of the natural gas.

In almost every case natural gas contains water vapor to some extent. The characteristics of the rock in the formation will determine largely the extent to which water occurs. In some cases the gas is supersaturated, which means that free water will be present. In other cases the gas is saturated at reservoir conditions, which would mean that at producing conditions it will be supersaturated. Finally, the water content can be much lower than saturation but higher than specifications to be satisfied for pipeline acceptance. The formation of free water with pressure and/or temperature reduction can result in the formation of hydrates if the temperature falls below the hydrate-forming temperature. This phenomenon is discussed more fully in the preceding section. In addition to the problems of hydrates, the formation of free water because of condensation can add to the horsepower requirements for pipelines because of increased pressure drops caused when water collects in low spots in the line and reduces the flow area of the gas. This condition is also conducive to corrosion in the pipe. Water vapors must be removed from the gas, and various methods used for this removal are discussed in the following.

Sour gas is the name commonly given to natural gas containing H_2S . This H_2S is found in concentrations varying from a trace on up to 30 mol%. The presence of H_2S causes severe corrosion to occur when free water is present in natural-gas pipelines. When burned it forms sulfur dioxide, which is very toxic and can be a serious problem on the marketing end of the pipeline. Various methods for removal of H_2S are discussed in the following.

A companion to H_2S is CO_2 . It occurs quite frequently in natural gas but is not nearly so serious a detriment as H_2S . The main difficulty encountered is the corrosive

characteristics of CO_2 in the presence of water. Since it is not combustible, it lowers the heat content of the natural gas, and this becomes a factor especially where large volumes of CO_2 are present. The same systems that are used to remove the H_2S also can remove the CO_2 . The presence of both these acid gases in the same wellstream will require larger recirculation and regeneration equipment than if only one were present.

Other impurities can be found in natural gas but their occurrence is not so frequent. Mercaptans, compounds similar to alcohols but with sulfur replacing the oxygen (RSH instead of ROH), are found occasionally. Because mercaptans contain sulfur, they will form sulfur dioxide on combustion and this could present a problem. In addition, mercaptans may present a problem because they are foul smelling. Interestingly, even if mercaptans have to be removed from the gas to make it salable, a small amount of mercaptan will normally be added to the gas intentionally before it is sold. This is done so that natural gas leaks can be detected by smell. Nitrogen is frequently found in natural gas. It has no detrimental effects other than lowering the heat content of the gas. Oxygen is sometimes encountered but the quantities are usually so low as to be negligible. Another impurity that is only rarely encountered is helium. Because manufacture of helium is all but impossible, and because of its importance in many industrial applications, the U.S. government has established helium-recovery facilities. Production of helium is a specialized low-temperature process that will not be discussed further.

Removal of Water Vapor

In the preceding sections the removal of liquefiable hydrocarbons is discussed. The basic processes used for this removal of hydrocarbons invariably result in the removal of water vapors. Experience has shown that the water-vapor dewpoint of the gas leaving the low-temperature separator in these processes is from 10 to 12°F below LTS temperature for systems not using hydrate inhibitors and from 20 to 40°F below LTS temperature for systems using hydrate inhibitors. Dewpoint depressions for selective adsorption systems will be discussed further, and the use of liquid desiccants will be covered for the field of gas dehydration in this section.

To understand water-vapor dewpoint and dewpoint depression better, refer to Fig. 14.5. As was explained, this curve shows the saturation conditions for water vapor in natural gas. The water dewpoint temperature is the same as the saturation temperature for a given pressure. Assume that gas is flowing into a dehydration unit at 1,000 psia and 100°F and that it must be dehydrated to 7 lbm water/MMscf gas to meet contract specifications. At 1,000 psia and 100°F the gas contains 62 lbm of water. The inlet water-vapor dewpoint temperature is 100°F. From the chart for 1,000 psia and 7 lbm water/MMscf the outlet water-vapor dewpoint temperature is 33°F. The dehydrator must be capable of producing a 67°F dewpoint depression and removing 55 lbm water/MMscf gas.

Dehydration With Organic Liquid Desiccants. Since 1949 the removal of water from natural gas with organic liquid desiccants has become one of the most widely accepted methods of dehydration. Though a large number of organic materials can be used as liquid desiccants, by

Fig. 14.19—Glycol-absorption gas dehydrator.

far the most generally used are the ethylene glycols. Ethylene glycol (EG), diethylene glycol (DEG), triethylene glycol (TEG), and tetraethylene glycol (TRG) all can be satisfactorily used for dehydration of natural gas. However, by far the most widely used and generally accepted is TEG. Figure 14.19 shows a schematic flowsheet for absorption dehydration of natural gas using an ethylene glycol. The flowsheet will vary little from one glycol to the next. Wet gas enters the absorber and flows up through a series of plates coming into contact with the concentrated glycol solution. The glycol removes from 75 to 95% of the incoming water vapor in the gas, depending on the efficiency of the overall system. This lowers the dewpoint of the gas and the dehydrated gas leaves the absorber top and flows to the sales gas line.

The dilute glycol solution leaves the bottom of the absorber and flows through a heat exchanger and is heated prior to discharging into the still column. The heated glycol flashes off solution gases and enters the still column and comes into countercurrent contact with vapor rising from the reboiler. These vapors are essentially steam but do contain some hydrocarbon vapor and a small amount of glycol. The cooler glycol feed tends to condense the glycol vapors but does not affect appreciably the flow rate of the steam or hydrocarbon vapors which are discharged from the top of the still column. The dilute glycol then dumps into the reboiler where it is heated to the temperature required for producing glycol of high enough concentration to allow the outlet gas to be sufficiently dehydrated. The regenerated glycol overflows the weir in the reboiler and flows into the storage tank. Glycol from the storage tank is pumped to the top tray of the absorber where it comes in contact again with the gas being dehydrated. The glycol flows through the absorber by gravity, removing water vapors from the gas. Since the gas contains more water with each subsequent lower stage, the water picked up on the lower trays is greater than that on the upper trays. The dilute glycol is dumped from the absorber by a liquid level controller (LLC). Some glycol dehydrators use spent glycol and some high pressure gas as the driving force for the diaphragm pump for circulating lean glycol. If this is done, the contactor will not have an LLC.

Fig. 14.20—Equilibrium (minimum) water dewpoint obtainable for a given lean TEG concentration and effective contactor temperature.

Glycol dehydration units have been designed for capacities ranging from a few Mcf/D to those designed for millions of scf/D. Where the dehydration required is within the range of the TEG unit, it generally will be the most economical method of natural gas dehydration.

TEG has gained its position of prominence in gas dehydration because of several advantages. The first is that TEG will give a greater dewpoint depression with less loss of glycol than with any of the others. For equal concentrations, DEG can theoretically produce greater dewpoint depressions than is possible with TEG. However, the temperature to which the glycol/water solution can be heated without decomposing the glycol is only about 330°F for DEG, whereas TEG begins to decompose at temperatures above about 400°F. This allows for greater concentrations of TEG in the glycol solution with consequently higher dewpoint depressions.

The concentrations of the glycol solution are normally given in weight percent. This is somewhat misleading as the absorption of water takes place on a mole-composition rather than a weight-composition basis; 98 wt% TEG contains almost 15 mol% water. Thus the weight concentrations can be somewhat misleading because of the great difference in molecular weight for TEG and water.

Fig. 14.20 shows the equilibrium dewpoint for natural gas streams in equilibrium with TEG solutions of a given concentration. You will note that the higher the contactor temperature, the higher the equilibrium dewpoint. The effective contactor temperature for a glycol absorber will

Fig. 14.21—Effect of stripping gas and vacuum on TEG regeneration.

be at the temperature of the wet gas coming to the absorber. Some heat is released when the water is absorbed but the masses of water and glycol involved are so small in comparison with the mass of the gas flowing that, in general, the contactor will operate at the gas temperature.

The dashed line on Fig. 14.20 shows the approximate concentration of TEG solution that can be obtained by a reboiler operating at 400°F and atmospheric pressure. This concentration is in the range of 98.5 to 98.7 wt% glycol. If a higher concentration of glycol is required to obtain the desired outlet dewpoint, some additional means of regeneration must be employed. This can either be stripping gas, whose effect on glycol concentration can be estimated by the use of Fig. 14.21, or there are a number of patented closed regeneration recycle processes that also give higher TEG concentrations. In addition, a vacuum pump can be used to lower the pressure in the reboiler and still column as indicated in Fig. 14.21.

One important variable in selecting the glycol to be used for dehydration is the loss of solution that can be expected. These losses result from vaporization, mechanical entrainment, and vaporization with the still overhead. TEG is more favorable from a loss or replacement standpoint because the consumption resulting from vapor losses is much less than for DEG or EG for the same operating conditions. The vaporization losses are directly proportional to the vapor pressure of the liquid and the vapor pressure of TEG is considerably less than for the other glycols. Glycol consumption can be kept to losses in the range of 0.1 gal/MMscf gas under normal operating conditions with contactor temperatures of 100°F or lower and

pressures above about 200 psi. Glycol contactors should always contain a well-designed mist pad to remove entrained glycol from the dehydrated gas.

There are practical limitations to using TEG for dehydration from both a dehydration-efficiency and an operating-cost standpoint. The lower the temperature in the contactor, the greater the viscosity of the glycol solution. As the viscosity of the solution increases, the efficiency of the contactor decreases, which results in less water-vapor removal per stage or plate. At temperatures below 50°F, a pronounced reduction in efficiency has been observed. At temperatures approaching the freezing point of water, the TEG solution becomes so viscous that the liquid is all but impossible to move through the system. As the contact temperature increases, the vapor pressure of the solution increases, which results in higher vaporization losses of glycol and higher outlet water content of the gas. If the contactor temperature is increased to 120°F the vapor pressure of a 99-wt% glycol TEG solution will be almost twice what it is at 100°F with consequently larger vapor losses of the circulating solution.

There is no reasonable pressure limitation on the use of TEG for dehydration. However, the maximum dewpoint depression appears to increase with pressure up to about 500 psi and then remains essentially constant for higher pressures. Dehydration units have been designed and operated satisfactorily at pressures as high as 2,000 psi.

The higher the ratio of glycol circulated to the water vapor removed from the gas, the less will be the dilution on the individual trays and the dewpoint depression will,

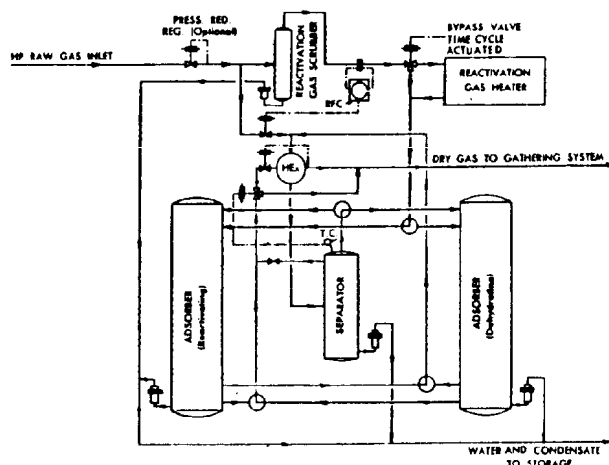

Fig. 14.22—Typical flow sheet for a dry-desiccant plant.

theoretically, be increased. However, since the dilution on the top tray is relatively small the overall effect of increasing the circulation rate is not appreciable. The overall effect could be obtained by increasing the number of plates or trays in the contactor. From an economic standpoint a circulation rate of 3 to 5 gal/lbm water absorbed appears best for most applications.

The number of trays in the contactor varies with the dewpoint depression desired. For normal pipeline-quality gas on a typical wellhead installation, four actual plates should be sufficient in the contactor. When higher dewpoint depressions are required, higher TEG concentrations are used and more trays are in the contactor. For high dewpoint depression operations as many as 10 to 12 or more plates may be installed in the contactor.

Various contaminants that enter the absorber under operating conditions can prove troublesome. A small amount of liquid water entering the absorber will have no serious effects on the system. If the water contains salt, however, the salt will be deposited in the reboiler and potentially can cause reduced efficiency of heat transfer and even the formation of hotspots and tube failures. Large quantities of water will overload the regeneration equipment causing inefficient regeneration of the glycol and perhaps other operational problems.

Liquid hydrocarbons are potentially a source of trouble for the system. An inlet separator capable of separating all liquid water and hydrocarbons before introducing the gas to the absorber is a must. Presence of liquid hydrocarbons will tend to clog the filter and flood the still column and reboiler. This may result in a serious fire hazard if the overhead from the still column is not piped away from the unit. Liquid hydrocarbons also can cause glycol foaming in the absorber and seriously reduce the capacity of the unit and increase glycol losses. Heavier hydrocarbon liquids will accumulate in the glycol and not be separated. Hydrocarbons may also decompose and deposit out on the firetube along with the decomposed glycol. This will cause the glycol to become discolored and also to lose its effectiveness for dehydration.

Ordinarily, there should not be serious corrosion in a TEG dehydrator unless CO_2 and/or H_2S is present. These acid gases do cause serious corrosion and other

operating problems in the dehydrator. Oxygen also causes glycol degradation. For this reason, storage tank and surge drums should be gas blanketed.

Dehydration by Adsorption. Water vapor also can be removed from natural gas by use of a solid desiccant as an adsorption medium. The adsorption process is a very complex phenomenon involving transfer of the component adsorbed from the gas phase to contact with the solid. For this reason the most effective adsorbents have extremely large surface areas per unit of mass. This means that their surface is honeycombed with capillaries that serve to provide the necessary surface area.

A flowsheet of a typical dry desiccant dehydration unit is shown in Fig. 14.22. There must be at least two desiccant beds for continuous operation because adsorption is a batch process. The main gas stream flows through an inlet separator where all free liquids are removed. Any liquids can be harmful to the dehydration process. Free water will reduce the capacity of the unit if not removed. Hydrocarbons can poison the bed if not properly regenerated. The main gas stream then flows through a pressure-reducing valve that controls the flow of the regeneration gas by inducing a pressure drop in the main gas stream. The gas then flows through one of the two adsorption towers where it contacts the desiccant and the water vapors are removed. The main gas stream flows to the sales gas line through a gas-to-gas heat exchanger where heat is removed from the regeneration gas.

The second adsorption tower is regenerated while the other tower adsorbs water vapor from the main gas stream. Regeneration gas (approximately 10 to 15% of the total gas flow) is taken from the main gas stream upstream of the pressure reducing valve and passed through a heater where the temperature is raised to approximately 450°F . The hot gas then passes through the desiccant bed. The water adsorbed through the bed is vaporized and swept out of the bed by the regeneration gas. The hot, wet regeneration gas passes through the gas-to-gas exchanger where it is cooled by the main gas stream. The water condensed from the gas is separated in the regeneration gas scrubber. The regeneration gas flows into the main gas stream downstream of the pressure-reducing valve. Because of the regeneration gas flow, the pressure drop through a solid desiccant dehydration unit will be higher than for a TEG unit and will be approximately 25 psi for the system.

An adsorption dehydration unit is controlled automatically on a time-cycle basis. The most frequently used cycle is 8 hours for the adsorption and regeneration. This requires that the towers be sized to handle 8 hours of flow from a water-vapor-capacity standpoint and that the heating and cooling requirements must be satisfied on the same basis. The time-cycle controller switches the three-way valves to place one tower on stream and the other on regeneration. The three-way valve on the heater system is controlled so that, when the heating cycle is completed, the valve switches to allow cool gas to flow through the system to cool the desiccant and tower prior to placing it on adsorption.

Some of the significant factors that must be considered in the design of these units are gas pressure and temperature, gas velocity, design outlet water content, adsorption capacity of the desiccant, and free liquids to be removed from the main gas stream. For good operation,

low spots in the flowlines and equipment where water might collect during the regeneration cycle must be avoided. Proper sequencing of the valve switching must be accomplished so that no unusual pressure or velocity surges will occur and no wet gas will be allowed to pass from the unit to the sales-gas line. Precautions should be taken to ensure that no high temperatures occur in the main gas stream.

There are a number of materials that can be used satisfactorily for desiccants. Activated aluminas, silica gel beads, and molecular sieves have all been used satisfactorily. Several grades or types of each desiccant are available and the final choice of the one to be used depends on the outlet water dewpoint required and an economic balance.

The capacities of the desiccants to adsorb water vary. However, in all cases, the initial desiccant capacity will indicate that the desiccant is capable of picking up far more water than can be designed for on a long-term basis. The capacities tend to drop off fairly rapidly initially and then gradually taper off until the desiccant becomes ineffective and must be replaced. The capacity and life of the desiccant are strongly dependent on the nature of the application. Under ideal operating conditions, a life of several years can be expected. Under severe fouling conditions the life of the desiccant may be reduced to one year or less. The design capacity to be used for the individual desiccant must be determined through an economic balance between the first cost of the unit and the additional operating cost for occasional desiccant replacement.

The heating required in the regeneration cycle is the sum of the heat of vaporization of the water adsorbed; the sensible heat to raise the desiccant, water, and water vapor to the regeneration temperature; and the heat required to heat the piping, vessels, etc. to regeneration temperature. Fuel requirements are directly proportional to the heat requirement. Cooling requirements are also directly proportional to the heat requirements. Proper design of the unit to minimize heat requirements can have a substantial effect on the size of heating and cooling equipment required.

The desiccant beds must be protected from slugs of liquid water and liquid hydrocarbons. Slugs of water will serve at least to decrease the adsorptive capacity of the unit and at worst can result in loss of the desiccant. Slugs of liquid hydrocarbons can cause fouling and reduce capacity for adsorbing water. The higher-molecular-weight hydrocarbons can plug the pores in the desiccant pellets and seriously affect the adsorptive capacity for water.

Protection of the beds is sufficiently important that an inlet separator must be included as an integral part of the unit. In addition, a guard or protective bed of desiccant placed ahead of the main adsorption vessel or as a top layer of desiccant in the adsorber can serve to protect the main desiccant bed from such items as compressor oil. The heavy oil when adsorbed on the desiccant can seriously affect the adsorptive capacity.

Corrosion usually is not considered a serious problem in dry desiccant dehydration. However, where there are large quantities of CO_2 and/or H_2S , corrosion may occur in the regeneration gas heat exchanger. At this point free water is condensing from the system and the water in combination with CO_2 and/or H_2S can create serious corrosion problems.

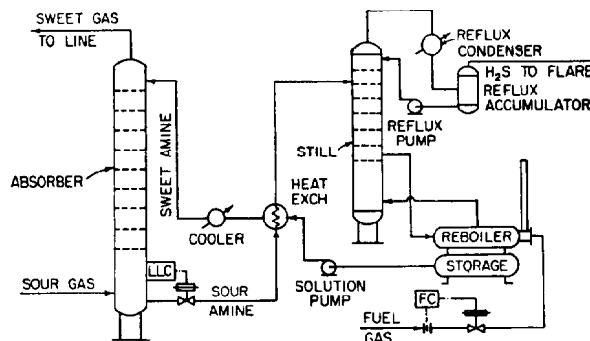

Fig. 14.23—Amine gas desulfurizer.

Removal of Acid Gases

The presence of acid gases, H_2S and/or CO_2 , in natural gas is undesirable from many standpoints. Perhaps the principal objection is the corrosion that results when free water is present. For this reason the H_2S and CO_2 normally are removed at the wellhead or relatively close to it. There are a number of systems that can be used for removal of acid gases.

Sweetening by Ethanolamines. Perhaps the most widely used type of acid-gas-removal system involves the use of an ethanolamine. A simplified flow diagram of a typical ethanolamine-type desulfurization unit is shown in Fig. 14.23.

In this process a solution of water and ethanolamine that may vary from about 15 to 60 wt% ethanolamine is used for removing H_2S and CO_2 from the incoming gas stream. The process is based on the principle that the acid gases, H_2S and CO_2 , will react with the ethanolamine at ordinary temperatures. The reaction can be reversed by reducing the pressure and heating the solution. The sour gas passes up through the contactor and the lean ethanolamine solution passes downward. The foul solution is discharged from the bottom of the contactor and flows through a heat exchanger before it discharges into the top of the still or regenerator column. The ethanolamine solution is boiled by application of heat in the reboiler. This boiling action supplies vapors, primarily steam, that pass up through the still column sweeping the H_2S and CO_2 from the ethanolamine solution.

The regenerated ethanolamine leaves the reboiler and passes through the amine-to-amine heat exchanger into a storage tank from which it is recirculated to the contactor with the amine pump. The H_2S and CO_2 leaving the top of the still column have a large volume of steam with them. To keep down the quantity of makeup water required and to minimize ethanolamine losses the overhead product usually is cooled. The water condensed in this cooling is returned to the regenerator as reflux.

A number of different types of ethanolamine can be used in the process. Monoethanolamine (MEA), diethanolamine (DEA), diglycolamine (DGA), and methyldiethanolamine (MDEA) are among those that are the most popular. There are a number of things that can affect the choice of ethanolamine to be used in a given system. MEA is a stronger base and has a lower molecular weight than

the others. This means that lower concentrations should be possible and that the removal of H_2S and CO_2 should be greater. DGA is also a primary amine with good removal properties but has the same molecular weight as DEA. DEA is a secondary ethanolamine and slightly less basic and therefore will not make specification sweet gas at as low a pressure as MEA and/or DGA. MDEA is said to offer selectivity when only H_2S removal is desired. Other sulfur compounds such as carbonyl sulfide (COS) also can affect the choice. COS reacts irreversibly with MEA and this requires the installation of a reclaimer to control MEA losses.

In many ethanolamine sweetening units, corrosion is the greatest operating problem. Corrosion can occur in the reboiler, storage tank, still column, heat exchangers, and the contactor. Most of the corrosion problems can be minimized by correct design. Limiting the heat flux in the reboiler and condenser can serve to minimize corrosion there. Maintaining pressure on the sour amine solution until it is passed through the heat exchanger and to the point of introduction to the still column can help minimize corrosion in the heat exchanger and piping. Limiting the amount of acid gas pickup per unit of circulating solution will also help. Limiting the temperature on the stream introduced to the top of the still column will help. The lowest possible pressure should be maintained on the still column because this lowers the boiling temperature of the ethanolamine solution.

Another severe problem that can occur in ethanolamine-type desulfurizers is foaming. This foaming most frequently occurs in the contactor and can result in excessive amine losses. Foaming has many causes but the presence of liquid hydrocarbons in the contactor is a frequent one. In addition, particulate matter can stabilize foam. A good filter should be used to remove any iron sulfide or other solid materials from the circulating solution. If oxygen enters the system it will cause problems. It can cause the

formation of thiosulfates and also cause direct degradation of the amine solution.

Iron Sponge Sweetening. Hydrated iron oxide can also be used for removing H_2S from natural gas. This process is "selective" and removes only the H_2S from the gas. It is suitable for removing small quantities (a few grains per 100 scf) of H_2S from natural gas streams. The flow sheet is similar for that of a solid desiccant dehydration unit except for the fact that there is no regeneration gas stream. The iron oxide or sponge is generally suspended on wood chips to disperse it and limit the heat release caused by the reaction of H_2S with the iron oxide. The iron oxide must be kept in a basic environment ($pH \geq 8$) so that soda ash or caustic soda solution is normally injected into the bed with the natural gas. The gas leaving the bed has essentially all the H_2S removed.

Since the iron sponge is consumed in the process and must be replaced frequently, the vessels must be constructed in such a way that the bed can be replaced easily. Iron sulfide will self-ignite when exposed to air, so extreme caution must be used when replacing the iron sponge bed. In addition, disposal of the spent sponge can present a problem because, when it burns, sulfur dioxide is formed.

In all desulfurization units, disposal of the H_2S gas presents a problem. Increasingly, government agencies forbid exhausting the H_2S to the atmosphere either as H_2S or, after incineration or flaring, as SO_2 . For this reason disposal of the removed H_2S must be an integral part of the planning for any desulfurization unit.

Chapter 15

Surface Facilities for Waterflooding and Saltwater Disposal

K.E. Arnold, Paragon Engineering Services*

Introduction

In producing operations it is often necessary to handle brine that is produced with the crude oil. This brine must be separated from the crude oil and disposed of in a manner that does not violate environmental criteria. In offshore areas the governing regulatory body specifies a maximum hydrocarbon content in water that it will allow to be discharged overboard. Currently this ranges from 7 to 72 mg/L depending on the specific location. In most onshore locations the water cannot be disposed of on the surface because of possible salt contamination and it must be injected into an acceptable disposal formation or disposed of by evaporation. On the other hand, it is often desirable to inject water into the producing formation to maintain reservoir pressure or increase recovery through waterflooding. Produced water that is properly treated to remove hydrocarbons and solids can be used for this purpose. In addition, supplemental sources of water from other formations or from surface sources could be used for waterflooding.

The purpose of this chapter is to discuss the equipment and design criteria that are employed in common systems for either waterflooding or for saltwater disposal. In both cases the design engineer may be concerned with designing piping systems, selecting pumps, separating solids from water, treating hydrocarbons from water, removing dissolved gases and solids from water, treating hydrocarbons from solids, and overall project management.

Piping System Design

In any waterflood or disposal system, it is necessary to gather the water from one or more sources for treatment and then to distribute it to one or more points for injection or disposal. This section discusses criteria for selecting pipe diameter, pipe materials, and wall thickness, as well as general design considerations for cross-country piping systems.

Pipe Diameter

The choice of pipe diameter depends on the pressure drop available, or on a range of acceptable velocities for fluid flow in the pipe.

Pressure at a Point. The pressure at any point in a system can be determined from Bernoulli's theorem, if the pressure at any other point is known. This theorem, which is derived from conservation of energy, is given by

$$Z_1 + \frac{p_1}{\rho_1} + \frac{(v_1)^2}{2g} = Z_2 + \frac{p_2}{\rho_2} + \frac{(v_2)^2}{2g} + Z_{fl}, \dots (1)$$

where

Z = elevation above a datum,

p = pressure,

ρ = density,

v = velocity,

g = gravitational constant, and

Z_{fl} = head loss due to friction between Points 1 and 2.

Darcy demonstrated that head loss was given by

$$Z_{fl} = \frac{fLv^2}{2gd_i}, \dots (2)$$

where

f = friction factor,

L = length, and

d_i = pipe ID.

The friction factor is, in turn, a function of the non-dimensional Reynold's number, given by

$$N_{Re} = \frac{\rho dv}{\mu} \dots (3)$$

* Authors of the original chapter on this topic in the 1962 edition were W.F. Ellison and R.H. Lasater.

where N_{Re} is the Reynold's number and μ is the viscosity. The relationship between Reynold's number and the friction factor is given in the classical Moody diagram (Fig. 15.1).

Pressure Drop in Liquid Lines. The pressure drop for liquid lines can be derived from Eq. 1 as

$$\Delta p = \frac{0.000115 f (q_L)^2 \gamma_L L}{(d_i)^5}, \dots\dots\dots (4)$$

where

Δp = pressure drop, psi,
 q_L = liquid flow rate, B/D,
 γ_L = specific gravity of liquid relative to water,
 L = length of line, ft, and
 d_i = pipe ID, in.

This relationship is shown graphically in Fig. 15.2.

For liquid flow in pipelines, a friction factor of 0.02 is sometimes used for preliminary calculations. In determining the actual friction factor from Fig. 15.1, it is sometimes convenient to use either of the following equations.

$$N_{Re} = 7,734 \frac{\gamma_L d_i v}{\mu} \dots\dots\dots (5)$$

or

$$N_{Re} = 92.1 \frac{\gamma_L q_L}{\mu d_i} \dots\dots\dots (6)$$

where v is velocity, ft/s, and μ is viscosity, cp.

The roughness, ϵ , to use in determining which relative-roughness, ϵ/d , curve governs in Fig. 15.1 depends on the age of the pipe and the material that lines its inside surface. Cast-iron pipe could be expected to be rougher than bare-steel pipe and bare-steel pipe rougher than plastic-lined steel pipe. Roughness factors for new pipe are given in Table 15.1. These should be increased by a factor of two to four to account for corrosion or incrustation effects that could occur with age.

In the past, the empirical Hazen-Williams¹ equation has been used by some engineers for flow of water through pipelines. With the advent of computers and programmable calculators, these empirical equations are no longer recommended. However, for completeness, the Hazen-Williams equation is given as

$$Z_f = 0.015 \frac{(q_L)^{1.85} L}{(d_i)^{4.87} (C_{HW})^{1.85}}, \dots\dots\dots (7)$$

where

Z_f = friction head loss, ft of liquid,
 q_L = liquid flow rate, B/D,
 L = length of line, ft,
 d_i = pipe ID, in., and
 C_{HW} = constant with a value of 80 to 140,
 depending on the inside pipe material
 and its age.

In determining the length to be used in either Eq. 4 or 7, it is necessary to include an allowance for valves, ells, tees, reducers, and entrance and exit losses from vessels. The most common way of accounting for these pressure losses is to include a certain additional length of pipe to the actual length of pipe in the value used for L . Table 15.2 shows the length of pipe that should be added for various valves and fittings.

Velocity in Liquid Lines. Although it is necessary that a selected pipe diameter ensures that the pressure drop is not excessive, in many cases the velocity in the line, and not the pressure drop, will determine the pipe diameter. In most of the short liquid lines within the plant, there will be more than sufficient pressure available to transport the liquid from one piece of equipment to another. However, if the entire pressure drop were taken in the piping, and only a marginal pressure drop were taken across a liquid-control valve, the velocities in the pipe would be high enough to cause noise, erosion of products of corrosion, or water-hammer problems. For this reason a maximum liquid flow velocity of 15 ft/s usually is recommended.

Consideration should also be given to a minimum velocity necessary to prevent solids buildup in the bottom of the pipe. Experiments have shown that when the liquid velocity falls below a certain value, any solids present will settle in a horizontal bed until an equilibrium velocity is reached over the bed. At this velocity, erosion of the solid particles on the surface of the bed is exactly balanced by the deposition of additional particles. It can be shown that, for situations likely to be encountered in oilfield pipelines, a velocity of between 2 and 4 ft/s is required to keep from building up such a bed. For this reason a minimum velocity of 3 ft/s is usually preferred for any liquid piping likely to contain solids.

The following equation has proved useful in calculating velocities.

$$v = 0.012 \frac{q_L}{(d_i)^2} \dots\dots\dots (8)$$

This equation is shown graphically in Fig. 15.3.

Choosing Pipe Diameters in Liquid Lines. The choice of a pipe diameter for a liquid line thus becomes one of choosing a diameter large enough for the pressure available while attempting to keep the velocity between 3 and 15 ft/s. On short lines within a plant, it is usually quicker to choose a diameter based on velocity considerations and then check for pressure drop. On longer lines, or on lines within a plant that flow between atmospheric tanks (low available pressure), it is usually desirable to choose a diameter based on pressure-drop considerations first and then to check velocity.

On lines that experience large variations in elevation, it is desirable to employ Bernoulli's theorem (Eq. 1) at all high points to ensure that there is sufficient positive pressure so that a vacuum is not created. Although it is possible to operate a line with a high-point vacuum, relying on a syphon effect may make it difficult to restart a line if the syphon ever loses its liquid seal. In addition, at any point where a vacuum exists, there is a very real feasibility of drawing oxygen into the system with resultant corrosion and bacteria problems.

Fig. 15.3—Velocity in liquid lines.

Sometimes, it is not feasible to satisfy minimum velocity criteria during the early stages of a project, where flow velocities are low, without violating pressure drop or maximum velocity criteria at peak flow rates. In such cases, engineering judgment is needed to choose between alternatives such as (1) installing a smaller line initially and either looping the line or installing more pumps at a later date, (2) allowing an equilibrium-solids bed to be deposited initially and relying on it being eroded as flow velocities increase, or (3) allowing a velocity greater than 15 ft/s at peak flow rates.

Pressure Drop in Gas Lines. Although this chapter deals primarily with liquid flow, it may be necessary to size gas lines as part of the project. Source water may come from gas-lifted wells, which would require a gas-lift gas-distribution system, produced water may have flash gas associated with its separation and treating equipment, flotation units and gas strippers require gas lines to operate, and fuel, instrument and utility gas undoubtedly will be required.

Flow in gas lines is considered isothermal. That is, there is sufficient heat transfer to and from the surrounding air, water, or soil to keep the temperature of the gas in the line from changing as the pressure changes because of friction losses. If we assume steady-state gas flow, an ideal gas ($z = 1.0$), and a constant friction factor over the length of the line, the following equation can be derived.

$$(p_1)^2 - (p_2)^2 = 25.2 \frac{\gamma_g (q_g)^2 T f L}{(d_i)^5}, \quad \dots \dots \dots (9)$$

where

- p_1 = pressure at pipe inlet, psia,
- p_2 = pressure at pipe outlet, psia,
- q_g = flow rate of gas at standard conditions, MMscf/D,
- γ_g = specific gravity of the gas at standard conditions relative to air, and
- T = temperature, °R.

When the Reynold's number is calculated to determine the friction factor from Fig. 15.1, it is often convenient to use either

$$N_{Re} = 20,102 \frac{q_g \gamma_g}{d_i \mu_{gf}} \quad \dots \dots \dots (10)$$

or

$$N_{Re} = 335 \frac{v_{gf} p_1 d_i \gamma_g}{T \mu_{gf}}, \quad \dots \dots \dots (11)$$

where v_{gf} is the velocity of gas at specific flow conditions, ft/s, and μ_{gf} is the viscosity of gas at specific flow conditions, cp.

Fig. 15.4—Hydrocarbon gas viscosity.

The viscosity of the gas at flow conditions can be derived from Fig. 15.4. Where

$$\frac{p_1 - p_2}{p_1} < 0.1,$$

Eq. 9 reduces to

$$\Delta p = 12.6 \frac{\gamma_g T f L (q_g)^2}{p_1 (d_i)^5} \quad \dots \dots \dots (12)$$

It is recommended that either Eq. 9 or 12 be used. However, in the past, two empirical equations were developed that have been used extensively. The Weymouth equation² is used for lines with high Reynold's numbers. It assumes that the friction factor is merely a function of pipe diameter. That is, flow is occurring in the flat part of the relative roughness curves on the Moody diagram. The Weymouth equation can be written as

$$(p_1)^2 - (p_2)^2 = 0.81 \frac{\gamma_g (q_g)^2 T L}{(d_i)^{5.33}} \quad \dots \dots \dots (13)$$

This equation would normally apply to short lines within the plant where gas velocities, and thus Reynold's numbers, would probably be high. Figs. 15.5 and 15.6 can be used to solve this equation.

For long gas lines, where velocities are likely to be less and the friction factor will depend on both the line size and the flow rate, the Panhandle equation² has been developed:

$$(p_1)^2 - (p_2)^2 = 0.2 \frac{\gamma_g^{0.96} q_g^{1.96} T L}{E d_i^{4.96}} \quad \dots \dots \dots (14)$$

where E is flow efficiency (1.00 for new pipe, 0.92 for average conditions, and 0.85 for unfavorable conditions).

Velocity in Gas Lines. As in liquid lines, there is a velocity consideration in picking a pipe diameter for a gas line. At high velocities, there could be problems with both noise and erosion of the layer of corrosion products on the inside of the pipe. The greater the rate of erosion of these products, the greater the rate of corrosion the line would experience.

From a noise consideration, the velocity in the pipe should be limited to 60 to 80 ft/s at actual flow condition of pressure and temperature. Experiments have shown that there is a correlation between velocity and erosion of the products of corrosion, which is given by

$$v_{gf} = \frac{C_E}{\sqrt{\rho_g}} \quad \dots \dots \dots (15)$$

where ρ_g is the density of the gas at actual conditions, lbm/cu ft, and C_E is a constant for erosional flow. Eq. 15 can be rewritten as

$$v_{gf} = 0.6 C_E \sqrt{\frac{T}{(\gamma_g) p}} \quad \dots \dots \dots (16)$$

API Recommended Practice 14E³ for offshore piping systems proposes using a value of 125 for intermittent service and 100 for continuous service for the constant C_E . Recent experimental data indicate a C_E as high as 300 may be appropriate for an allowable corrosion rate of 10 mil/yr.

The choice of a value to use between 100 and 300 depends on the judgment of the design engineers as to the corrosivity of the gas and the cost of being overly conservative. Where pressures are below 1,000 to 1,500 psi, the noise criteria will govern and the erosional criteria can be neglected.

If the gas is saturated to the extent that liquids are likely to condense from the vapor phase because of ambient cooling, it is recommended that a minimum velocity of 10 ft/s be maintained. This will sweep the liquid out of the line. At lower velocities, liquid may accumulate at low spots, accelerating corrosion and potentially leading to liquid slugging in the line.

Choosing a Pipe Diameter in Gas Lines. As in liquid lines, the choice of pipe diameter will depend on satisfying both the pressure-drop and velocity criteria. For almost all lines within the plant, the velocity criteria will govern, and the pressure drop will probably not even have to be checked. For long gathering or distribution lines the pressure drop available may govern, or a study of pipe diameter and cost vs. compressor horsepower and cost may be necessary.

Materials

Selection of materials for pipe, valves, and fittings for any piping system must take into account the pressure rating of the application, the corrosivity of the fluid, and the location of the line. There is some economic cost over life for each selection and this must be taken into account in determining the types of material to use for a given application.

Asbestos-Cement Pipe. Because of its resistance to corrosion and low cost, asbestos-cement pipe is recommended for use in large-diameter lines on gravity or low-pressure water systems (200-psi maximum working pressure). The joint connection consists of asbestos-cement couplings with rubber rings. The pipe itself is not flexible, but a deflection of 6° can be obtained at the coupling. This proves advantageous in eliminating abrupt bends when it is necessary to lay pipe on horizontal or vertical curves. Care must be exercised in the actual laying of the pipe by providing a conditioned ditch for the pipe. Installation guides have been published by the manufacturers of asbestos-cement pipe and are available to the design engineer on request.

Asbestos-cement pipe can be coated internally with plastic or fiberglass to lower the friction factor and to protect against seepage of any crude oil that may be in the water stream. Asbestos-cement has the disadvantage of being more brittle than steel pipe, which could make it susceptible to damage from external loads. In addition, proper bedding and backfill compaction is required to prevent future pipe movement resulting from external loads, which could cause joint leakage.

Fig. 15.5—Gas flow based on Weymouth formula.

Fig. 15.6—Gas flow based on Weymouth formula.

Plastic Pipe. In recent years, there has been a continuing increase in the use of the various types of plastic pipe especially in moderately low-pressure (300 psi), small-diameter (6 in. and lower) water service. Plastic pipe is not susceptible to either internal or external corrosion, it has a low friction factor, and its light weight makes it easy to install. This is a rapidly developing field and there are numerous proprietary brands. However, in general, plastic pipe can be purchased in accordance with the following API specifications: Spec. 5LE for polyethylene line pipe (PE),⁴ Spec. 5LP for thermoplastic line pipe (PVC and CPVC),⁵ and Spec. 5LR for reinforced thermosetting resin line pipe (RTRP).⁶

The latter category, which includes fiber-reinforced plastic (FRP) pipe, is the strongest, with PVC next, and PE last. All plastic pipe is sensitive to temperature and must be derated as temperature increases. PE pipe is limited to 100°F, PVC pipe to 140°F, and RTRP pipe is limited to 150°F unless specific tests are run by the manufacturer.

The pressure rating of plastic pipe also depends on the fluid being handled. PE pipe handling crude oil has 50% of the pressure rating of the same pipe handling water. PVC pipe must be derated to 40% of its water strength if handling crude oils because of the long-term effect of hydrocarbons on the material. The deration of RTRP pipe is specified by the manufacturer.

Because of the superior strength and greater resistance to heat and hydrocarbons, the use of FRP pipe is increasing. Pipe is available in diameters to 12 in. and pressure ratings that exceed those in 5LR by a factor of two. However, plastic pipe has the disadvantage of being extremely brittle. This can lead to damage in installation. More important, if the ditch is not prepared correctly in rocky soil, over time as the line settles, rocks can come in contact with the underside of the line and cause a stress concentration and eventual failure. It also has the disadvantage of becoming brittle with time when exposed to direct sunlight.

Cast-Iron Pipe. Satisfactory installations of cast-iron pipe have been made on systems where pressures are more than 200 psi but less than 250 psi. Cast-iron pipe has a high corrosion-resistant quality. This pipe has a higher initial cost than either asbestos-cement or plastic pipe. While it is less susceptible to impact and temperature effects than plastic pipe, it is more brittle than steel pipe. For this reason, it must have flat-faced flanges and care must be exercised to ensure that it is not connected to a valve fitting with a more standard, raised-face flange.

If cast-iron pipe is subjected to a fire and then hit by a stream of cold water, it is susceptible to cracking. For this reason, it is not generally acceptable for services containing hydrocarbons.

Carbon Steel Pipe. The most commonly used material for piping systems is Grade B line pipe (35,000-psi yield) manufactured in accordance with API Spec. 5L for line pipe.⁷ Because of its strength, this material can withstand high pressures and is available in diameters to 64 in.

Steel pipe has excellent impact resistance and flexural strength. Unfortunately, it is much more susceptible to both internal and external corrosion, and its installation is more expensive than the lighter plastic pipes.

Where oxygen is excluded from the system, internal corrosion may not be a problem. External corrosion can be reduced by burying and protecting the pipe with a cathodic-protection system. The system could consist of sacrificial zinc or aluminum anodes, which are attached electrically to the pipe at specified intervals. For long pipelines, an impressed-current system may be considered, which would enable the use of fewer anodes.

External corrosion could also be combatted with a coating system. For pipe that is exposed to salt air, a three-coat epoxy-paint system is often specified. Less-elaborate systems are employed in less-severe atmospheres. Underground or underwater pipe may be protected by a thin-film-epoxy, coal-tar-epoxy, or extruded-plastic system. Thin-film-epoxy systems seem to be more popular lately, because of their greater toughness to potential handling and installation damage.

Most long pipelines are protected both with a coating system and cathodically. The coating system decreases the current demand, while the cathodic-protection system provides protection for any breaks, gaps, or scratches that develop in the coating.

Where internal corrosion is anticipated, carbon steel can be protected in four ways.

1. **Cement lining.** Individual joints have a $\frac{3}{8}$ -in. cement-mortar mix applied by a centrifugal spinning procedure. The field joints are protected by an asbestos welding gasket compressed between the joints. Cement-lined pipe is available in sizes from 3 to 24 in. API RP 10E⁸ specifies cement thickness vs. pipe size. The accepted tolerance is $\pm 1/32$ in.

2. **Coal-tar-epoxy lining.** Typically this is a $\frac{3}{32}$ -in. lining that is centrifugally spun into the pipe section after a field joint is made. This technique is limited to large-diameter lines.

3. **Plastic lining.** Various types of epoxies have been installed in steel lines. These can be installed in a small section at a time, or by use of cylindrical devices (pigs), which are run into the line in sections up to 1 mile long. Some success has been reported with plastic lining used to protect pipe against further deterioration, but the necessity of cleaning the pipe wall before applying the plastic coating makes this very difficult. At the present time, manufacturers claim the smallest pipe that can be internally plastic coated is 1 $\frac{1}{4}$ in. nominal.

4. **Use of liners.** There have been several successful installations of FRP and other liners in steel pipe. The steel provides the strength to resist high pressures and the liner provides corrosion resistance. Other than the high cost of installation, this system has the further drawback in that because of long-term permeability through the liner, the pressure in the annulus between the liner and steel can reach an equilibrium with the line pressure. When the line is depressured for maintenance, this may cause collapse of the liner if the system is not carefully designed. Liners have been installed in pipe from 2- to 30-in. diameter and for distances as long as 0.5 mile in a single pull.

TABLE 15.3—DESIGN PROPERTIES AND ALLOWABLE WORKING PRESSURES FOR PIPING*

*ASTM A106, grade B seamless pipe—petroleum refinery piping code for pressure piping ANSI B31.3-1976—corrosion allowance = 0.05.

Exotic Metals. In some highly corrosive environments, especially those associated with CO₂ floods, stainless-steel pipe has been employed. This is extremely expensive. However, it may be the only acceptable long-term solution.

Pressure Ratings for Steel Pipe

Pipe-Wall Thickness. Water-injection lines may have to withstand extremely high pressures. In addition, some of the piping in the plant may include high-pressure gas, oil, or water piping. Thus, steel pipe-wall thicknesses other than "standard" weight may be needed.

The thickness for any pipe depends on the pressure rating, temperature, diameter, and piping code applicable to that pipe. Piping codes generally used are: (1) ANSI B31.1—power piping,⁹ (2) ANSI B31.3—chemical plant and petroleum refinery piping,¹⁰ (3) ANSI B31.4—liquid petroleum transportation piping systems,¹¹ and (4) ANSI B31.8—gas transmission and distribution piping systems.¹²

Generally, B31.1 and B31.3 have the same equation for determining pipe thickness. This tends to be more conservative than that contained in the other two codes. Wall thicknesses determined from this equation are shown in Table 15.3. These are primarily used for steam piping at all locations, for all piping on offshore platforms, and in large onshore plants that represent a large capital investment.

B31.4 and B31.8 have the same equation for pipe-wall thickness. The allowable pressure in a given pipe is dependent on the "construction factor," which is a measure of the potential cost of failure at a given location. The greater the hazard to the public because of failure, the smaller the construction factor. Allowable pressures for various grades of steel and construction factors are given in Table 15.4 and 15.5.

Generally, oil or water lines can be specified with a construction factor of 0.72. The factor for lines containing gas depends on the location of the line. Table 15.5 indicates, in general, the factors to be used. However, care should be taken, since there are specific definitions

Looped Networks. In large gathering and distribution systems, the potential savings associated with looping the system (i.e., installing pipelines parallel to existing lines to increase the system's capacity) or installing pumps at different locations must be investigated. Although simple loops may be calculated by hand, the ready availability of many fine looped-network computer models make this a fairly easy choice. In most instances, some simple calculations and assumptions can be made that narrow the choices to a few practical alternatives. An experienced engineer can use these techniques to greatly reduce computer time and costs.

Gravity Systems. In gravity-systems design, careful consideration must be given to pressure drops in the pipe. Valves and fittings must be considered in these calculations since there is normally little room for error. It is absolutely necessary that accurate elevations of all tanks and equipment and an accurate profile be determined along the line of the pipe. The hydraulic gradient must be plotted along this profile for worst-case conditions of working levels in the tanks or operating pressure in vessels. The hydraulic gradient should be higher than the pipe at each point to ensure that a syphon is not developed. Fig. 15.7 shows an example profile.

High-point vents should be installed in the line to keep gas from accumulating and potentially blocking the flow. Gas eliminators such as those used in lease automatic custody transfer (LACT) units can be installed for this purpose.

Pigging. On long lines where paraffin, scale, or solids may be deposited, periodic pigging of the line may be required. A pig is a sphere or cylinder, often containing scrapers, which is injected into the line at the beginning in a "pig launcher" and collected in a "pig trap" at the end.

Launchers and traps must be installed wherever the pipeline changes size and at all junction points. Where pigging is expected, care must be exercised in selecting valves and radius of curvature of the pipe to allow the pig to move through the line. Fig. 15.8 shows a typical pig trap which can be used to remove a pig from a line without having to shut in flow.

Selecting Pumps and Drivers

Pumps are used in all water gathering, treating, and disposal systems. Indeed, the most costly single piece of equipment in a water-injection system is often the injection pump and driver. The factors to consider in the selection of pumps include capacity, head, suction lift,

TABLE 15.8—API PRESSURE RATINGS

20,000	20,000	—	—
30,000	30,000	—	—

space, efficiency, flexibility to varying throughput and pressure conditions, and type of prime mover. It is beyond the scope of this chapter to discuss any of these in detail. Instead, a broad description of commonly used pump types and their characteristics, types of drivers and their characteristics, and some comments as to pump piping and installation are presented.

Pump Types

There are many types of pumps in use. However, most of the common ones can be classified as either positive displacement or centrifugal by the action they employ to move the liquid to a higher pressure level.

Positive-Displacement Pumps. Positive-displacement pumps employ a moving piston, plunger, diaphragm, or rotor to move a fixed volume of liquid per revolution of the pump. The amount of liquid pumped per revolution is independent of the speed of the pump or the discharge pressure.

Reciprocating pumps are positive-displacement pumps that operate as a result of the movement of a piston or plunger inside a cylinder. Piston pumps can be double-acting in that the fluid could be forced out of the cylinder into the discharge piping ahead of the piston and liquid drawn into the cylinder behind the piston regardless of the direction of the piston travel. If liquid is pumped during a piston movement in one direction only, the pump is classified as single-acting. Pumps with two cylinders are called "duplex," three cylinders "triplex," etc.

Advantages of reciprocating pumps are (1) for a given speed, the rate of discharge is practically constant, regardless of head, and the pump is limited only by the power of the prime mover and the strength of the pump parts; (2) efficiency is high regardless of the head and speed; (3) owing to low operating speed and the low velocities of fluids, they are well adapted to handling viscous fluids; (4) they are usually self-priming.

Disadvantages of reciprocating pumps include (1) heavy weight and large physical size; (2) valve trouble can occur, especially when pumping liquid containing solids; (3) pulsating flow in both suction and discharge lines; (4) high net positive suction head requirements; (5) not generally suitable for handling liquids containing solids, abrasives, or dirt.

Rotary pumps are positive-displacement pumps that operate by having a rotating member turn inside a housing in such a way that it creates one or more cavities that move from suction to discharge forcing the trapped liquid through the pump.

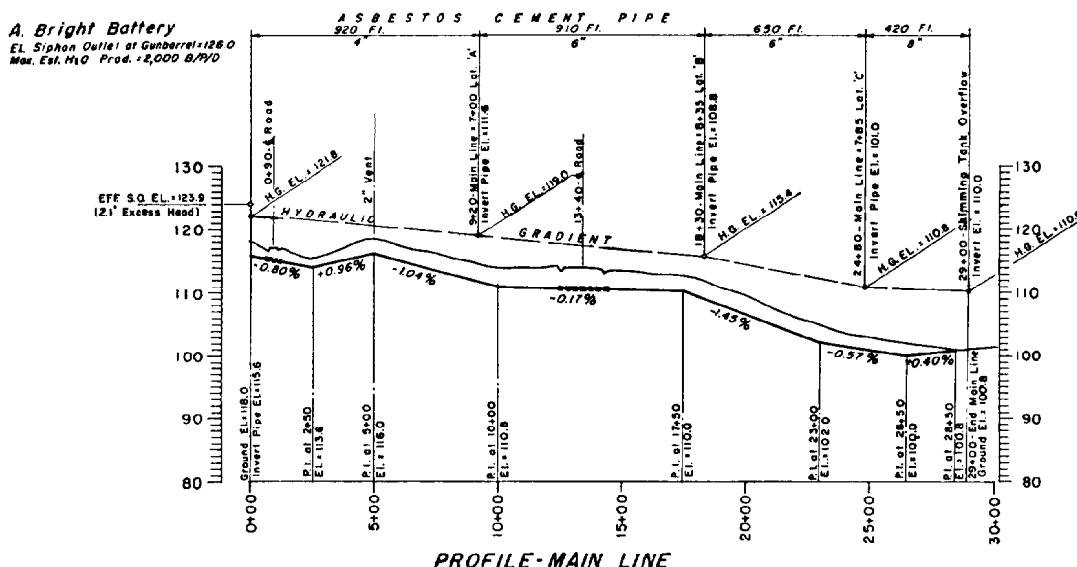

Fig. 15.7—Profile of the main line in a gravity system.

Advantages of rotary pumps are (1) in general, these are the same as for reciprocating pumps; (2) rotary pumps are relatively inexpensive and require small space; (3) they will operate over wide ranges of capacity, head, and viscosity; (4) rotaries are self-priming and are good vapor-handlers; (5) they deliver relatively pulsation-free flow.

Disadvantages of rotary pumps are (1) close clearances and/or rubbing contacts restrict the choice of materials for construction; (2) close clearances require that liquids to be pumped have lubricating value and be noncorrosive—therefore, they are suitable for oil but not suited for water; (3) rotaries have low volumetric efficiency at low speeds because the slip approaches the displacement. This effect increases directly with the pressure/viscosity ratio.

The **diaphragm pump** is a type of reciprocating positive-displacement pump that operates by the action of a diaphragm moving back and forth within a fixed chamber. Raising the diaphragm creates a vacuum, drawing liquid (or air) into the pump through the suction check valve. Lowering the diaphragm forces the liquid (or air) out through the discharge check valve. This type of pump will handle clear water or water containing large quantities of mud, sand, sludge, and trash. Its popularity for low-volume applications stems from its ability to operate where the quantity of water varies considerably so that much of the time air is being pumped. The suction effect of the diaphragm motion makes the pump self-priming. For high discharge pressure requirements, diaphragm pumps are limited to very low fluid rates. Although they tend to be easy to repair in the field, the frequency of maintenance required is higher than with other pump types.

Centrifugal Pumps. A centrifugal pump contains a central rotating wheel, called an impeller, which imparts high velocity to the liquid by centrifugal force and then

converts most of this velocity to pressure. The liquid flows from the pump even against considerable discharge pipe pressure. By its very nature, the centrifugal pump operates at relatively high rotative speeds. It is the most common type of pump used today.

Centrifugal pumps can be of radial-flow construction, axial-flow construction, or some combination of the two. In radial-flow pumps, flow enters the center of the wheel and is propelled radial to the outside. Radial construction provides maximum head per stage.

Axial flow pumps develop their head by the propelling or lifting force developed in the fluid by the impeller vanes, which, in cross section, are shaped like airfoils. The flow is parallel to the pump shaft axis. The diameter of the impeller is the same at the suction and discharge sides. Velocity energy is converted to pressure by stationary diffuser vanes.

Advantages of centrifugal pumps are (1) simple construction, quiet operation; (2) inexpensive; (3) small space requirement in relation to capacities; (4) no close clearances, therefore, it can handle liquids containing dirt, abrasives, large solids, etc.; (5) low maintenance, dependable; (6) low net positive suction head requirements; (7) capacity adjusts automatically to changes in head. Thus, capacity may be controlled over a wide range at constant speed.

Disadvantages of centrifugal pumps are (1) cannot achieve high pressures like reciprocating pumps; (2) viscosity effects on head, capacity, and efficiency are appreciable at 200 Saybolt Universal Seconds (S.S.U.) and serious at 500 S.S.U.; (3) low efficiencies when compared to reciprocating pumps; (4) efficiency is a function of flow rate. At throughput rates and pressures less than design, considerable additional horsepower may be required.

Pump Drivers

Depending on the location, type of pump, availability, and cost of natural gas for fuel, pump drivers will be gas

Fig. 15.8—Pig trap.

engines, gas turbines, or electric motors. The amount of horsepower required for a given installation can be calculated from

$$P_{bh} = \frac{q_L \Delta p}{1714 E_p} = \frac{q_L Z \gamma_L}{3960 E_p}, \quad \dots \dots \dots (17)$$

where

- P_{bh} = brake horsepower,
- q_L = flow of liquid, gal/min,
- Δp = differential pressure, psi,
- E_p = pump efficiency at flow conditions, %
- Z = head of liquid, ft, and
- γ_L = specific gravity of liquid relative to water.

Bump efficiencies of between 80 and 90% for reciprocating pumps and 55 and 65% for centrifugal pumps are common.

Natural Gas Engines. The reciprocating internal-combustion natural-gas engine is the leading prime mover in the oil field because of its high efficiency, availability, and ease of maintenance. Both two- and four-cycle engines are in use.

In general, for a given engine, the horsepower output depends on engine speed in rev/min and whether an exhaust-gas turbocharger is installed to increase the flow

of air to the power cylinders. At higher operating speed, the engine is capable of producing greater horsepower. A turbocharged engine will be able to develop more horsepower than a naturally aspirated engine. Unfortunately, maintenance costs and downtime increase as an engine is accelerated above a certain limit and when turbochargers are added. A turbocharged engine has the added disadvantage of being able to load itself to mechanical destruction.

Most engine drivers are built to operate in the 900- to 1,400-rev/min range. For sustained operations, most mechanics do not like to operate their engines above 1,000 to 1,200 rpm. Turbocharged engines can be expected to use 7,000 to 8,000 Btu/bhp-hr of fuel while naturally aspirated units will use 8,000 to 10,000 Btu/bhp-hr. Fuel efficiency is fairly constant over large ranges in bhp.

Care must be exercised with nitric and nitrous oxide (NO_x) emissions on large installations (over 2,000 hp) or in nonattainment areas. Catalytic converters are available for most engines if this becomes a problem.

Gas Turbines. Gas turbine engines have three basic sections—an air-generation section, a combustion section, and a power-turbine section. In the compressor, or air-generator section, ambient air is drawn into the turbine

and compressed with a combination of radial and axial flow elements for delivery to the combustion section. Fuel is mixed with the air in the combustion section and the combustion products are mixed with additional air to provide a specific temperature at the power turbine inlet. The hot gas expands across the power turbine providing power to drive the air generator and the load.

Advantages of turbines over gas engines include the following.

1. Gas turbines can be made very light and compact in relation to horsepower ($\frac{1}{4}$ to $\frac{1}{2}$ lbm/hp) in jet aircraft. The weight/horsepower ratio varies from 1 to 12 lbm/hp for industrial turbines. High-speed turbocharged gas engines weigh from 15 to 40 lbm/hp.

2. Turbine maintenance cost is normally lower and its availability higher. This is true, however, only for turbines in continuous service. Starting and stopping units has a severe effect on maintenance costs.

3. Turbines reject large quantities of high-temperature heat in their exhaust, which can be used to provide process heat.

4. Turbines are available in larger sizes (100,000 hp and higher).

5. Turbines are clean burning from an air pollution standpoint and do not require catalytic converters.

Disadvantages of turbines are (1) high fuel consumption if waste heat is not needed (9,000 to 11,000 Btu/hp-hr at peak efficiency) and (2) large falloff in fuel efficiency when operating at less than peak load.

Electric Motors. In areas where electricity is available from either commercial sources or onsite generators, electric-motor drives are the least expensive in initial capital and maintenance costs. Their use is recommended where the additional cost of purchasing or generating electricity is not too great.

Pump Piping and Installation Details

Suction Piping. It is essential that a flooded suction be furnished for reciprocating pumps. A pump should never be allowed to run "dry" or "starved." The net positive suction head (NPSH) recommended by the manufacturer is shown on the performance curves for the pump and must be provided. To furnish this head and ensure a flooded suction at all times, it is necessary that (1) the storage tank or basin supplying the pump be set at a sufficient elevation above the fluid end of the pump and (2) that the suction piping be of sufficient size to minimize friction losses in the pipe between the storage tank or basin and the pump. In cases where it is possible to secure sufficient elevation head between the storage tank and pump, a centrifugal pump, commonly called a "booster pump," is employed. Normally the booster pump is tied into the storage tank and delivers the water in sufficient quantity to the suction header of the reciprocating pumps to furnish the flooded suction and provide the required NPSH.

The recommended NPSH curve, supplied by manufacturers of reciprocating and centrifugal pumps, is the NPSH that results in a 3% drop in capacity. Cavitation usually starts at a higher NPSH. In cases where no cavitation damage can be tolerated, the NPSH required for no loss in capacity should be used for designing suction and charge systems.

The following features relative to suction-piping installations should be provided.

1. Suction pipe should be as large as or, preferably, larger than the pump suction-inlet size. Table 15.9 indicates acceptable flow velocities in suction lines.

2. Long-radius elbows are recommended to eliminate sharp turns.

3. Suction lines should be laid to a constant grade from the storage tank to pump to eliminate high points where vapor may accumulate.

4. For reciprocating pumps, a pulsation dampener should be installed. These can be elastomer diaphragm or acoustic in design. One common alternative is to install an air- or gas-volume chamber. The chamber allows the pump to fill properly by relieving excessive acceleration and deceleration of the fluid with each stroke of the pump. The required size of an air-volume chamber and its air space depends on the type of pump, displacement per revolution, and speed of the pump. The air-volume chamber may vary from two to eight times the piston displacement of a single stroke. A sight glass is also installed for gauging the liquid level in the chamber so that gas or air can be added periodically to replace what is absorbed by the liquid being pumped.

5. The suction piping should be flushed out and cleaned prior to starting the pump to remove slag, mill scale, rust, welding splatter, etc.

Discharge Piping. As in the suction piping, the discharge piping should be well planned with a minimum of turns, fittings, restrictions, etc. The discharge piping should be of sufficient size to minimize friction losses in the pipe to furnish the required pressure of the pump discharge. Other factors to be considered in discharge piping include the following.

1. A pressure-relief valve must be employed on positive-displacement pumps in the discharge line ahead of any other valve or restriction.

2. A pulsation damper, or desurger, should be installed in the discharge line near a reciprocating pump to relieve shock or vibratory forces. These forces are the result of pressure variations, or surges, prevalent in positive-displacement pump operation. They also result from water hammer because of valve closures and restrictions in the line.

The design and theory of pulsation dampers, or desurgers, are based on the concept that a constant pressure can be maintained if the liquid can be accumulated as the pressure increases and discharged as the pressure decreases. Several types of dampers, or

TABLE 15.9—TYPICAL FLOW VELOCITIES (ft/sec)

	Suction velocity	Discharge velocity
Reciprocating pumps		
Speeds up to 250 rev/min	2	6
Speeds 251 to 330 rev/min	1½	4½
Speeds above 330 rev/min	1	3
Centrifugal pumps	2 to 3	6 to 9

desurgers, are available. Operational features should be investigated and a damper, or desurger, selected to fit each condition.

3. On installations where the fluid is pumped to a level higher than the pump outlet, a gate valve or check valve should be placed downstream of the pressure-relief valve near the pump in the discharge line. This permits shutoff of fluid backing through the pump while pump valves or plungers are being serviced.

The general practice is to connect pumps in parallel through a common suction and discharge header on systems where two or more pumps are installed. A better but somewhat more costly practice is to use separate suction lines for each pump. Headers should be sized to ensure sufficient capacity for satisfactory operation. Each reciprocating pump should have its own separate pressure-relief valve to ensure protection regardless of which pump may be shut down or out of service.

Foundations. For adequate support to maintain alignment and to reduce vibration, a foundation of sufficient size and strength should be provided. Steel-reinforced-concrete foundations are ordinarily used for rotating equipment and are recommended for onshore locations. The pump and prime mover must be set level to ensure good operation. To accomplish this, the pump and mover are mounted on a skid base; the skid base is set on the concrete foundation, leveled, and approximately 1 in. of grout is used to set the equipment.

The required dimensions of the foundation will vary relative to the size and shape of the equipment. The depth to which the foundation must be carried depends on the soil conditions where the foundation is to be set.

The foundation should have sufficient bearing area, which is calculated by using the allowable soil-bearing capacity. Where unbalanced forces are unknown, a rule of thumb that the weight of the concrete-mass foundation should be from 1.5 to 2 times the weight of the reciprocating equipment is sometimes used. Under certain combinations of poor soil and large unbalanced forces, the foundation weight may have to be as much as four times the weight of the equipment.

The size and shape of the skid base will determine the plan dimensions of the foundation and, with acceptable soil conditions, the depth of the foundation is carried to a point that will furnish the required mass. Temperature stresses in normal concrete foundations for pumps and engines govern the amount of steel reinforcing used. The amount of such steel can be estimated by: area of steel (sq in./sq ft of slab area) = $0.002 \times$ cross-sectional area (sq in. of concrete slab). Maximum spacing between bars should not exceed 18 in. Where unbalanced forces and couples are known and for large offshore installations where weight is important, a more detailed dynamic calculation should be made.

Separating Suspended Solids From Heater

The water that is being treated may have suspended solids such as produced sand, rust, and scales. These can be separated from the water stream by gravity settling, cyclone desanders, centrifuges, filters, or flotation.

Gravity Settling

Solid particles, because of their heavier density than water and net negative buoyant force, will settle to the bottom with a terminal velocity that can be derived from Stoke's law as

$$v = \frac{\Delta\rho(d_p)^2}{18\mu_L}, \dots\dots\dots (18)$$

where

$\Delta\rho$ = difference in density of the particle and the liquid,

d_p = solid particle diameter, and

μ_L = viscosity of the liquid.

This equation can also be expressed as

$$v = \frac{1.78 \times 10^{-6} \Delta\gamma(d_p)^2}{\mu_w}, \dots\dots\dots (19)$$

where

d_p = particle diameter, microns,

$\Delta\gamma$ = difference in specific gravity relative to water,

μ_w = viscosity of water, cp, and

v = velocity, ft/sec.

This equation can be used to size a tank, vertical pressure vessel, horizontal pressure vessel, rectangular sedimentation chamber, or a device of any other configuration to allow a particle of a certain diameter and specific gravity to settle to the bottom.

$$t_s = \frac{Z_f}{v_s} \quad t_w = \frac{L_e}{v_w}$$

$$t_w = t_s$$

$$v_w = \frac{L_e v_s}{Z_f}$$

Fig. 15.9—Model for calculation of sedimentation flume capacity.

Most sedimentation basins are rectangular flumes with length-to-width ratios of 4:1 or greater to limit crossflow. The width of the flow channel can be determined by setting the time required for a particle to settle from the top of the flume to the bottom equal to the time required for the water to traverse from the inlet of the flume to the outlet as shown in Fig. 15.9. This can be expressed as

$$b = \frac{36q_w \mu_w}{\Delta\gamma(d_p)^2 L_e}, \dots\dots\dots (20)$$

where

b = width (breadth) of flow channel, ft,

q_w = water flow rate, B/D, and

L_e = effective length, ft.

Note that the width and length of the settling chamber are independent of its depth. The API Manual on Disposal of Refinery Wastes¹⁵ recommends a turbulence and short-circuiting factor of between 1.3 and 1.8, depending on the ratio of water velocity to solids settling velocity. Using a factor of 1.8, Eq. 20 can be rewritten as

$$b = \frac{65q_w \mu_w}{\Delta\gamma(d_p)^2 L_e}, \dots\dots\dots (21)$$

API also recommends that water velocity be limited to 15 times the settling velocity, or 3 ft/min, whichever is less. The settling velocity can be calculated from Eq. 19 and the water velocity can be calculated from

$$v_w = 6.5 \times 10^{-5} \frac{q_w}{h_f b}, \dots\dots\dots (22)$$

where v_w is the velocity of water, ft/sec, and h_f is the height of flume, ft. For practical considerations, b should be between 6 and 20 ft and ratio of h_f to b should be between 0.3 and 0.5.

The flume can be concrete lined or constructed as a soil pit. Solids that settle in the bottom of the flume can be cleaned out with a bucket. A mechanical sludge scraper run on a chain could be installed to concentrate the solids in one location for easy removal.

Cyclone Desanders

Cyclone desanders are conical-shaped devices that make use of centrifugal force to separate the heavier particles from the liquid. Fig. 15.10 shows the basic operation of a cyclone desander. Pressurized fluid enters a common inlet manifold, which distributes the stream to individual cyclones. Flow proceeds through a tangential feed inlet, which directs the fluid against the wall of a cylindrical section above a truncated cone. The fluid and solid particles move downward in a spiral pattern forcing the heavy particles to move toward the outer perimeter of the cone. Gravity forces these particles to slide downward and to be rejected at the cone apex and carried away in the "underflow" slurry. The water moves toward the vacuum created at the center of the cone, and is drawn off as the "overflow."

The size particle that is separated depends on the pressure drop through the cone. The pressure drop, in turn, depends on the flow rate. Thus, there is a minimum flow and a pressure drop that must be provided for each cone to settle a certain size particle. With pressure drops in the range of 25 to 50 psi, cyclones can be used to remove 99% of the 30- to 100-micron particles.

Fig. 15.10—Hydrocyclone operation.

Fig. 15.11—Cartridge filter.

Centrifuges

Centrifuges are used on drilling rigs to separate low-gravity drill solids and reclaim high percentages of the heavy solids. They have not found wide use in producing operations because of the high maintenance associated with their use. Normally, if it is desirable to separate particles of diameter less than that resulting from sedimentation or cyclones, filters are used.

TABLE 15.10—CARTRIDGE DESIGN CONDITIONS
FOR BRINE

Cartridge Type	Particle Size (microns)	Flow Rate for 3-in. OD x 36-in. Element (gal/min)
Pleated wire screen	80	12
Pleated cellulose paper	5 to 10	4
Rolled laminated cotton and acrylic excelsior filler	5 to 10	2 to 3
Molded fiberglass	2	6

Filtration

To avoid plugging the injection formation it may be necessary to separate small-diameter suspended particles by filtration. Filters cannot handle the volume of solids that can be handled by sedimentation and cyclones. By proper choice of filter element, filters can remove fine solids in the 0.5- to 50-micron range and are used as a form of secondary treatment.

Cartridge Filters. Cartridge filters are the simplest to install, require no backwash, and are capable of removing solid particles of 2-micron or larger diameter. Their drawback is that they can take only very low solid loadings. The filter vessel must be taken out of service, depressured, and the cartridges replaced whenever the volume of solids trapped causes the differential pressure to exceed a predetermined maximum (usually 25 psi). Some modern cartridge filters can be backwashed.

Fig. 15.11 shows a typical cartridge filter. The cylindrical filters are encased in a pressure vessel. Flow enters the vessel and flows from the outside of the cartridges to the center, where it enters a perforated pipe that is open on the bottom. A bypass mechanism is included that will automatically allow flow to pass from the inlet to the outlet chambers if the differential pressure exceeds the capacity of the cartridges.

Table 15.10 indicates the particle size that can be separated and the recommended flow rate through various standard-size cartridges. The molded fiberglass has the least solid storage area and the pleated wire screen and pleated paper the most.

Sand Filters. Sand filters have beds of graded sand, gravel, anthracite, or graphite. The beds may be of a single medium or may be graded from coarse to fine media to allow for greater solids loading.

The media are arranged in a pressure vessel for either downflow filtration and upflow backwash as shown in Fig. 15.12 or for upflow filtration and upflow backwash. Conventional downflow filters are limited to flow rates of 2 to 5 gal/(min-sq ft) and total solids loads (before backwashing) of ½ to 1½ lbm/sq ft. With appropriately designed distribution systems, high-rate filters can be operated at 7 to 15 gal/(min-sq ft). This higher loading forces the solids farther into the bed allowing for solid loadings of between 1 and 4 lbm/sq ft.

Upflow filters have a greater capacity for solids loading. Flow tends to loosen the bed allowing for greater penetration of the solids. This allows up to 6 lbm/sq ft of solid loading. However, because of the danger of losing the bed, upflow filters are limited to flow rates of 6 to 8 gal/(min-sq ft). They also require longer backwashing time and more backwash fluid.

Walnut hulls are used as filter media in some new filters. There is a system that removes, cleans, and returns this medium to the filter automatically.

Sand filters are good for separating 25-micron particles. Some manufacturers claim their filters are good for 5- to 10-micron separation.

Diatomaceous Earth (DE) Filters. For filtration of 0.5- to 1.0-micron particles, DE filters are used. Typically, these have low solids-loading capabilities [½ to 1 gal/(min-sq ft)]. A typical DE filter is shown in Fig. 15.13.

The individual leaves, which are spaced at approximately 3-in. intervals, are made up of a wire screen of corrosion-resistant materials such as stainless steel, Monel®, or Inconel®. A precoat slurry of DE is mixed and flowed through the filter to provide an approximately $\frac{1}{16}$ -in.-thick coating to the leaves. Flow then is turned into the filter with a "body feed" of "filter aid" (DE and cellulose fiber or perlite) equal on a weight basis to the amount of solids to be filtered. The body feed helps to build an even, permeable filter cake on the leaves.

When a pressure differential of 25 to 35 psi is reached, the unit must be taken out of service and the filter cake removed. This can be done by backwashing alone, backwashing and vibrating, or backwashing and water sluicing the cake. Water with good filtering characteristics may build up a large permeable filter cake that requires backwashing before a large pressure differential is developed.

Flotation

It is possible to remove small particles by use of dispersed or dissolved-gas flotation devices. These units are used primarily for treating hydrocarbons from water and are discussed in that section. Normally gas is dispersed into the water or released from solution in the water and forms bubbles approximately 30 to 120 microns in diameter. The bubbles form on the surfaces of the suspended particles and create a particle whose average density is less than that of water. These rise to the surface and are mechanically skimmed. Because of the difficulty of predicting particle removal efficiencies with the method, it is normally not used in oil field land operations. However, it is being used increasingly in off-shore operations and in some underground disposal systems.

Treating Hydrocarbons From Water

Produced water, which may have to be treated, will enter the water treating plant from a three-phase separator, free water knockout, gun barrel, heater treater, or other lease equipment, which are discussed in previous chapters. This water will contain small amounts (100 to 2,000 mg/L) of suspended hydrocarbons in oil droplets. Since the water flows out of these pieces of equipment through dump valves or pumps, the oil particle diameters will be very small.

Theory

Treating equipment to handle this problem relies on one or more of the following principles: gravity separation of the lighter oil droplets from the water, coalescence of the smaller oil droplets, or gas flotation of the oil droplets. In applying these concepts, one must keep in mind the dispersion of large oil droplets to smaller droplets, which will take place if energy is added to the system.

Gravity Separation. As in the case of settling of sand from water, Stoke's Law, Eqs. 18 and 19, holds true for the buoyant rise velocity of an oil droplet in a water-continuous phase. Several immediate conclusions can be drawn from this equation.

1. The larger the size of an oil droplet, the greater its vertical velocity. That is, the bigger the droplet size, the

Fig. 15.12—Sand filter.

less time it takes for the droplet to rise to a collection surface and thus the easier it is to treat the water.

2. The greater the difference in density between the oil droplet and the water phase, the greater the vertical velocity. That is, the lighter the crude, the easier it is to treat the water.

3. The higher the temperature, the lower the viscosity of the water, and thus, the greater the vertical velocity. That is, it is easier to treat the water at high temperatures than at low temperatures.

The last conclusion requires some further elaboration. Heat is the primary mechanism used in treating small water droplets from oil in oil-treating equipment because of the effect heat has on the oil viscosity, which prompts more rapid settling, and because of the effect heat has on the emulsifier stabilizing the water-in-oil emulsion. Heat is not commonly used in water treating because (1) the percentage change in viscosity per degree of temperature change is much greater in oil than in water, (2) water-in-oil emulsions tend to have a higher percent of the dispersed phase than oil-in-water emulsions, and the dispersed phase tends to have larger-diameter droplets stabilized by heat-sensitive emulsifiers, and (3) it takes twice as much heat input to raise a barrel of water as it takes to raise a barrel of oil to the same temperature.

The time it takes to “grow” a large droplet from a relatively small droplet, in a “quiet” gravity settler, is approximated by

$$t = \frac{(d_d)^4}{2f_v K_s}, \quad (24)$$

where

d_d = droplet diameter,
 f_v = volume fraction of the dispersed phase, and
 K_s = empirical settling constant.

While it is impossible to determine K_s for an actual installation, the following qualitative conclusions can be drawn.

1. A doubling of residence time will cause an increase in droplet size of only 19%.

2. The more dilute the dispersed phase, the greater the residence time needed to grow a given particle size. That is, coalescence occurs more rapidly in concentrated dispersions.

Gravity Separation Devices

Most water-treating equipment makes use of gravity separation of the oil droplets. Included in this category are skim tanks, API separators, plate coalescers, and skim piles. Unfortunately, it is necessary to know both the oil concentration in the effluent water and the particle size distribution to design a gravity separator to meet a certain effluent quality.

This information can be determined from experience-derived relationships such as those shown in Fig. 15.14. Further work is needed to define these relationships. For the present, the design engineer must rely on a judgment factor or on laboratory tests for the particular crude oil and water.

Skim Tanks and Vessels. The simplest form of treatment equipment is a skim tank or pressure vessel. These are normally designed to provide large residence times during which coalescence and gravity separation can occur. They can be either pressure vessels or atmospheric tanks.

Skim tanks can be either vertical or horizontal in configuration. They may be set up for vertical downward flow of the water with or without inlet spreaders or outlet collectors. They may also be designed as horizontal vessels where the water enters on one side and flows over a weir on the far end.

In vertical vessels the oil droplets must flow upward against the downward velocity of the water. For this reason, horizontal vessels are more efficient in gravity separation of the two liquid phases. In spite of this, vertical vessels and tanks are sometimes used for two reasons.

1. Sand and other solid particles can be more easily handled in vertical vessels with either the water outlet or a sand drain off the bottom. Experience with elaborately designed sand drains in the large horizontal vessels has not been very satisfactory.

2. Vertical vessels are less susceptible to high-level shut-downs because of liquid surges. Internal waves resulting from surging in horizontal vessels can trigger a level float even though the volume of liquid between the

Fig. 15.14—Form of empirical curves for oil concentration and droplet size distribution.

normal operating level and the high-level shut-down is equal to or larger than that in a vertical vessel.

Tracer studies have shown that large skim tanks, even those with carefully designed spreaders and baffles, exhibit poor flow behavior and short circuiting. This is probably because of density and temperature differences, deposition of solids, corrosion of spreaders, etc. In one case, a tank with a design mean residence time of 33 hours had a breakthrough of the tracer with a peak within minutes of tracer injection.

As seen previously, the provision of residence time to allow for coalescence does not appear to be cost efficient. However, a minimum residence time of 10 minutes to one hour should be provided to ensure that surges do not upset the system and to provide for some coalescence.

Horizontal Pressure Vessel Sizing. The required diameter and length of a horizontal cylinder operating one-half full of water can be determined by use of a model similar to that used for settling solids. The following equation can be derived from the model.

$$d_i L_e = \frac{1000 q_w \mu_w}{\Delta \gamma_{ow} (d_d)^2} \quad (25)$$

where

- d_i = vessel ID, in.,
- q_w = water flow rate, BWPD,
- μ_w = water viscosity, cp,
- d_d = oil droplet diameter, micron,
- L_e = effective length in which separation occurs, ft (for design use 75% of the seam-to-seam length), and
- $\Delta \gamma_{ow}$ = difference in specific gravity between oil and water.

While Eq. 25 will govern the design, it is also necessary to check for adequate retention time.

$$t_r = 0.7 \frac{(d_i)^2 L_e}{q_w} \quad (26)$$

where t_r is the retention time in minutes.

Vertical Cylindrical Vessel. The required diameter of a vertical cylindrical pressure vessel or tank can be determined from

$$(d_i)^2 = 7,000 F \frac{q_w \mu_w}{\Delta \gamma_{ow} (d_d)^2}, \quad (27)$$

where F is a factor to account for turbulence and short circuiting. For small-diameter vessels (48 in. or less), $F=1.0$. For larger diameters, F depends on the type of inlet and outlet spreaders, collectors, and baffles that are provided. Large tanks (10 ft or more in diameter) should be considered to have an $F > 2.0$, depending on the inlet and outlet conditions. Tanks greater than 10 ft in diameter should be discouraged because of short circuiting.

The height of the water column can be determined from retention time requirements:

$$Z_w = 0.7 \frac{t_r q_w}{(d_i)^2}, \quad (28)$$

where Z_w is the height of the water column in feet.

API Separators. An API separator is the name given to a horizontal, rectangular cross-section, atmospheric oil skimmer that follows the sizing equations and guidelines included in the *API Manual on Disposal of Refinery Wastes*.¹⁵ Fig. 15.15 shows a typical API separator. The equations for sizing and their derivations have been discussed previously in the solids settling section.

Plate Coalescers. The use of flow-through parallel plates to help the gravity separation in skim tanks was pioneered in 1959¹⁶ as a method of converting existing API separators to treatment of droplets less than 150 microns in diameter.

Various configurations of plate coalescers have been devised. These are commonly called parallel plate interceptors (PPI), corrugated plate interceptors (CPI), or crossflow separators. All of these depend on gravity separation to allow the oil droplets to rise to a plate surface where coalescence and capture occur. Flow is split between a number of parallel plates spaced a short distance apart. To facilitate capture of the oil particles, the plates are inclined to the horizontal.

As shown in Fig. 15.16, an oil droplet entering the space between the plates will rise in accordance with Eq. 19. At the same time, it will have a forward velocity equal to the bulk water velocity. By solving for the vertical velocity needed by a particle entering at the base of the flow to reach the coalescing plate at the top of the flow, the resulting diameter can be determined. A restriction is placed on the Reynold's number for the water to ensure that turbulence in this flow does not affect the oil sheet on the coalescing plate.

General Sizing Equation. For a plate coalescer with flow either parallel to or perpendicular to the direction of flow the general sizing equation for the droplet size removal is:

$$(d_d)^2 = \frac{4.7 q_w L_p \mu_w}{\cos \theta Z_p b_p L \Delta \gamma_{ow}}, \quad (29)$$

where

- d_d = design oil droplet diameter, micron,
- q_w = bulk water flow rate, BWPD,
- L_p = perpendicular distance between plates, in.
- μ_w = viscosity of the water, cp,
- θ = angle of the plate with the horizontal,
- Z_p = height of the plate section perpendicular to the axis of water flow, ft,
- b_p = width of the plate section perpendicular to the axis of water flow, ft,
- L = length of plate section parallel to the axis of water flow, ft, and
- $\Delta \gamma_{ow}$ = difference in specific gravity between oil and water.

Experiments have indicated that Reynold's number for the flow regime cannot exceed 400, on the basis of the hydraulic radius as the characteristic dimension. Thus the maximum flow rate is given by

$$(q_w)_{\max} = \frac{1562 Z_p b_p}{L_p} \quad (30)$$

Fig. 15.15—API oil-water separator.

Parallel Plate Interceptor (PPI). The first form of plate coalescer was the PPI. This involved installing a series of plates parallel to the longitudinal axis of an API separator (a horizontal, rectangular cross-sectioned skimmer). The plates form a "V" when viewed perpendicular to the axis of flow so that the oil sheet migrates up the underside of the coalescing plate and to the sides. Sediments migrate toward the middle and down to the bottom of the separator, where they are removed.

Corrugated Plate Interceptor (CPI). The most common form of parallel plate interceptor used offshore is the CPI. This is a refinement of the PPI in that it takes up less platform space (length) for the same particle size removal, and has the added benefit of making sediment handling easier. Fig. 15.17 is a typical design using a corrugated plate.

In CPI's, the parallel plates are corrugated (like roofing material) with the axis of the corrugations inclined to an angle of 45° . The bulk water flow is forced downward. The oil sheet rises upward counter to the water flow and is concentrated in the top of each corrugation. When the oil reaches the end of the plate pack it is collected in a vertical channel and brought to the oil/water interface. CPI's require frequent cleaning of the plate packs where large amounts of sediments are handled.

Crossflow Devices. Recently manufacturers have

modified the CPI configuration for horizontal water flow perpendicular to the axis of the corrugations in the plates. This allows the plates to be put on a steeper angle to facilitate sediment removal and to enable the plate pack to be more conveniently packaged in a pressure vessel. The latter benefit may be required if gas blowby through an upstream dump valve could cause relief problems with an atmospheric tank.

Fig. 15.16—Plate coalescers.

Fig. 15.17—CPI separator flow pattern.

Fig. 15.18—Skim pile flow pattern.

Crossflow devices can be constructed in either horizontal or vertical pressure vessels. The horizontal vessels require less internal baffling as the ends of nearly every plate conduct the oil directly to the oil/water interface and the sediments to the sediment area below the water flow area. The vertical units, although requiring collection channels on one end to enable the oil to rise to the oil/water interface and on the other end to allow the sand to settle to the bottom, can be designed for more efficient sand removal. Crossflow separators are used where sand is considered a problem and it is not removed in the process upstream of the CPI.

Practical Limitations. Stoke's law theory should apply to oil droplets as small in diameter as 1 to 10 microns. However, field experience indicates that 30 microns sets a reasonable lower limit on the droplet sizes that can be removed. Below this size small pressure fluctuations, platform vibration, etc., tend to impede the rise of the droplets to the coalescing surface. Thus, the practical limit for sizing plate coalescers is 30-micron removal.

Skim Pile. Skim piles are gravity water-treating devices that are used offshore. As shown in Fig. 15.18, flow through the multiple series of baffle plates creates quiescent zones that reduce the distance a given oil droplet must rise to be separated from the main flow.

Once in the quiescent zone, there is plenty of time for coalescence and gravity separation. The larger droplets then migrate up the underside of the baffle to an oil collection system. Skim piles are used extensively to treat deck drainage of washdown or rainwater that has been contaminated with oil. They have the added benefit of providing for some degree of sand cleaning. Sand traversing the length of a skim pile will abrade on the baffles and be water washed. This removes the free oil, which is then captured in a quiescent zone.

Skim Pile Sizing—Deck Drainage. Field experience has indicated that acceptable effluent is obtained with 20 minutes of retention time in the baffled section of the pile. Using this,

$$(d_i)^2 L_{bs} = 14.3 (q_w + 0.356 A_d q_r), \dots (31)$$

where

L_{bs} = length of baffle section, ft,

A_d = area of deck, sq ft, and

q_r = rainfall rate, in./hr.

Intermittent Flow. During periods of no flow, oil droplets rise to the area of the quiescent zone and become trapped and protected from being swept back into the flow stream when flow is resumed. The net effect of the baffles is to reduce this rise distance. Each time flow is stopped as the water traverses the baffled section more oil particles are trapped in the quiescent zone.

This phenomenon can be used when it is desired to use a skim pile downstream of a skim tank or CPI for further treating. By use of a snap acting water dump on the influent, intermittent flow is established in the pile.

If t is the time in seconds for the dump cycle,

$$N_c = \frac{41.7 (d_i)^2 L_{bs}}{q_w t} \dots (32)$$

Fig. 15.19—(a) air flotation process; (b) circular flotation chamber details.

where N_c is the number of cycles of no flow a particle sees as it traverses the baffle section.

If t_c is the time the valve is closed, the removal efficiency on any cycle of a particular drop size is

$$E_{rc} = \frac{4.3 \times 10^{-5} (\Delta \gamma_{ow}) (d_p)^2 t_c}{\mu_w d_i} \quad (33)$$

The overall removal efficiency of that particle size can then be determined by

$$E_{ro} = 1 - [1 - E_{rc}]^{N_c} \quad (34)$$

Gas Flotation Units

Flotation units are the only commonly used water-treatment equipment that does not rely on gravity separation of the oil droplets. In fact, the action of these units is independent of the oil droplet size. In gas flotation units, large quantities of small-diameter gas bubbles are injected into the water stream. The bubbles attach to the oil droplets suspended in the stream and cause them to rise to the water surface as a froth. Experimental results have shown that very small-diameter oil droplets in dilute suspension can be removed easily by flotation. High percentages of oil removal are achieved.

Two distinct types of flotation units have been used, which are distinguished by the method employed in producing the small gas bubbles needed to contact the water. These are dissolved-gas units and dispersed-gas units.

Dissolved-Gas Units. Dissolved-gas designs take a portion of the treated water effluent and saturate the water with natural gas or air in a contactor. The higher the pressure, the more gas can be dissolved in the water.

However, most units are designed for a contact pressure of 20 to 40 psig. Normally, 20 to 50% of the treated water is recirculated for contact with the gas.

The gas-saturated water is then injected into the flotation chamber as shown in Fig. 15.19. The dissolved gas breaks out of solution in small-diameter bubbles when the flow enters the chamber, which is operated at near-atmospheric pressure.

Design parameters are recommended by the individual manufacturers but normally range from 0.2 to 0.5 scf/bbl of water to be treated and flow rates of treated plus recycled water of between 2 and 4 gal/(min-sq ft). Retention times of 10 to 40 minutes and depths of between 6 and 9 ft are specified.

Dissolved-gas units have been used successfully in refinery operations where air can be used as the gas and where large areas are available. In treating produced water for injection, it is desirable to use natural gas to exclude oxygen. This requires the venting of the gas or installation of a vapor recovery unit. Field experience with dissolved-natural-gas units have not been as successful as experience with dispersed-gas units.

Dispersed-Gas Units. In dispersed-gas units, gas bubbles are dispersed in the total stream either by use of an inductor device or by a vortex set up by mechanical rotors. Fig. 15.20 shows a schematic cross section of such a unit.

Most dispersed-gas units contain three or four cells. Bulk water flow moves in series from one cell to the other by underflow baffles. Field tests have indicated that the high intensity of mixing in each cell creates the effect of plug flow of the bulk water from one cell to the next. That is, there is virtually no short circuiting or breakthrough of a part of the inlet flow to the outlet weir box.

Fig. 15.20—Dispersed-gas unit with inductor device.

Field tests and theory both indicate that these units operate on a constant percent removal basis. Within normal ranges, their oil removal efficiency is independent of inlet concentration or oil droplet diameter. The design of the induction nozzle or rotor and internal baffles is critical for determining overall efficiency.

Field experiments indicate that most designs can be expected to have efficiencies of about 90%. Because the gas is recycled by the unit, a natural gas blanket can easily be maintained with little or no venting. The low required retention times makes this an ideal choice for offshore facilities where space and weight are at a premium.

Dissolved Gas Removal

Often, produced or surface waters will contain dissolved gases, which must be removed by the water-treating plant. Oxygen in concentrations of 0.05 ppm in hydrogen-sulfide-free water and 0.01 ppm in water containing hydrogen sulfide is generally considered to be sufficient to cause corrosion problems in the facilities and bacteria plugging problems in an injection reservoir. For this reason, attempts are made to exclude oxygen from produced-water systems by maintaining gas blankets on all tanks. However, sometimes these

systems must be designed to handle rainwater, which may introduce dissolved oxygen in sufficient quantities to require removal. The location of surface water intakes can be arranged to minimize the oxygen content in the surface water but, in almost all cases, oxygen may have to be removed.

Some waters may contain ammonia, H_2S , or CO_2 , which must be removed. Dissolved gases are commonly removed by either chemical scavenging, gas stripping, or liquid extraction. It is beyond the scope of this book to deal with the design of the complex processes and equipment that can be employed in removing all dissolved gases. Since oxygen is the most common contaminant, we will briefly describe the treatment processes commonly in use to remove dissolved oxygen.

Oxygen Scavengers

Chemical scavengers are used quite often to remove dissolved oxygen from water streams of less than 10,000 B/D. Sulfite is the most common scavenging agent for water treating. The most common forms are sodium sulfite, sodium bisulfite, ammonium bisulfite, and sulfur dioxide. To speed the reaction rate, a catalyst such as cobalt is required.

Gas Stripping

The basic principle employed in gas stripping is that the quantity of oxygen dissolved in the water is directly proportional to the partial pressure of the gas that is in contact with the water (Henry's law). Since partial pressure of the gas is a function of the mole fraction of that gas, the addition of other gases to the solution will decrease the partial pressure of oxygen and thus the concentration of oxygen in the water.

In a typical gas stripping column, natural gas or steam, if available, is introduced in the base of a packed or trayed column (similar to the familiar glycol contactor used in gas dehydration) and flows upward countercurrent to the water, which is introduced in the top of the column and flows downward.

If natural gas is used, the oxygen-contaminated gas from the top of the tower can be used for fuel, compressed for inclusion in the sales gas stream, or vented, depending on the process design and gas sales contract. Stripping gas usage of between 2 and 5 scf/bbl is common.

It is also feasible to strip oxygen from water by use of a concurrent flow. This is common in cases where lift gas is used as the artificial-lift mechanism for obtaining the water from a reservoir or subsea source. Sometimes, the gas is injected into the water with a static mixer in concurrent flow in a pipe. While this may require more stripping gas, it may be more economical from the standpoint of equipment cost, space, and weight when the value of the stripping gas is low. Stripping gas usage in concurrent flow can be in excess of 10 scf/bbl.

Vacuum Deaeration

Since the partial pressure of oxygen in the gas is a function of the total pressure of the system, the partial pressure of oxygen can also be reduced by applying a vacuum to the water-gas system. Vacuum deaerators can be combined with either counterconcurrent or concurrent

stripping gas to provide very low oxygen concentrations in the water. Stripping gas usages of a fraction of a cubic foot per barrel are common. Vacuum stripping towers are used where no stripping gas is available, the available stripping gas contains contaminants such as CO_2 and H_2S , and stripping gas has a high value.

Dissolved Solids Removal

The removal of dissolved solids is of major importance if the water is to be used in steam generation or for some EOR projects. In particular, magnesium and calcium ions in the water may cause boiler scale, react adversely with an EOR chemical, or precipitate in the reservoir as a plugging solid.

Various processes have been used to create chemical reactions to cause the dissolved solids to form precipitates, which can then be settled or filtered out of the water. Aeration has been used to oxidize soluble ferrous compounds to insoluble ferric compounds, and soluble bicarbonates to insoluble carbonates. However, this process introduces dissolved oxygen, which must then be stripped out of the solution.

The addition of chemicals, such as lime and soda ash, under correct conditions of temperatures and pH can form insoluble carbonates. Alum or other coagulants are then added to help in the settling or filtering of the precipitate. The equilibrium constants for these reactions are usually such that the low total dissolved solids (TDS) required cannot be easily met. For this reason, ion exchange has become the most common process for control of dissolved solids.

Ion exchange can be defined as a reversible exchange of ions between a solid and a liquid in which there is no significant change in the structure of the solid. Ion-exchange solids of various types can be used. The usual ion-exchange material takes the form of granules, or beads, ranging in size from approximately 0.3 to 1.0 mm in diameter.

As a very broad generalization, the synthetic ion-exchange resins can be categorized into four groups.

1. **Strong acid resins.** These are polystyrene resins that are strongly acid, have a high exchange capacity, and are not damaged by strongly alkaline hot water.

2. **Strong base resins.** Typical resins in this category incorporate a quaternary ammonium type of structure. The hydrocarbon groups may include methyl groups, polymeric benzyl groups, ethanol groups, and the like.

3. **Weak acid resins.** These resins usually contain carboxylic groups as the active, or functional, ion sites. They have a limited use in water treatment, but can be used to remove basic materials from solution.

4. **Weak base resins.** Typical resins in this category are of the polyamine type. They usually contain a mixture of primary, secondary, and tertiary amine groups and their chemical properties are analogous to amine or ammonium hydroxide solutions. They can be used to remove free acids from solution.

Table 15.11 presents general guidelines for the use of different combinations of resins.

In ion-exchange units the influent water flows through the bed of ion-exchange material. Ions from the bed are exchanged for the undesirable ionic species in the water. When a bed is close to breakthrough, it is regenerated

TABLE 15.11—GUIDELINES FOR CATALYST SELECTION

Feed		Resin	Process
TDS	Hardness		
<2,000	<700	strong acid	single bed
700 to 5,000	<2,000	strong acid	series bed
5,000 to 10,000	<500	weak acid	single bed
5,000 to 10,000	500 to 2,000	strong to weak acid	series operation
10,000 to 25,000	<2,000	weak acid	series bed
>25,000	<500	chelating	single bed

with a strong solution of the ionic species originally contained in the ion-exchange material. The exit solution from the regeneration stage is thus a concentrated solution of the contaminants removed from the water.

Removing Hydrocarbons From Solids

Fortunately, most solids that must be handled in a water treating plant are water-wet. Reservoir sand in its in-situ condition is almost always water-wet. As it flows up the tubing and through the process system, it may become coated with an oil layer but, since this layer is on top of a water-wet solid, it is easily removed. The two most common solids cleaning processes are abrasion and water washing.

In separating solids with a hydrocyclone, the solids rub against the inside wall of the cone and against each other. The high centrifugal velocities involved abrade the oil layer, cleaning the solid. In most applications, one pass through a hydrocyclone is sufficient to clean the solids sufficiently for disposal. Some installations include two or three cyclones, in series, to ensure adequate cleaning. In some installations, an air flotation step is used between cyclones to separate any oil that may exit through the cyclone underflush.

Another cleaning method involves the routing of the underflush to a batch cleaning vessel. Water is induced in the vessel to agitate and wash the solids. The solid bed is then allowed to settle while the oil is skimmed from the top. The procedure is repeated several times until the solids are clean enough to be educted from the bottom of the vessel and disposed of as a slurry.

On offshore platforms, skim piles have been used effectively to water wash and abrade solids. The solids move down the pile and are abraded as they bounce along the baffle surfaces. These are water-washed in the mixture around the end of each baffle. Oil removal occurs in the normal manner within each baffle section.

Process Selection and Project Management

The process selection for a specific project must provide an overall cost-effective system using the individual techniques described previously. In some cases, the process selection and design of the system may be obvious and easily handled by hooking up some standard pieces of equipment in the field with no further engineering design. However, in most cases, several alternative schemes may have to be analyzed, and the process will be complex enough to require the system to be engineered to work as designed. Cost may be significant

enough to necessitate competitive bids for equipment and installation.

Every project, no matter how small, must proceed through the following steps. On small projects, the engineer alone may handle some of these steps in a matter of minutes. On larger projects, these may take months of analysis and work by teams of individuals.

Conceptual Studies

The first step of any project, the conceptual study, investigates one or more means of accomplishing the objective. An economic and technical assessment and comparison of the various methods or schemes is made. Block diagrams may be used to develop a selected process or alternative into specific descriptions and recommendations for equipment. Equipment type and arrangement are studied and a design philosophy established. An analysis of cost and economic benefit of each alternative is performed and a recommendation made.

Project Definition

The next phase is to define the project for the scheme selected in the conceptual study. Tools used are process flow sheets, layout drawings, preliminary cost estimate, and project execution plan.

The block diagram is converted into a process flow sheet to better define the project. The flow sheet shows all major equipment, main piping, and operating pressures and temperatures. Instrumentation that controls the main process flow is shown and every major line is assigned a stream number. A table is included listing pertinent operating data for these streams.

Layout drawings locate the equipment on the process flow sheets. A well-planned layout is the key to good operation, economical construction, and efficient maintenance. The layout drawing must be integrated with the development of the process flow sheet and must be settled before detailed piping, structural, and electrical design can begin.

A plan of execution for a project begins when the first information is received. This plan must consider the alternatives for breaking the job down into individual work items for bid solicitation. It must balance time and ease of management against cost for such decisions as (1) the scope of work to be included in individual work, (2) degree of engineering to perform prior to bid, (3) potential suppliers' work load, capability, and competitive situations, and (4) operator sole source preferences.

The preliminary cost estimate is an important tool in the generation of the initial authority for expenditure (AFE). For effective cost control, the preliminary estimate must be made accurately and upgraded when information is received that affects it. Revisions may be necessary because of a change in scope or a realization that the amount of work was over- or underestimated.

Design Engineering

Once the need and extent of engineering assistance is determined, design engineering must begin to translate the process flow sheets into specific objectives and to determine activities required to attain these objectives. The basic item on which all other activities depend and which must be completed early in an engineering design project is the mechanical flow sheet.

Mechanical flow sheets are established from the process flow sheets and show every piece of equipment for the entire facility, including process, utilities, fire-water system, safety systems, spare equipment, etc. Every instrument, valve, and specialty item is shown schematically. Piping should be shown with flow arrows and line numbers indicating size, pressure rating, heat tracing, and insulation.

Vessel and equipment specifications are established for long-delivery items to expedite both the design and purchasing effort. Every facility is designed for a specific function, and thus the criteria by which the equipment is selected are applicable to that facility only. Therefore, this equipment is not normally produced off-the-shelf items. However, an experienced engineer will maximize the use of standard items to minimize cost and delivery time.

Detail Engineering

Once design engineering is completed and major equipment items have been specified and sent out for bid, the next step is to perform the detail engineering. This consists of piping drawings, structural drawings, electrical one-line drawings, instrument data sheets, and control schematics.

Piping drawings translate to the fabrication contractor the piping arrangement, as defined in the mechanical flow sheets. In many cases, a good set of piping drawings is the key to any easy to build and operate facility. In all cases, a good set of drawings is required to speed installation and keep the cost for extras to a minimum.

Structural drawings for an onshore facility detail the foundation site development and road work required, as well as detailing any pipe supports or skids for the production equipment. For an offshore facility, these drawings can include platform drawings as well as those for production skids themselves. The skids could be installed on wooden or concrete piles, steel or concrete barges, or steel jackets with steel decks.

Procurement

A large part of the *engineering* effort is involved in bidding, evaluating, expediting, and coordinating vendors and vendor information. This is true whether the work is performed by the operator, the engineering consultant, or a turnkey contractor.

Special, long-delivery equipment, vessels, and instrumentation usually are ordered as soon as the

specification can be written, checked, bids obtained and evaluated, and the purchase order issued.

All bids should be opened at one time to minimize any possibility of a bidder receiving an unfair advantage. While it is possible to play one bidder against another by "bid shopping," any experienced project engineer knows that in the long run this will be counterproductive. If vendors expect the work to be given to the low bidder, they will put their best effort into the price. If an auction is expected, the bid price will reflect this.

Inspection and Expediting

An important phase of the project is inspection. It is the inspector's responsibility to ensure that the finished equipment or material is of acceptable quality and complies with all requirements of the purchase order.

The inspector witnesses tests on mechanical equipment such as pumps and compressors, observes and approves fabrication methods of vessels, pipe, and structural steel, and generally ensures that the best workmanship is being performed on the purchased equipment.

The purchaser's expeditor can do much to ensure that the estimated delivery dates will be met by working with both the manufacturer and his own organization. The expeditor should seek and study all information that might affect delivery, anticipate delays or bottlenecks, and resolves these with the vendor. He should assist the vendor in obtaining priorities and solving procurement problems by communicating with subsuppliers. If delivery schedules must change, he should advise his employer as early as possible. On small projects, these functions are performed by the inspectors.

Startup

The conscientious preparation of a startup and operations procedure is the best possible check of the practicability, operability, and safety of a system. The procedure may contain only a few pages or may take the form of a book. In any case, it describes (1) overall purpose and design of the installation, (2) operation of the process, (3) details and operating descriptions of all systems, including overall instrumentation (pneumatic and/or electronic) electrical, data transmission, utility and fire-water, etc., (4) instructions for equipment installation, (5) purge and preparation for operation, and (6) procedure for starting.

Project Execution Format

Every project goes through the steps of project management described above. This is true no matter whether the tasks are performed by the operator's staff, the engineering consultant, or contractors. The project must progress from one step to the next; engineering, procurement, and inspection must be accomplished; and the cost of performing these functions must be borne by the project.

There are several different project execution formats that must be considered. The choice of a specific format will determine which of these functions will be performed by a particular organization.

Although there are almost as many formats as there are projects, most can be separated into the following four basic types which we shall call turnkey, negotiated turnkey, modified turnkey, and cost plus.

Turnkey. The turnkey format is used when the work is not completely designed. The conceptual study and project definition are normally complete. In this case, the scope of the contractor's work would include the design engineering, detail engineering, procurement, inspection and expediting, and possibly, startup.

Five advantages are claimed by proponents of this format: (1) the project cost is established before work starts, (2) a single point of responsibility is established, (3) the contractor can design to take advantage of construction efficiencies, (4) the contractor can speed up equipment delivery by performing engineering in such a manner as to get long lead time equipment on order sooner, and (5) the contractor assumes risk.

Several problems have been experienced with this format.

1. Owner loses design control or can exercise it only at high cost in extra work.

2. Competition is limited to select firms with total design and construction capability.

3. Most large firms have different engineering and construction profit centers. Many large contractors bid the work to outside engineering firms. In either case, the contractor's engineers may be no more or less aware of construction efficiencies than a third party.

4. Because of the design risks assumed by the contractor, a contingency factor will be added to the price.

5. By necessity, there will be a large number of subcontractors furnishing individual items of equipment to the turnkey contractor. Other than initial approval, the owner has no control over subcontractors.

6. The contractor's and owner's interests are not identical. The contractor has an incentive to provide the least costly quality for the fixed price and does not profit or lose nearly as much as the owner with timely delivery. Therefore, the owner must provide inspection and expediting. It is very difficult to do this for subcontractors where no direct commercial relationship exists.

Negotiated Turnkey. The negotiated turnkey format recognizes that, before the detail engineering is complete, it is difficult for a contractor to provide a fixed price for the work while maintaining adequate owner control. In this format, the design and detail engineering are performed (normally for a fixed fee), so that long-delivery items can be placed on order prior to completion of detail engineering. Once the scope of work is defined, a turnkey price is negotiated.

The advantages claimed for this format are the same as those for the turnkey format with the added advantages of maintaining owner control and reducing contractor's design risk. The disadvantages are identical with the added disadvantage of eliminating much of the owner's leverage when it comes to negotiating the final contract.

Modified Turnkey. In the modified turnkey format, each work item is separated and bid turnkey as the scope of that work item is defined. In the previous two formats, the prime contractor does this in bidding out items of equipment to subcontractors. The difference in this format is that the owner, or engineering consultant, do the bidding, awarding, and expediting. In addition, those items which are "sole sourced" to the contractors construction arm in the two previous formats must be bid

and evaluated. The main advantages claimed for this format are (1) control of the project is maintained, (2) competition is maximized as individual work items can be bid to firms specializing in such work, (3) owner's inspectors and expeditors have a direct commercial relationship to all suppliers, and (4) contractor's risk and contingency is controlled to the extent desired by owner. For example, scope of work contingency can be eliminated while weather contingencies are included.

The disadvantages with this format are (1) increased coordination of the contracts is required by either the owner or the engineering consultant, (2) the owner, or consultant, must develop and monitor the plan of execution rather than this being a function of the turnkey contractor, and (3) engineering and project management costs are explicitly determined and not hidden in contract cost.

Cost Plus. The cost-plus format requires the contractor to be reimbursed for all direct costs plus a percentage of costs for overhead and profit. Typically, this format is used where risk is high, or when there is insufficient time to solicit firm bids. Such a case would occur if construction were required within an operating plant, it were necessary to repair storm damage, or a simple field routing job were envisioned. The major disadvantage of this format is that the owner bears the risk of inefficient labor and job organization.

Comparison of Formats. The type of project format to employ depends on the nature of the project, the type of contractors available and their competitive position, and the priorities of the owner. There is no one answer as each project is different and competition and priorities change from time to time.

The author had the opportunity to be involved in two similar projects for the same owner, which occurred almost simultaneously. One was set up as a turnkey format and the other in a modified turnkey format to test the validity of the claimed advantages and disadvantages. The cost of the modified turnkey approach was 15% less, and it took 10% less time to complete because of greater owner control of the schedule. On another recent project, the design was done by the owner and each work item bid out separately. In addition, two turnkey bids were solicited from companies who expressed a desire to construct the complete installation. The additional cost for awarding the low turnkey bid would have been 40% more than the cost of awarding 10 individual bids.

Project Control

No matter what the project execution format, it is necessary to implement procedures for controlling both project cost and timing. The most important part of project control begins at the outset of the project with controlling the engineering effort. Priorities set and decisions made at this point will affect project timing and cost throughout the job.

An activities schedule will help in project scheduling. This is a detailed plan of execution for the project's engineering phase and is similar to, but more detailed than, the overall project plan of execution described previously. When preparing the activities list, an effort should be made to separate activities into logical cost categories.

The main tool for project cost control is the preliminary cost estimate developed during project definition, which lists budget costs for each item in the plan of execution. Budgets should be established for scheduled work packages. It is important for cost control purposes that activities have definite starting and ending points.

Costs are periodically updated as the project becomes better defined. Differences can then be explained and total project cost revised—even before the first item is purchased. As bids are awarded and commitments are made, the total project amount can be adjusted accordingly.

Accounting for costs can be routine, but controlling costs is another matter. Once a project is committed, a large part of final cost is beyond control of the project engineer. It is not unusual for bid items to vary significantly from time to time because of contractor work load, weather conditions, and availability of equipment. Also, difference in price between low bidder and next low bidder can vary 10 to 20%. If the low bidder had not been included in the bid list, item cost would be that much higher. On a recent project, the sum of second low bidders' prices was 5% higher than that of low bidders.

Early in the project, timing is controlled through the engineering effort to ensure that bids are sent out, evaluated, and awarded in accordance with the project plan of execution. Once bids are awarded, the inspector and/or expeditor are responsible for determining if work is progressing on schedule. A schedule thus must be worked out with the successful bidder, preferably before bid award. When delays are spotted, meetings with the contractor are required to return the job to schedule. On occasion, it may be necessary to appeal to higher levels of management in both companies. The sooner a problem is spotted, the better the chance that corrective action can be agreed on. On large complex projects, the use of computer-based network analysis of activities is sometimes beneficial.

Nomenclature

A_d = area of deck, sq ft
 b = width (breadth), ft
 b_p = width (breadth) of the plate section perpendicular to the axis of water flow, ft
 C_d = dispersion constant
 C_E = constant for erosional flow
 C_{HW} = constant with a value of 80 to 140, depending on the inside pipe material and its age
 d_d = oil droplet diameter, micrometers
 $(d_d)_{\max}$ = maximum oil droplet diameter, micrometers
 d_i = pipe inside diameter, in.
 d_p = particle diameter, microns
 E = flow efficiency, fraction
 E_p = pump efficiency at flow conditions
 E_{rc} = removal efficiency on any cycle of a particular drop size
 E_{ro} = overall particle removal efficiency

f = friction factor
 f_V = volume fraction of the dispersed phase
 F = factor to account for turbulence and short circuiting
 h_f = height of flume, ft
 K_s = empirical settling constant
 L = length of line or length of plate section parallel to the axis of water flow, ft
 L_1 = inlet distribution section
 L_2 = outlet gathering section
 L_{bs} = length of baffle section, ft
 L_e = effective settling section
 L_p = perpendicular distance between plates, in.
 N_c = number of cycles of no flow a particle sees as it traverses the baffle section
 N_{Re} = Reynolds number
 p_{bh} = brake horsepower
 p_1 = pressure at pipe inlet, psia
 p_2 = pressure at pipe outlet, psia
 q_g = flow rate of gas at standard conditions, MMscf/D
 q_L = liquid flow rate, B/D
 q_r = rainfall rate, in./hr
 q_w = bulk water flow rate, BWPD
 t = time for the dump cycle, seconds
 t_c = time valve is closed, seconds
 t_r = retention time, minutes
 t_s = time particle is falling while in effective section of flume
 t_w = time water is in effective section of flume
 v_{gf} = velocity of gas at specific flow conditions, ft/sec
 v_s = settling velocity, ft/sec
 Z_{fl} = friction head loss, ft of liquid
 Z_p = height of the coalescer plate section perpendicular to the axis of water flow, ft
 Z_w = height of water column, ft
 γ_g = specific gravity of the gas at standard conditions relative to air
 γ_L = specific gravity of liquid relative to water
 $\Delta\gamma$ = difference in specific gravity relative to water
 $\Delta\gamma_{ow}$ = difference in specific gravity between oil and water
 θ = angle of the plate with the horizontal
 μ_{gf} = viscosity of gas at specific flow conditions, cp

Chapter 16

Automation of Lease Equipment

G.R. Burrell, Exxon Co. U.S.A.*

Introduction

Automation in the oil and gas producing industry covers a broad spectrum of supported functions. In a simple application, automation may be defined as linking together instruments and controls to perform lease-operating procedures automatically in a predetermined manner. Automation in a more complex environment will have digital computers in some form of a supervisory control and data acquisition (SCADA) system. Automation in the industry has tended to evolve as new tools become available and are accepted by industry and regulatory agencies. Generally, automation has advanced by a more complex linkage of instruments and control devices. Some of the more important tools and/or techniques that have enhanced lease automation are (1) solid-state electronics, (2) lease automatic custody transfer (LACT), (3) tank battery consolidation, and (4) SCADA.

Solid-State Electronics

The development of solid-state electronics first as discrete components and then as integrated circuits has been a key factor in advancing lease automation. Electronics have provided the base for improvements in instrumentation, control elements, communication, and digital computers that form the primary components of enhanced automation facilities. Pneumatic and electromagnetic (relay) logic have been, and will continue to be, used in various forms of automation, but the extent of logic implementation is limited substantially compared with that available for electronics. Pneumatic and/or electromagnetic functions are effective as complementary features to electronic forms of automation and as stand-alone automation for less complex applications.

Microprocessors and their extension to microcomputers are having an impact on automation that may well

exceed that of integrated circuits in the initial form of "hard-wired" logic. Microcomputers combine the advantages of electronic components and program instructions into a flexible, capable, and reliable form that has substantial advantages for automation. These functional advantages have been complemented by a reduction in cost compared to implementation with integrated circuits. Microcomputers are being used in almost every component of automation related equipment from individual instruments through digital computers.

Lease Automatic Custody Transfer (LACT)

LACT is the process of transferring (running) lease-produced oil into a connected pipeline on an unattended basis. LACT includes the capability to determine automatically the quantity and quality of oil being transferred and the control functions to prevent transfer of unacceptable quality and/or volumes. Before LACT, lease oil was produced into a tank, quantity and quality (opening gauge and thieving, etc.) were determined, and a valve was opened to the pipeline to initiate transfer. When the transfer was complete, the pipeline valve was closed and a final (closing) gauge was made as basis for determining net volume transferred. All these steps were manual activities with some related duplication of effort between the lease operator and the pipeline gauger. In addition to being labor intensive, the process was inherently inefficient in use of related treating and storage facilities. LACT is an important tool in the evolution of lease automation. LACT is a significant automation element and has been widely accepted and implemented by industry. In addition, it has become an important building block for other forms of automation in lease operations.

Tank Battery Consolidation

Many oil and gas fields have multiple operators or working interest owners. In addition, most fields consist of a number of separate leases (common royalty ownership,

* Author of the original chapter on this topic in the 1962 edition was Don R. Patterson.

etc.) that require individual oil and gas processing (separation, treating, storage and transfer, etc.) facilities to account for production to each owner.

LACT initially was applied to these separate lease operations. The automatic transfer of produced oil and recycling of unacceptable quality oil [high basic sediment and water (BS&W) content] to treating facilities increased the effectiveness of treating and storage equipment. In addition, the incremental cost of larger meters, pumps, and related equipment of LACT's was low compared to the increased oil volume transfer capability. Thus, a technical basis was available to process and transfer much higher produced-oil volumes than present on the average lease.

Historically, individual lease oil-production volumes had been treated to pipeline quality (2% BS&W or less) before custody transfer from the lease. In the 1960's, regulatory agencies began to approve operator requests to commingle wet-oil (not pipeline quality) production from multiple leases into a common or central oil processing and custody transfer facility. Oil production from each lease was determined by measuring the wet-oil volume (separator positive-volume or positive-displacement meters, etc.) and correcting for water content with automatic samplers and later with capacitance probes and related net-oil computers. Final sales volume to each separate lease was determined by allocating the custody transferred (sales) volume back to each lease on the basis of its proportion of total wet-oil lease measurements. In other cases, tank battery consolidation was implemented when a field was unitized under a single operator for initiation of secondary recovery activities.

Tank battery consolidation eliminated oil treating and storage facilities on the individual lease. In some fields, the pipeline trunk lines used to gather individual lease oil volumes were converted to wet-oil gathering lines for the consolidated tank battery operation. Tank battery consolidation converts a field's operation from a number of stand-alone lease functions to a central process with multiple inputs. Oil treating and storage, water treating and disposal, vapor recovery facility, etc., became more efficient and controllable in the consolidated environment.

Supervisory Control and Data Acquisition (SCADA)

SCADA is a common name applied to computer-driven automation systems used in oil and gas production operations. Basic functions generally include status/alarm reporting, production volume accumulation/reporting, well testing, and control. These systems vary from small units that are applied to only a few leases in a single field to large units that serve multiple fields containing several thousand total wells.

SCADA systems are tied directly to the instrumentation and control devices on the process equipment used in oil and gas production. This provides timely and continuous access to the operational information being sensed by the instrumentation. Some SCADA systems emphasize data gathering and reporting to operating personnel for "open-loop" control while others use program logic to analyze input information and initiate control actions directly ("close-loop" control). SCADA

systems may be oriented primarily to operating personnel needs, or they may be multipurpose by providing functions for operating, accounting, engineering, and management groups.

SCADA is a logical extension of automation in the sequence from manual lease operation, to use of LACT, and then to centralized treating, storage, and automatic custody transfer (ACT) with tank battery consolidation. This sequence moved from essentially independent individual lease operations to a single overall process that has a number of closely related functions. SCADA provides the ability to obtain timely operational information for optimization of the interrelated process functions. For example, if a compressor outage reduces the gas processing capacity below a field's gas-producing rate, well-test information from SCADA allows shutting-in of wells with high GOR's and thus minimizes reduction of the related oil producing rate. In general, timely and accurate operational information can be used to obtain maximum utility of existing process equipment and minimize need for stand-by capacity.

Some form of automation is used on every lease that produces oil and gas. The extent of practical automation depends primarily on economics. Some of the benefits of automation that may be used in the economic justification are as follows:

1. Capital investment in lease production equipment is reduced.
2. Operating expenses are reduced through savings in labor costs, maintenance expenses, travel expenses, and power and fuel costs.
3. Ability to initiate and document actions required for regulatory compliance is improved.
4. Surveillance capability of management and supporting staff groups is improved.
5. The quantity and quality of operational information available for making business decisions is increased, which results in revenue increases and operating cost decreases.

Automation in oil and gas production activities will continue to evolve as additional tools are developed and applied. Most advances (including improved communications and "smart" end devices) will take the form of (1) improvements in existing devices, (2) new devices with improved capability/reliability to replace older equipment, and, less frequently, (3) new devices with new features/functions that are applicable to the production process. Much of the basic instrumentation and control equipment (primarily pneumatic-based) that has been used for years with oil and gas processing facilities will continue to be applicable. Implementation of some form of enhanced automation (as described earlier) will be a primary force to increase use of electronic and electronic/pneumatic equipment. On this basis, it appears reasonable to elucidate the topic of automation first by discussing some of the commonly used equipment and then by depicting equipment application in automation systems.

Automatic Production-Control Equipment

Automatically Controlled Valves and Accessories

Automatic control valves can be classified in a number of ways, but classification by the energy medium that actuates the valve operator is most pertinent to automation.

By using this method of classification, automatic control valves can be grouped into three major categories: fluid-controlled valves, electrically controlled valves, and fluid-electric-controlled valves. In the latter category a fluid energy generally is used to operate the valve and electric energy is used to control the fluid-energy source.

Fluid-Controlled Valves. The most common types of automatic fluid-controlled valve operators are diaphragm operators and fluid cylinders. Both of these valve operators can be used on any style of valve body whose inner valve can be positioned by longitudinal displacement of the valve stem. The fluid cylinder operator normally is used with valve-body styles requiring 90° rotation for operation. Diaphragm operators most commonly are applied to valves that have globe, angle, butterfly, and Saunders-type valve bodies. Fluid-cylinder operators are more commonly used with plug valves.

In oilfield applications, the most common fluid used to actuate both valve operators is natural gas, generally taken directly off a separator or heater-treater on the lease. If natural gas is not available, or if for some reason the available natural gas supply is not suitable, a bottled gas (nitrogen, etc.), compressed air, or hydraulic fluid could be used. Diaphragm operators normally require only 15- to 30-psi fluid pressure to actuate the valve. Pressures up to 100 psi and over often are desired for the fluid cylinders because, the higher the fluid pressure available to operate the cylinder, the smaller size the cylinder may be, and consequently the lower the cost. Valves using these types of operators, as a class, are frequently called "pneumatic control valves" even though the control fluid may be something other than air.

Some fluid-controlled valves can be controlled with the fluid flowing in the line in which the valve is located. These types of valves generally use the differential pressure principle for control purposes. A reference control pressure is established by spring-loading or pressure-loading the valve operator. The control valve is actuated when the line pressure upstream and/or downstream sensed by the valve operator algebraically exceeds the reference control pressure—i.e., the valve can be actuated by pressures either excessively high or excessively low, or both. This feature makes this type of valve particularly suited for use as safety shut-in valves on wellheads.

Electrically Controlled Valves. Automatic electrically controlled valve operators are of two general types, electric-solenoid (or magnetic) and electric motor. Magnetic operators are used for valves requiring longitudinal motion to position the inner valve. The use of magnetic operators generally is limited to valves 2 in. and smaller in size and of relatively low working pressures. Electric-motor operators can be used with any type of valve but in all cases must include accessories that provide a torque-limiting means and a limit switch to prevent damaging the motor when either extreme valve position is reached. On valves requiring longitudinal motion to seat the inner valve electric-motor, operators also must include a gear rack and pinion to convert the motor's rotary motion to longitudinal displacement. Because of the relative expense of electric-motor

operators, they normally are used only on large-sized valves and/or valves having high working pressures.

Fluid-Electric Controlled Valves. Self-contained valve operators in the third category are generally hydroelectric-type operators. Operators of this type essentially consist of a self-contained reservoir of hydraulic fluid, a small electric motor, a pump, and a fluid-cylinder device—all within a single housing. The fluid-cylinder principle limits this type of operator to valves requiring longitudinal motion or 90° rotation to seat the inner valve. Valve operators of this type are available for a wide variety of valve sizes and working-pressure ranges.

In addition to the hydroelectric-type operators, any of the fluid-controlled operators mentioned can be made combination-type operators. By the addition of electric-solenoid valves in the fluid-control lines, an electric signal can be used to control the release of fluid energy to the valve operator. Combination-type operators of this kind are commonly called "electropneumatic operators."

Valve Switches. It is frequently essential that an automatic control system be able to sense the position of certain valves whether automatically or manually operated. This is accomplished by means of a "valve switch" coupled directly to the stem of the valve in question. In electrical control systems, the valve switch may be a mercury switch, a microswitch, or a position-sensing switch. In pneumatic control systems, the "valve switch" is a three-way pilot valve. The switches may be adjusted to open or close a circuit as the valve opens and closes. One of the most common applications of valve switches is on tank-run valves, in which case they are generally called "pipeline valve switches." Another common use of valve switches is to indicate remotely the operational position (open, closed, etc.) of automatic control valves on wellheads, well manifolds, metering-tank inlets and outlets. In these general applications, valve switches normally will be referred to as "limit switches." When interlocked with an automatic control system, valve switches perform the very important function of preventing subsequent steps in an automatic operation from proceeding unless certain valves are in the proper position. Other type devices can be used to sense "control" valve positions at intermediate points (or continuously) between the open and closed positions.

Automatic Production Programmers

Time-Cycle Controller. Automatic production programmers are scheduling devices that control the particular times and lengths of time that operating functions are performed. The simplest form of automatic production programmer is a time-cycle controller. A time-cycle controller basically consists of a clock with a timing wheel or wheels, containing a number of programming points at regular intervals around its circumference. The clock may be electrically driven, gas driven, or mechanically driven by a spring. It may have a 1-, 2-, 4-, 6-, 8-, 12-, or 24-hour rotation period, the rotation period being the time required for the timing wheel(s) to

make one complete revolution. Programming is accomplished by positioning the contacts on the timing wheel(s) such that the rotation of the wheel(s) generates the proper control signal to open or close valves controlled by the time-cycle controller at the proper times.

As commonly applied, a time-cycle controller in conjunction with a diaphragm control valve compose a "stopcock controller" and/or an "intermitter controller." The primary difference in a stopcock controller and an intermitter controller is in the application. A stopcock controller generally is installed in a well's flowline at the Christmas tree. It controls the times that the well is opened for production, normally for short intervals several times a day. An "intermitter controller" is installed in high-pressure-gas supply line at the wellhead of a well being gas lifted intermittently. It controls the times that gas is admitted to the well to actuate the gas-lift valves and lift the fluid to the surface. A time-cycle controller in conjunction with any type of automatic control valve may be used to produce a naturally flowing well where it is desired to produce the well less than 24 hours per day and/or 7 days a week.

A time-cycle or percentage-time controller plus a motor starter basically compose an automatic production programmer for an electrically driven rod-pumping unit. The rod-pumping unit controls also generally contain several safety devices: undervoltage relay, which drops out on power failure, overload relays to prevent burning up the motor, lightning arrester, circuit-breaking devices, etc.

The electronic (solid state) timer frequently is used in new installations that require timer functions. Mechanical and electro-mechanical timers will continue to be used in many existing installations.

Any time that these automatic production-programming devices are actuated electrically, the control point for individual wells may be centralized at the well manifolds, a central point on the lease, or even a point remote from the field. The time-cycle controllers, automatic control valves, motor starters, etc. still may remain located at the wellheads while control is exercised remotely. This is not true for similar devices that are actuated pneumatically unless the pilot gas for these devices is controlled electrically. Too much dampening and distortion occurs in pneumatic control signals for effective control when transmitted distances of more than about 150 ft.

Other Programmers

The programmers discussed previously have been used in oil and gas production facilities for many years. Currently, the more complex sequential control will be electronic- and combined electronic/pneumatic-based in many applications. This trend is expected to increase as general-purpose programmable controllers, developed initially in the plant applications, find more use in oil and gas production. The functions of the programmable controller and the remote terminal unit (RTU) may well be combined into a more capable unit for oil and gas production monitoring and control applications.

Production Safety Controls

In some respects, virtually all automatic control equipment is also safety-control equipment: automatic control

equipment nearly always is made to be "fail safe"—i.e., upon loss of power from the controlling energy medium, the controls return to the position that will result in the safest condition. Some automation controls, however, primarily perform safety functions rather than normal operational functions. These include high-/low-pressure safety shut-in valves, excess-flow valves, pressure and temperature switches, and pump-off controls.

Safety Shut-In Valves

High-/low-pressure safety shut-in valves and excess-flow valves are both fluid-controlled valves of the type that is actuated by line fluid. This valve type was discussed briefly in the section on automatic control valves. The use of an excess-flow valve or low-pressure control with a safety shut-in valve primarily safeguards against a flowline break and the resultant loss of oil and surface property damage. High-pressure control with a safety shut-in valve guards against pressures in excess of the allowable limit building up in the flowline. Either of these two kinds of valves normally would be installed at the wellhead.

Pressure Switches

Another means of protecting against excessive flowline pressures and/or flowline breaks is the use of a pressure switch and an automatic control valve. Pressure switches are available that produce either an electric or pneumatic signal, as required, to actuate the automatic control valve. On rod-pumped wells, the control signal from the pressure switch also must shut down the pumping unit—i.e., turn off the switch on an electric motor or ground the magneto on an internal-combustion engine. On rod-pumped wells that have no tendency to "head" or flow when the pumping unit is shut down, the automatic control valve may be omitted.

A "pressure switch" in the sense it is used here consists primarily of a pressure-sensing element, limit pressure contact(s), and an electrical, mechanical, or pneumatic means to transmit the control signal to the object(s) controlled by the pressure switch. The pressure-sensing element is commonly a bourdon tube, though some requirements could necessitate the use of a helical-, spiral-, diaphragm-, piston-, or bellows-type pressure-sensing element. In electrical control systems, the displacement of the pressure-sensing element is made to "make" or "break" an electrical switch, normally a mercury or microswitch, when the line pressure reaches the preset pressure limit(s). In pneumatic control systems, reaching the preset pressure limit(s) may actuate a pneumatic transmitter, relay, or slide valve.

Liquid-Level Controls

Another automatic safety-control device, which also frequently performs an operational-control function, is a liquid-level controller. These devices commonly are used to control liquid levels in separators, heater-treaters, storage tanks, surge tanks, accumulator vessels, metering vessels, etc. They may be used (1) to control high liquid levels to prevent running over a vessel, (2) to control low liquid levels to maintain pump submergence, (3) to control intermediate operational levels to open and close dump valves, to start and stop pumps, etc., or (4) to maintain the interface of two liquids at a given level.

There are many types of liquid level controls. Some of the more common types of level control devices used in production equipment are float operated, pressure operated, ground-level tank gauges, electric and/or electronic, sonic, and vibration. A float-operated level switch generally consists of a spherical or cylindrical float attached to one end of a mechanical lever with either an electrical switch or a pneumatic relay on the other end. The switch or relay is located in a separate portion of the device housing and is isolated from the float area with a pressure seal. The float is displaced by the rise and/or fall of the liquid level being controlled and the motion is transmitted through the pressure seal to activate the switch/relay. A pressure level control switch may control liquid level on the basis of either differential or static pressure. The differential type devices commonly are used as a form of "pilot operated" dump valves on pressure vessels. The static pressure devices frequently are used for well shut-down service and level control in tanks.

Ground level tank gauges consist of tape, tape drum, and a tank gauge float that are linked to cause the tape to be spooled on and off the tape drum as the liquid level rises and falls within the tank. By extending the tape drum shaft and using appropriate cams, gears, etc., electrical or pneumatic control systems may be activated to control liquid levels in the tank. One type of sonic level control consists of a sound transmitter and receiver that are suitably arranged for separation by the liquid being controlled. The transmitter and receiver are driven with an electronic circuit that can measure the intensity of the sound reaching the receiver. The change in the received sound intensity between air/gas and the liquid as the separation material can be used to sense and control a liquid level. Ultrasonic level devices sense the reflection of a sound wave from the gas/liquid interface and use the delay time between transmitting and receiving to determine distance from sensor to liquid level.

Some liquid level devices induce vibration into a detecting element. The degree of vibration dampening caused by the medium surrounding the element can be sensed to differentiate between gas and liquid materials. Electric and/or electronic level controls depend on the different electrical properties (capacitance, conductance, etc.) of the liquid to be controlled and that of the related medium (air, gas, and/or other liquid). An electronic circuit is used to sense the change in electrical property as the liquid level changes and thus controls the level as required.

Other types of level controls are available for specific installation needs. Level controllers should be selected to provide the required function in the least complex and most reliable form. It is advantageous to select equipment that has demonstrated satisfactory application experience within the operating environment that is to be controlled.

Automatic Quantitative Measurement

Gross volumes frequently must be adjusted by quantitative measurements such as water content, temperature, pressure, and density before net volumes at standard conditions can be determined. Several of these quantitative parameters are necessary for automation of lease operations.

Liquid Measurement

There are three types of quantitative (volume) devices commonly used for automatic liquid measurement on the lease: positive-volume meters, positive-displacement meters, and inferential meters. Positive-volume meters are essentially extensions of tank measurement with automatic "filling" and "running" functions. Positive-displacement meters "trap" a fixed volume of liquid within moving elements of the meter. Inferential meters measure liquid by detecting some property of the moving stream that is a basis for determining volume indirectly.¹

Positive-Volume Meters. Positive-volume meters operate on a "fill" and "dump" cycle rather than being a continuous operation. This type meter is essentially the automatic gauging of a tank by using level controls to move a fixed volume through the tank on each complete cycle. The volume that is "dumped" or measured is related to the displacement volume in the meter between the high "fill" point and the low "dump" point in the meter. Various types of level controls are used to control the fluid levels in the meter. Each complete "fill" and "dump" cycle is registered on a counter as a basis for total volume determination. Since the positive-volume meter is cyclic with a separate "fill" and "dump" period, allowance for handling produced volumes while the meter is in the "dump" cycle must be made. Continuous operation is possible by having a pair of meters that are sequenced to have alternating cycles. This essentially requires duplication of facilities and some increased complexity in the controls. A more common arrangement is to provide surge volume capacity upstream of a single meter.

Volume-type dump tanks or meters have been built in a variety of shapes and volumes. Capacities per dump have ranged from less than ¼ bbl to several hundred barrels. The metering chamber may be in a stand-alone vessel or it may be an integral portion of a vessel such as a separator or heater treater. The positive-volume meter is not as compatible with qualitative measurement as the positive-displacement and inferential meters since the volume measurement cannot be separated easily into smaller increments to drive sampling and other qualitative measurement devices.

Positive-Displacement Meters. A positive-displacement meter, regardless of specific type, consists of two primary elements: a stationary case and a mobile element, which acts to isolate within the case fixed volume of fluid each cycle of operation. The mobile element may be a rotor with sliding vanes, rotatable vanes, or rotatable buckets. It may be two rotors that mesh somewhat similarly to two helical or cycloidal gears as they rotate. The mobile element may be a disk that nutates about a camlike follower in three-dimensional motion or a cylinder that oscillates about a cam follower in two-dimensional motion. Or, finally, the mobile element could be a conventional piston such as that found in a power pump. Most positive-displacement meters are, in fact, closely akin to positive-displacement pumps.

Positive-displacement meters rapidly became the standard for ACT use. The positive-displacement meter provided a less costly and less complex facility than the

positive-volume meter. In addition, the positive-displacement meter provides a means to drive samplers and/or net oil computers with signals on a small increment of volume that is more compatible with automatic qualitative measurement requirements.

Care must be exercised in the installation design for a positive-displacement meter. All free gas must be removed upstream to avoid spinning the meter, which would cause erroneous readings and, possibly, damage to the meter. For greatest accuracy, a constant flow rate should be maintained through the meter and at a rate at least 15% or greater of the rated capacity of the meter. Standards for calibration frequency, methods, etc., are set forth in API Std. 1101.¹

Inferential Meters. The turbine meter and the orifice meter are commonly used inferential meters for liquid measurement. These meters indirectly determine volume by sensing some property of the moving stream that can be related to volume. For example, the rotation of the turbine blades in the turbine meter and the differential pressure developed across the orifice plate in an orifice meter can be used as basis of volume determination.

Turbine meters became important in volume measurement when electronics were accepted as an element of a measuring device. The rotation of the turbine blades can be sensed electronically without need for any mechanical connection to the turbine rotor. This provides a simple arrangement that is inherently reliable and particularly suitable for high-pressure service. Thus, turbine meters initially were applied to measure injection water volumes. However, high-viscosity fluids drastically reduce the range of turbine meters.

Turbine meters are being used for well testing and wet-oil lease production measurements when combined with net-oil computers. These meters tend to be more tolerant of short over-range periods and sandy fluid than are positive volume meters. Turbine meters also are being used for ACT, particularly for high-volume and/or high-pressure service.

Orifice meters are used more commonly for gas measurement but they have some applications in liquid measurement. Compressible liquids that require pressure correction for volume determination frequently are measured with orifice meters.

Gas Measurement

The primary device for lease gas volume measurement has been and continues to be the orifice meter, which initially measured gas volume by using a mercury manometer before development of the bellows-type chart recorder. Orifice meters have these advantages: (1) no moving parts in the gas stream, (2) the ability to handle wide range of flow rates (long term) by means of plate size changes, (3) reliable and nonexternal powered recorder, and (4) a reliable sensor (bellows). The chart recorder is not compatible with automatic data acquisition; other types of gas measurement devices are used with SCADA. These gas measurement devices include positive-displacement meters, gas-flow computers, turbine meters, and vortex meters.¹

Positive-Displacement Meters

The installation of SCADA systems with automatic well

testing generated a need for gas measurement over a wide flow range with direct readout capability. The "rotary" positive-displacement gas meter is similar to the liquid "lobed-impeller" or gear-type meter. The rotary gas meter has the capability to measure gas accurately over a range of about 15 to 1 compared with about 4 to 1 for an orifice meter with a fixed orifice plate size. The rotary meter can be equipped with mechanical compensation on indicated volume for static pressure and flowing temperature corrections. The rotary meter needs to be protected from over-range and liquid accumulation within the measuring elements. These meters are usually applied to low-pressure gas measurement service.

Gas-Flow Computers

Gas-flow computers were developed to use existing orifice-meter runs and to provide a direct readout of gas volume that was compatible with SCADA. These devices use static and differential pressure electrical transducers on a standard orifice meter as a basis for gas measurement. The computer integrates the signals from the transducers and combines with fixed data on meter run size, plate size, etc. to develop a gas volume. The volume readout will be in the form of a switch closure that will register on an internal counter and provide input to electronic counter in an RTU.

Some gas-flow computers can accept a temperature transducer input to measure temperature of flowing gas stream for improved accuracy of volume measurement. Computers also may have capability to use two differential pressure transducers (e.g., 0 to 20 and 0 to 200 in.) and to select input from the unit providing most accurate instantaneous reading for integration. Early gas-flow computers were analog devices. Many current designs are digital units based on a microcomputer. The flow computer integration function also is being done by the microcomputer-based RTU. All designs have integration accuracy compatible with the basic measurement capability of the orifice meter.

Gas Turbine Meters

Gas turbine meters also are used to obtain direct readout on gas volume measurement that is compatible with SCADA. Turbine meters can measure gas volumes accurately over a range of about 20 to 1 at medium pressures. Rangeability tends to increase with increasing static pressure. These meters are usually somewhat less subject to over-range damage than the positive-displacement meter if over-range period is of short duration. Meter proving and checking may require installation of prover loop for a master meter. Gas turbine meters can be equipped with temperature and static pressure volume compensation capability. Many gas (or liquid) turbine meters are destroyed when they are over-ranged while pressuring up the system.

Vortex Meter

Vortex meters have a "bluff body" that spans the flow area through the meter and causes vortices to form in the flowing medium. These vortices are shed off the bluff body at a frequency that is proportional to the volumetric flow rate through the meter. The vortices can be

“counted” with suitable pressure or other flow pattern sensors, which are connected to an electronic component for flow accumulation. Vortex meters have rangeability characteristics similar to positive displacement and turbine meters without the moving parts of these devices.

Temperature Measurement

Types of temperature-sensing devices commonly used in oil and gas production include filled-thermal, resistance thermal detection, thermocouple, thermister, and solid-state. The filled-thermal device operates on the basis of the principle that a fluid expands or contracts with changes in temperature. The device consists of a temperature-sensitive bulb connected by capillary tubing to an expansible element that is sensitive to pressure change. The bulb may be filled with a liquid, a liquid and its vapors, or a gas. The expansible element may be a diaphragm, a bellows, or a bourdon tube.

The *filled-thermal* device has sufficient output force to be used directly for temperature compensation on positive-displacement meters used for LACT. The bellows assembly is connected to an infinitely variable transmission, which corrects the meter's volume output to a base temperature of 60°F.

A *resistance thermal detector* (RTD) works on the principle that a change in resistance of a wire is related directly to a change in temperature of the wire. The device consists of a resistance element (sensing element) and a related electrical circuit, which uses the changing resistance of the element to control an output signal. The output signal can drive recorders and controllers.

A *thermocouple* works on the principle that heat applied to one end of two strips of metal of different composition, which are bonded at either end, develops an electromotive force (EMF) that is proportional to the temperature. Thermocouples may be of the wire type, in which both elements are in wire form, or of the Pyrod type, in which one element is a closed tube and the other a wire welded to the inside bottom of the tube. The thermocouple is connected to an electrical circuit, which senses the generated EMF and develops an output signal that can drive recorders and controllers. Thermocouple devices are used in applications where temperatures may exceed 1,000°F.

Thermister and *solid-state* devices exhibit a resistance change with temperature change. Both these devices respond rapidly to a temperature change because of the small mass of the sensing element. Electrical circuits are required to convert the “sensed” resistance change into an output signal that is proportional to temperature.

Automatic Sampler

An automatic sampler is a device that removes a representative volume of fluid from a moving stream and retains it in a container for later processing and analysis. Factors that improve probability of obtaining a representative sample include the following: (1) sampling probe should be located in a vertical downrun of pipe at the center of the pipe and with probe opening facing upstream; (2) the total flowstream should be in turbulent flow; (3) sample size and sampling interval should be such that the sample is proportional to the total stream flow; (4) sample metering chamber should be closely coupled to sampler probe and located below the center

line of sample probe; and (5) samples should be collected and stored at pressures exceeding the vapor pressure of the sample liquid to prevent evaporation and deterioration during storage.

Samplers also are used with positive-volume and positive-displacement meters in well testing and wet-oil (not pipeline quality) lease volume measurements. Representative sampling becomes more difficult with increasing water content in the oil stream. For improved accuracy, fluid mixtures that may have both free water and oil emulsion (oil-external phase) components should be processed through a three-phase separator before the remaining oil emulsion stream is sampled.

The capacitance probe and net-oil computer have not replaced the automatic sampler on most LACT installations because (1) crude oil value frequently is based on gravity (determined on sample volume), (2) the gross-oil volume available directly from LACT counters is satisfactory for daily operating needs, and (3) the potential operating cost reduction by eliminating sampler use is not significant. Most major purchasers will have a recommended (or required) design for automatic sampler installation.

BS&W Monitor

Pipelines specify the maximum BS&W content that a crude oil may contain to be acceptable for transfer. The development of LACT equipment required a means to monitor the quality of crude oil as it was being measured and transferred automatically to a pipeline. The commonly accepted device for this function is a capacitance probe BS&W monitor. The dielectric constants of crude oil and water are about 2 and 80, respectively. The BS&W monitor uses a concentric probe, which senses the apparent dielectric constant of a fluid stream by measuring its capacitance between the probe electrodes.

The capacitance probe generally is installed in a vertical riser on the premise that a more uniform mixing of stream components will result and thus, that a more accurate sensing of water content is ensured. Temperature compensation is required since dielectric constants of oil and water vary with temperature. The BS&W monitors used with LACT generally have a 0 to 3% BS&W range. The monitors have a variable set-point that is used to divert the oil stream back through the treating facilities when the selected BS&W content is reached and/or exceeded. In this application, a BS&W monitor controls the crude oil stream being transferred to the pipeline, but it does not determine the BS&W content as basis for gross volume adjustment.

Net-Oil Computer

The application of SCADA systems to production operations increased the need to read directly the net-oil content of an emulsion stream for well testing and lease oil production measurements. The basic principle of the capacitance probe used in BS&W monitors was extended to oil emulsions of higher water content by probe redesign.

The capacitance probe, with modification to give a linear output, provides a technique to obtain instantaneous value of water content in an oil emulsion stream. By combining the probe output with volume output from a positive-displacement or turbine meter, the net-oil and

water volumes in an emulsion stream can be determined. The device that combines the capacitance probe and meter volume information to obtain net-oil and water volumes is designated as a net-oil computer.

The net-oil computer can determine the oil/water content of an emulsion stream with reasonable accuracy (1 to 2% in oil measurement to about 35% water). The capacitance probe will continue to indicate water content above this value (if in an emulsion form), but the decreasing oil percentage of the total stream causes increased error in the measured oil fraction. A limitation of the capacitance probe is that any "free" water moving across a probe with oil emulsion will distort the indicated water content and cause substantial errors. Applications with water cuts above 35% can be measured by using three-phase separators (for well testing and/or lease oil production). Treating chemicals can be used with three-phase separators, if necessary, to keep water content in the emulsion to 35% or less. With these procedures, well testing and lease oil production can be processed with total water production of more than 99%.

Supervisory Control and Data Acquisition (SCADA) Systems

SCADA systems applied to oil and gas producing operations vary in function and overall capability. Some systems are oriented primarily to local operating personnel needs and may only monitor/control a few wells in a single field. Other systems are applied to multiple fields that have several thousand total wells. Even with the wide variations, SCADA systems consist of the following basic elements: (1) supervisory control/data acquisition equipment, (2) field instrumentation and cabling systems, (3) communication facilities, and (4) digital computer systems.

SCADA Equipment

This equipment functions to interconnect digital computer systems and instrumentation and control devices that are related to the oil and gas producing process. The equipment consists of a communication adapter and RTU's. A communication adapter is attached directly to the digital computer by a high-speed data link and attached indirectly to RTU's by communication circuits. The communication adapter serves as a data concentrator for the digital computer, which can drive several communication circuits simultaneously. A number of RTU's generally share a common communication circuit.

The communication adapter and the RTU's are designed to use a specific message protocol or structure for the transmission of information. This message structure generally will contain the RTU address, function being requested, function modifiers, and supplemental information used for checking validity of message transfer. A primary feature shared by the communication adapter and the RTU's is the checking for valid message transmission between the devices. Manufacturers use different techniques to ensure receipt of valid messages and most of these have a high probability of detecting invalid transmissions. Earlier communication adapters were designed with "hard-wire" logic and were separate devices. Many of the current designs are microcomputer-based units that may be an integral part of the digital computer rather than a separate unit. These units fre-

quently can handle multimessage protocols to allow more flexibility in attached devices.

RTU's are electronic devices that connect the SCADA system directly to the oil and gas production facilities that are being automated. An RTU has the capability to store information from several input points and to transmit this information in a serial mode over a single communication circuit to a digital computer on demand. The RTU also may receive control information from the computer that it routes to a selected control point. The RTU generally is located within a few thousand feet of its connected instrumentation and control equipment but may be up to several hundred miles from the computer location.

RTU's commonly sense input information related to status/alarm (on-off, etc.), volume accumulation (oil and gas meter counts), and instantaneous analog values (temperature, pressure, flow rate, etc.). The RTU can provide control output in the form of relay activate (on-off, start-stop) and a set-point value. The set-point is commonly a 4 to 20 mA or 10 to 50 mA signal that is compatible with control devices. Although these basic RTU capabilities may appear limited, most data input and control output functions related to oil and gas production can be implemented directly. Some specific functions may require supplemental logic in local control panels for implementation.

The basic RTU functions described previously are common to units designed with "hard-wired" logic. Many of the current and most future RTU designs will be microcomputer-based. The microcomputer allows substantial increases in RTU functions with relatively small incremental hardware expansion and cost. For example, RTU's are being used to replace stand-alone gas-flow computers simply by adding to the microcomputer program logic that integrates static pressure, differential pressure, and temperature transducer data from an orifice meter. The microcomputer in the RTU can handle all basic RTU functions and process gas-volume accumulation for 30 to 50 m runs without timing constraints. With continuing developments in electronic technology and improving program support, the outlook is for significant expansion in RTU capability.

Initial RTU designs that incorporated microcomputers tended simply to implement "hard-wired" logic in the microcomputer. In addition, microcomputers used with RTU's generally did not have any internal error checking such as parity on memory, data bus, and address bus transfers. These conditions resulted in microcomputer-based RTU's that were difficult to trouble-shoot when malfunctions were experienced. Self-diagnostic capabilities should be the first functional extension of microcomputer-based RTU's. Good diagnostic features usually will require a combination of extended hardware and software. Diagnostic checks should be run at startup and at frequent intervals during the regular operation of the RTU. RTU's should have a "watch-dog" timer that will attempt to restart the microcomputer if it stalls as a result of hardware and/or software malfunction. The restart feature also should provide a means to document its use.

The RTU as an electronic device has two primary environmental factors that adversely affect operational reliability. These factors are heat and electrical tran-

sients. All solid-state electronic components suffer decreased life with increasing operating temperatures. Many users of RTU's routinely have placed these units in air-conditioned buildings to decrease the mean time between failures. More recent introduction of low-power electronic components such as complementary metal-oxide silicon (CMOS) may minimize the need to provide cooling below normal ambient temperatures.

Solid-state electronic components are subject to damage by extremely short-duration (microseconds) higher voltage electrical transients (e.g., noise, spikes). These transients may enter an RTU by means of primary power or by the many signal loops connecting the RTU to the instruments and control devices associated with the production process. RTU's frequently are provided battery backup power to allow for continued operation with primary power outages. Common procedure is to operate the RTU continuously on battery power with primary power driving a battery charger. This arrangement provides relatively good isolation for the RTU from power line transients.

All RTU input/output connections to the field cable system also must be protected from voltage transients. Status/alarm and accumulator input points frequently use optical isolation between field cables and internal circuitry. Each field signal loop also should use a gas tube (or similar device) to route induced voltage transients to earth ground. Lightning can induce sufficient energy to literally evaporate protective components in extreme cases but many of the otherwise damaging transients can be suppressed with proper protection equipment. Electrical noise also may be caused by inductive devices such as relay and solenoid valve coils. Inductive components should have suppression diodes placed across the input terminals to minimize electrical transient generation.

Field Instrumentation and Cabling Systems

Field instrumentation and control devices are selected primarily to meet needs of the oil and gas producing facilities. If these devices are also to interface with the RTU of a SCADA system, some additional features may be required. RTU status/alarm and accumulator inputs require an electrical switch closure to convey information to the RTU. For example, a separator high-level float control may have a pneumatic switch for control valve activation. An electrical pressure switch may be added to the pneumatic control line to allow the RTU to sense the position of the high-level control. In general, reliability of interface increases when the primary instrumentation has a direct electrical connection compared to the example that required a pneumatic to electrical conversion.

Meters for liquid and gas measurement also need to have an electrical switch activation to indicate some increment of volume accumulation. Liquid meters, for example, frequently will have an electrical switch closure at nominal 1-bbl volume increments. The switch closure must be maintained for some minimum time increment (about 50 milliseconds) to ensure that electrical transients will not cause invalid volume counts. The RTU will have a separate signal loop (wire pair) and internal electronic counter associated with each meter being monitored.

Pressure, temperature, flow rate, position, and similar

operational parameters are sensed by the RTU as an analog input value from electrical transducers. Nominal electrical transducer output ranges of 1 to 5, 4 to 20, and 10 to 50 mA usually can be processed by the RTU. A current output transducer is preferred since the signal is less susceptible to electrical transient distortion than a voltage output.

Multiconductor cables are used to connect the RTU to the instrumentation and control devices associated with the production process. The signal cables consist of individually insulated copper wires generally of 19 or 22 gauge that commonly are used for commercial telephone service. The cables usually are buried to minimize probability of mechanical damage and electrical noise intrusion. Cables can be damaged when buried and repairs should be made immediately to prevent further deterioration. Cable lengths are controlled by cost relationships between installing more RTU's at separate locations and the amount of cable required for interconnection. Most cable systems will be limited by economics to a few thousand feet.

Radio communication links between RTU's and a central location within a field can reduce overall cabling costs substantially. This technique can use a master radio station in a "polling" mode to communicate with the individual RTU's. Separate transmit and receive frequencies enhance the radio communication procedure. In this arrangement, the master radio transmits an outbound message to all RTU's and the RTU's will decode the address portion of the message. The addressed RTU then will decode the function portion of the message and reply to the master radio by bringing up its transmit radio link for the period required by the return message. The master radio is linked to a regular four-wire communication circuit for communication outside the field area.

The low-energy signals used in the cable system require careful connection of wiring to instrumentation. Any damage to wiring insulation or collection of moisture at connection points may result in sufficient signal leakage to cause invalid sensing of operational information. Some installations are made with the signal loop power supply "floating" or not connected to earth ground. Maintenance checks then can be made to determine current leakage to the positive and negative terminals of the power supply from earth ground as a measure of signal leakage. With selective isolation of the signal loops, leakage problems usually can be identified. Common practice is to design alarm-signal loops to be in normal condition when the sensing device has a closed electrical switch. This feature makes the alarm signal more fail-safe in that any failure of the signal path will cause indication of an alarm condition also. Less critical "status" loops frequently are open in the normal state to minimize total power needs.

Communication Facilities

SCADA systems require capable and reliable communication facilities to connect the communication adapters on the digital computer system with the RTU's that are located in fields being automated. Most SCADA systems use dedicated or nonswitched communication circuits that have a four-wire configuration. The four-wire designation provides two independent communication paths that will support simultaneous data transfer in

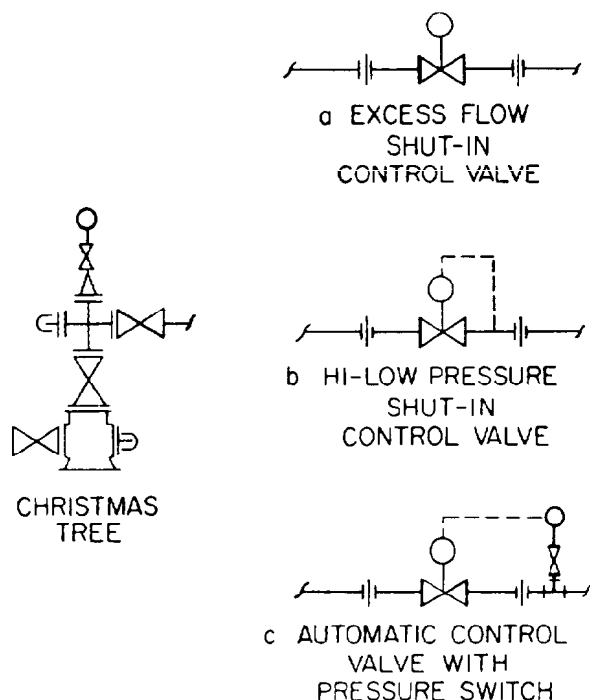

Fig. 16.1—Automatic wellhead safety controls.

two directions (full duplex). Data transmission in SCADA generally is operated in one direction at a time (half duplex) with transmit over one path and receive over the other path but at different time periods. Data are transmitted over the communication circuits with the aid of modems. Modems are electronic devices that convert voltage or current level from the communication adapter into analog signals that can be transmitted over the communication circuit. A similar modem at the RTU receives the analog signals and converts them into voltage or current levels that are compatible with the electronic circuitry in the RTU. A data transmission from an RTU to the communication adapter operates in the reverse cycle.

SCADA can use commercially available voice-grade (telephone) communication circuits. Communication speeds of 1,200 bits/sec can be used with long term reliability over these circuits by using conventional modem equipment. Higher communication rates can be obtained by using more complex modems and higher quality communication circuits if the application being monitored requires more critical timing responses. Increased communication rates tend to require more maintenance time or fine tuning of communication equipment to achieve a constant reliability of performance.

SCADA communication circuits may require multiple ownership and maintenance responsibility links to reach particular locations. Circuits with divided maintenance responsibility tend to have more reliability problems. In these cases, adequate test facilities at the computer site can aid in defining the particular link causing problems. The four-wire circuit is compatible with testing since it can be turned around to receive a transmitted test signal from the computer site. If remotely operated turn-around

devices are located at each link interconnection, the circuit can be tested and problems isolated to the responsible maintenance group.

Digital Computer Systems

SCADA became possible with the development of process-control-type computer systems in the late 1950's. The process control computer was a special hardware implementation that provided for direct connection to plant instrumentation and control equipment. This same hardware also provided a means to interconnect with the communication adapter of a SCADA system. The SCADA equipment then allowed the process control computer to be connected indirectly to oil and gas facility instrumentation at remote locations.

Process control computers had software operating systems with program execution control that was compatible with SCADA needs. The operating systems were designed to recover automatically from minor program malfunctions to minimize computer operator needs in the continuously operating SCADA applications. Early process control computers had limited memory size that tended to require assembler language routines for some functions. Frequently, bulk storage (disk or drum) devices also were limited in capacity. Most earlier SCADA systems were based on a central computer system concept.

Currently, SCADA systems have extremely capable computer systems available for system implementation. Process-control-type computers are available with few practical limitations on memory size, speed of execution, and random access storage capacity. In addition, many of the general-purpose-type computers (business and scientific applications) now have extensive communication capabilities and operating system features that are compatible with most SCADA requirements. Distributed computing, which uses multiple computers at remote sites, became practical in the mid- to late 1970's as manufacturers developed capable network software. The network software provided capability to develop application programs at central locations and download through communication links into computer systems at field locations. Increased use of distributed computers in SCADA is anticipated.

Basic application software is generally available from manufacturers of the SCADA systems. The rapidly changing technology, however, has made it difficult for suppliers to develop general purpose application software that is transportable to new computer systems. Most larger SCADA systems have tended to be specialized software applications that have continuing program development to meet the changing operational needs. Application software for both small and large SCADA systems should have flexibility to allow changes/additions to the implemented functions.

Typical Automatic-Control Installations

Automatic Well Control

Automatic Wellhead Controls. Wells may be controlled at the wellhead or at the well manifold. Frequently, it is necessary or desirable to control them at both places. Fig. 16.1 depicts three different types of

Fig. 16.2—Automatic controls for rod-pumped wells.

places. Fig. 16.1 depicts three different types of automatic control valves that could be installed at the wellhead immediately adjacent to the tubing wing valve. Although Fig. 16.1 pictures a naturally flowing well, the same types of automatic controls would be applicable for artificially lifted wells of all types, if required. The excess-flow valve shown in Fig. 16.1a generally is used only to protect against flowline breaks when the wells are choked and controlled at the well manifold. The high/low pressure shut-in valve in Fig. 16.1b may be used whether the well is choked at the wellhead or at the well manifold. It is protection against both flowline breaks and chokes cutting out or plugging. The control valve and separate pressure-sensing element shown in Fig. 16.1c perform exactly the same functions as the high/low pressure shut-in valve.

Rod-Pumped-Well Control. The typical automatic-control system for a rod-pumped well is shown in Fig. 16.2. The high-low pressure safety shut-in valve is necessary only when the well has a tendency to flow naturally when the pumping unit is shut down. The excess-flow valve, again, is protection against flow-line breaks. Some operators use them; others do not. They are not always effective unless line pressures are high enough, and the size of the break large enough, to create a substantial pressure drop. The pressure switch is the most common automatic safety control used with rod-pumped wells, particularly where the wells are remotely controlled. Regardless of which of these three types of controls are used, when the control pressure is reached, that automatic control must furnish a signal to shut down the pumping unit. This is accomplished by grounding the magneto of a gas engine or shutting off an electric motor. A pump-off control, if used, would be installed in the flow line immediately adjacent to the pumping tee.

Gas-Lift-Well Control. Fig. 16.3 shows a typical arrangement of controls on the gas-supply line to a well that is produced by an intermitter-type gas-lift installation. The "time-cycle controller" shown on the right is an automatic production programmer. It automatically opens and closes the diaphragm control valve, to which it is connected by instrument lines, according to the schedule manually created in the programmer. The "flow-control valve" is a manually actuated valve used to control the rate at which gas is admitted to a well. Automatic-control valves on the flow line, if required, would be one of the types shown in Fig. 16.1.

Hydraulic-Pumped-Well Control. Fig. 16.4 depicts the typical automatic controls for a hydraulic pumping

Fig. 16.3—Typical automatic control of gas-lift well.

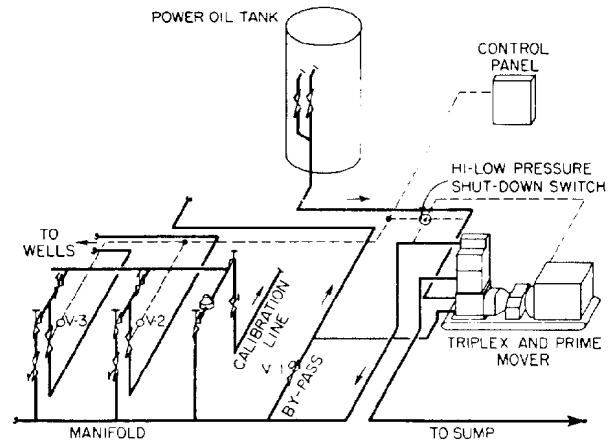

Fig. 16.4—Typical hydraulic-pumping-system control.

system. A high/low pressure switch protects the triplex pump and its prime mover against overloading from abnormally low suction pressures and/or high discharge pressures. In either case, the pressure switch would shut down the prime mover. Automatic Control Valve V-1 in the manifold bypass is generally a diaphragm-type regulator valve which is normally closed. It would open at a pressure slightly under the setting of the high/low pressure shutdown switch and divert sufficient power oil back to the power-oil tank to maintain system pressure at a safe level. Automatic Control Valves V-2 and V-3 are in the power-oil lines to individual wells. They would be closed automatically in the event the pressure switch shut down the triplex and prime mover. With an appropriate programmer, they could also be used to produce individual wells selectively on an intermittent schedule.

Automatic Well Manifolds. In Figs. 16.5 and 16.6 are shown two typical automatic well manifolds designed for controlling the wells at the well manifold rather than at the wellhead. The single-wing well manifold shown in Fig. 16.5 has a maximum of flexibility to meet any system of stage separation and/or treating that might arise. It has another advantage in that it could be installed initially on new leases as they are developed without the automatic-control valve and still add the valve later with a minimum of expense. The dual-wing well manifold shown in Fig. 16.6 is limited to situations where all production in a well manifold is processed through a single vessel or a common sequence of vessels. Both these manifold designs would require flow lines capable of withstanding full wellhead pressure and

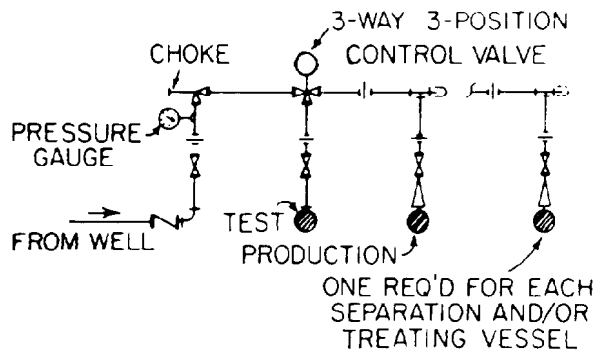

Fig. 16.5—Typical single-wing automatic well manifold.

Fig. 16.6—Typical dual-wing automatic well manifold.

would choke and control the wells at the manifold. All manifold designs should provide for monitoring valve leakage.

Some operators prefer to use three-way, two-position control valves in the well manifold and to control the wells at the wellhead. Automatic-control valves of the types shown in Fig. 16.1 then would be installed at the wellhead in addition to the control valves in the well manifold. Other operators would prefer to use a two-way control valve in each riser to each pressure vessel served by the well manifold.

Automatic Well Testing

A typical automatic well-testing system is illustrated in Fig. 16.7. The sequence control logic for conducting the test and for calculating test results may be self-contained in the control panel or it may originate in a SCADA system that is remote from the site. In either case, a three-way control valve in the test/production manifold is activated to divert the selected well to the test vessel when the related signals are received from the control panel. The test vessel may be either a separator or a heater treater. The liquid-metering elements commonly will be either positive-displacement or turbine meters. The oil meter will be combined with a capacitance probe and net-oil computer to provide measurement of net-oil and emulsion-water volumes. The free water volume will be measured by a separate water meter. Well-test control logic will combine the emulsion-water and free water measurements to obtain total test water volume.

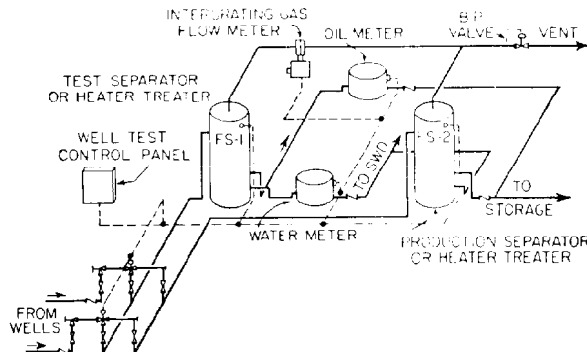

Fig. 16.7—Typical automatic well-testing system.

The test-gas volume can be determined with a positive-displacement meter, turbine meter, or gas-flow computer. The three-way control valves should be equipped with position switches that can be used to confirm that only the selected well is in the test vessel. The test vessel normally will have a high-level float switch that will automatically divert the on-test well back to production status when a high liquid level is detected. The same switch can be used to notify the SCADA system of the test vessel malfunction.

Some operators have extended the use of measurement equipment, as described for well testing, to total lease production. For example, with more logic in the control panel and manifold of dump lines from test and production vessels, the oil-measurement equipment can be time-shared to measure both test and production oil volumes. The control panel determines (one at a time) which vessel dumps through the oil-measurement equipment and routes the volume counts to the related counter. Separate gas-measurement facilities are required for test and production volume determination.

The time-sharing concept has been extended further in certain instances. For example, a number of separate leases, each having only a few wells, were arranged to have all production separators located at a common site. The oil production from each separate lease production separator was determined by time-sharing a single oil-measurement facility. In addition, a single test separator was used to test all wells at the site. The site control panel routed test volume counts to the test counters and to the appropriate lease counters related to the well on test.

LACT

The first efforts to design an acceptable LACT installation tried to incorporate the existing equipment on the lease and familiar operating principles insofar as possible. Thus, understandably, the first officially accepted LACT system was a weir-tank system installed by Gulf Oil Corp. on its Ames Lease in the Bloomer field, KS, in 1955. Shell Oil Co. also pioneered in the development of the weir-tank-type LACT system on its leases in the Antelope and Wasson fields in Texas, beginning unofficial experiments as early as 1948. The next significant development in LACT system design was the meter-tank-type system.

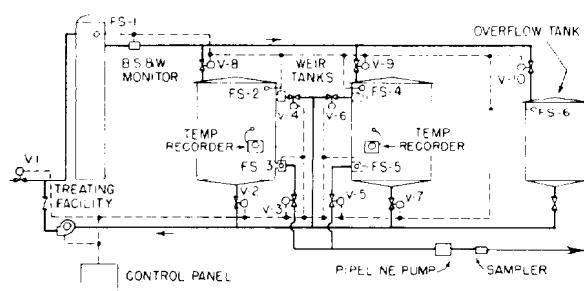

Fig. 16.8—Typical weir-tank-type automatic-custody-transfer system.

The meter-tank-type system is closely akin to the weir-tank system in many respects, but perhaps it deserves consideration as a separate category because these vessels were designed solely as measuring vessels. The great similarity between measurement with the larger-sized positive-volume dump meters and conventional lease tanks assured their early acceptance. Officially accepted LACT installations of this type of the Phillips Petroleum Co. and Amoco in Oklahoma and Texas followed closely on the heels of the Gulf weir-tank-type system in Kansas. The third type of LACT design which has gained wide acceptance to date is the positive-displacement-meter-type system. Exxon Co. U.S.A. was perhaps the strongest early proponent of this type of system, and they performed much development work on their leases in south Texas.

The positive-displacement-meter-type equipment rapidly became the LACT standard primarily because of substantial cost and operating reliability advantages over the other two units. The positive-displacement-meter LACT assembly was skid-mounted for relatively simple installation within existing production facilities. Figs. 16.8 and 16.9 are included for reference to the historical development of LACT as an important element of lease automation.

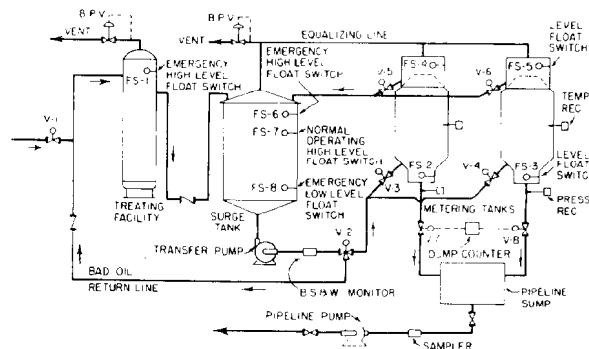

Fig. 16.9—Typical automatic-custody-transfer system using metering dump tanks.

Positive-Displacement-Meter LACT System. Fig. 16.10 shows a positive-displacement-meter LACT installation. Option B indicates a two-meter arrangement that was recommended strongly in earlier installations for improved measurement reliability. Operational experience found the single meter arrangement (Option A) to have satisfactory reliability and most LACT's were installed with the single meter. Some LACT's have two meters but most of these operate the second meter in a stand-by mode rather than simultaneous measurement through both meters. Most major purchasers have recommended (or required) certain designs for LACT installations.

The routine operation of crude-oil transfer is controlled by the normal operating high-level float switch with an override to shut down on emergency with the low-level float switch. The BS&W monitor will divert fluid stream to the treating facility on detection of high BS&W content. The strainer is used to protect the meter from particles that could damage the meter. The meter is temperature-compensated to indicate oil volume at 60°F standard condition. Daily and monthly volume limit switches prevent overrun of lease on either daily or monthly allowable volumes. A calibration loop is located downstream of the meters to allow convenient

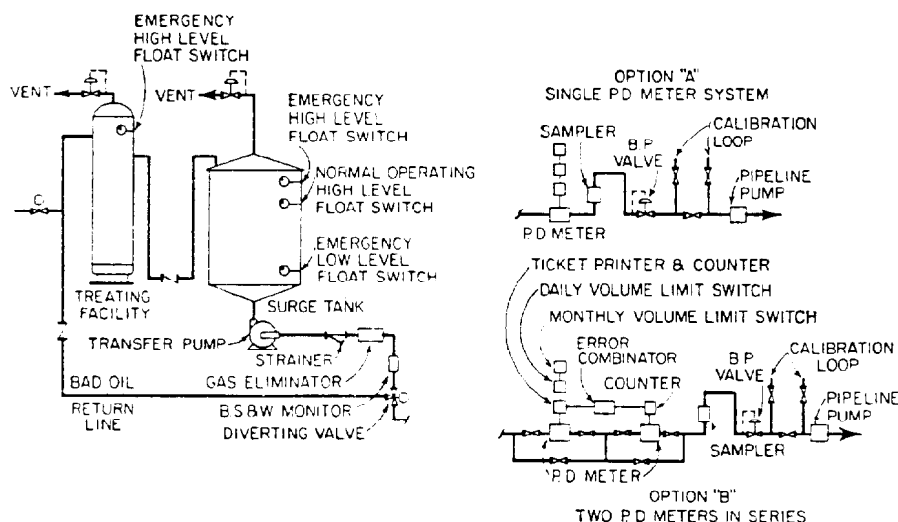

Fig. 16.10—Typical automatic-custody-transfer systems using positive-displacement meters.

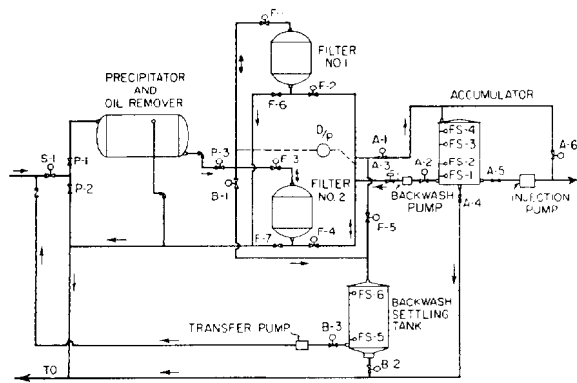

Fig. 16.11—Automatic backwash of rapid sand filters in water-treatment plant.

Fig. 16.12—Typical method of controlling injection-pumping rate.

meter-proving or calibration with a master meter. A sampler is used to collect sample volumes for basis of BS&W correction and oil gravity determination. The back-pressure valve is used to minimize gas break-out or "flashing" in the crude stream prior to being metered. A check valve (not shown) should be located downstream from the back-pressure valve (or combined with it). API Standards 1101, 2502, 2531, 2542, 2544, and 2546, and supplements thereto provide recognized industry codes for liquid petroleum measurement.²

Automatic Lease Process Control

There are many normal lease-operating processes that may be automated or that already are automated completely and not recognized as such by the average individual. Space limitations will permit only a brief look at a few of these control systems to show what can be and is being done.

Automatic Water-Treating Plant. Fig. 16.11 depicts a rather elaborate automatic backwash system for rapid sand filters in water-treating plants. Normal flow is from the precipitator and oil remover through the sand filters into the accumulator. When the differential pressure across the bank of filters reaches a predetermined value, the backwash cycle is initiated automatically. Valves

Fig. 16.13—Automatic control of water-supply wells.

P-3, F-1, F-3, F-4, and A-1 are closed; Valve A-2 is opened; and the backwash pump is started. After a slight delay, Valves F-1 and B-1 are opened and Filter 1 is backwashed into the backwash-settling tank for a predetermined, but adjustable, time. At the end of this time, Valves B-1 and A-2 are closed and Valves P-3 and F-5 are opened. Normal flow is permitted through Filter 1 into the backwash-settling tank for a short interval to settle the filter bed. At the end of this interval, Valves P-3 and F-5 are closed, Valves A-2 and F-4 are opened, and the backwash pump is started. After a slight delay, Valve F-3 opens and the same cycle is completed for Filter 2.

Four float switches are required in the accumulator. Float Switch FS-1 is an emergency low-level float switch, which maintains a flooded pump suction and prevents gas from locking the pump since the accumulator normally will be gas-blanketed. The volume between Float Switches FS-1 and FS-2 is large enough to backwash the filters. Normally the fluid level is not permitted to fall below FS-2. If it should, the injection pump is shut down if it has an electric prime mover, or Valve A-6 is opened and the injection-pump output is bypassed back into the accumulator if the injection pump has a gas-engine prime mover. When the fluid level reaches Float Switch FS-3, the normal injection process is resumed. Float Switch FS-4 is an emergency high-level control that would cause Valve S-1 to close to prevent running over the accumulator.

Valve A-3 is shown as a backpressure valve that is intended to keep a constant head on the backwash pump. The backwash pump probably will be a centrifugal pump because of the high rate normally recommended for proper backwashing. If the injection process ceases for the backwash cycle, then gas pressure applied to the top of the accumulator can be used in place of the backwash pump.

After all the filters have been backwashed and settled into the backwash-settling tank, the solids in the water are permitted to settle out in the bottom of the tank. Then Valve B-2 is opened automatically to permit the solids to be washed out to the pit. Then Valve B-2 closes, Valve B-3 opens, and the transfer pump returns the clear water back through the system. Float switch FS-5 is for the purpose of maintaining a flooded suction on the transfer pump, and Float Switch FS-6 is to prevent running over the vessel.

The system just described represents a composite situation. All automatic water-treating plants would not have to be this elaborate. For example, a backwash-settling tank would be desirable only where it was necessary to keep the water going into the pit at a minimum. On the other hand, by a few small changes,

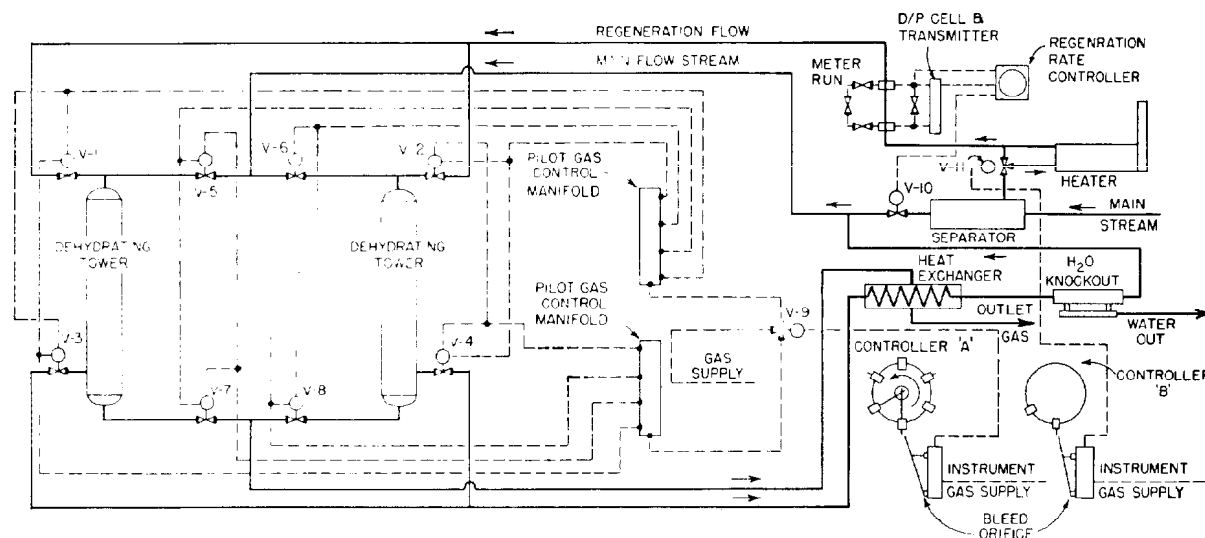

Fig. 16.14—Automatic cycling of desiccant beds in dry-desiccant-type gas dehydrators.

the systems shown in Fig. 16.11 could also be altered to provide for continuous through-put and injection while one of the filters was being backwashed.

Automatic Control of Injection-Pumping Rate. Fig. 16.12 shows a typical method of controlling the injection-pumping rate of a gas-engine-driven injection pump. A float switch and pilot valve, acting through a snap-active pneumatic relay, controls the position of (1) a low-level bypass regulator, and (2) a bellows-operated pneumatic motor that adjusts the engine throttle linkage relative to the position of the float switch in the clean-water tank. In the event the fluid level drops too low in the clean-water tank, the pilot valve sends a signal to a low-level shutdown switch, which grounds the magneto on the engine and shuts it down.

Automatic Control of Water-Supply Wells. Fig. 16.13 shows a method of using float switches to control the operation of several water-supply wells to maintain an adequate supply of water in the raw-water tank. As always, high- and low-level emergency float switches are provided. Additional float switches are included to program the addition and subtraction of supply wells feeding the system to assure an adequate volume of water is always in the raw-water tank. The well-on float switches would be actuated by a dropping fluid level, and the well-off float switches by a rising fluid level.

At the water-supply wells, there are several ways to control the pumping equipment. If the pump is driven electrically, it might be necessary to start up and shut down the pump motor only as called for. If the water-supply well were artesian or had a tendency to flow naturally, it would be necessary, of course, to furnish a shut-in valve. If the pump is driven by a gas engine, it would be necessary either to provide the engine with an electric ignition system (battery or electric motor) and a startup sequence programmer or to install a diverting valve and leave the engine running while diverting production back into a casing annulus.

Automatic Control of Dry-Desiccant-Type Gas Dehydrators. As a final example, let us consider a lease

process that has been fully automatic since its inception, but one which is rarely thought of in terms of automation: the automatic cycling of desiccant beds in dry-desiccant-type gas dehydrators. Fig. 16.14 is a schematic of a typical dry-desiccant-type dehydrator. The wet gas stream enters the horizontal separator and is divided, with a part of the gas going to the regeneration stream and the remainder continuing in the main gas stream through the dehydrating tower. The proportioning of the flow between the two streams is controlled by the regeneration-rate controller. The rate of flow in the regeneration gas line is measured by a differential-pressure cell and transmitted to the regeneration-rate controller. The regeneration-rate controller, in turn, acts to position Automatic-Control Valve V-10 to maintain the predetermined rate of flow of gas through the regeneration system.

Automatic-Control Valve V-11 in the regeneration gas line is controlled by Controller B. Each time the controller rotates until the pin on the next trip clamp unlatches the pilot arm, Valve V-11 reverses its position. In the one position, it diverts gas through the heater to provide hot gas for expelling moisture from the desiccant bed of the tower being regenerated. In the other position, it bypasses the heater and provides unheated gas to cool the desiccant bed in the same tower before placing it back into service. By the time the controller rotates one more position, the regeneration valves on the towers will have switched so that the hot gas goes to the other tower.

Automatic-Control Valves V-1, V-2, V-3, and V-4 control the flow of regeneration gas to dehydrating towers, and Valves V-5, V-6, V-7, and V-8 control the flow of the main gas stream. Valves V-1, V-3, V-6 and V-8 are always in the opposite position from Valves V-2, V-4, V-5, and V-7. The main-stream valves and the regeneration-stream valves are manifolded in such a manner that only one tower at a time receives the main-stream gas and that tower is blocked off from the regeneration gas. The other tower receives the regeneration gas and is blocked off from the main-stream gas. The position of all these valves is controlled by Controller A acting through relay Valve V-9 and the pilot-

gas-control manifolds. Each time the controller rotates until the pin on the next trip clamp unlatches the pilot arm, instrument gas will flow through the bleed orifice instead of flowing to the Relay Valve V-9. Relay Valve V-9 then will reposition itself and allow instrument gas to flow to the other pilot-gas-control manifold and vent the gas from the pilot-gas-control manifold supplied in its original position. This, in turn, will cause each of these control valves to reverse their positions, and thus the flows of main and regeneration gas streams will also reverse. The length of each cycle is controlled by the spacing of the trip clamps on the controller.

Chapter 17

Measuring, Sampling, and Testing Crude Oil

Don G. Chancey, ARCO Oil & Gas Co.*

Introduction

In the early days of the petroleum industry, crude oil was sold by the producer in various-size containers called "the barrel." It was not until 1866 that the Pennsylvania Oil Producers had a meeting and established the size of a standard oil barrel to be 42 U.S. gal at 60°F. As the value of the oil increased and as the size and number of sales grew, it became necessary to establish a set of codes or standards by which the oil could be measured accurately and a net volume determined.

The American Petroleum Inst. (API) first established its Code 25 in April 1929, under the tentative title "API Code on Measuring Field Production and Field Tanks." This code was superseded by API Standard 2500, "Measuring, Sampling, and Testing Crude Oil" in 1955. API now publishes a two-volume, comprehensive *Manual of Petroleum Measurement Standards*, which represents all branches of the industry and is the recognized standard. It serves as the unified method and practice in measuring, sampling, and testing crude oil. As the manual is revised and as new chapters are completed, the standard designations will be replaced by chapter designations. The manual is being updated continually and care should be taken that the current standard or chapter is used.

Procedure for Typical Measuring, Sampling, and Testing

The procedure given here is the API method currently in effect for running a field tank of crude oil. Since there are many variables that would alter this method, this procedure is applicable *only* under specific conditions.

1. The tank is vertical, nonpressurized, fixed roof with side outlets, and it is to be gauged by the innage method.

2. The oil is less than 100 seconds at 100°F (Saybolt universal viscosity) and is a liquid at atmospheric temperature and pressure.

3. A cup case thermometer is used to read temperature of the oil in the tank.

4. A thief is used to obtain fluid samples from the tank.

5. The API gravity scale hydrometer test method is used to determine the API gravity of the oil; the temperature of the oil has to be near 60°F ($\pm 5^\circ\text{F}$).

6. The water and sediment in the oil is to be determined by the centrifuge method with a 203-mm [8-in.] cone-shaped tube.

The following outline gives the sequence of steps to be taken and the key points to be noted at each step.

1. Isolate the tank to be checked.

2. Use face mask and fresh air bottles if H₂S hazard exists.

3. Ground your body to stair railing or tank shell before reaching the top. This prevents static electrical discharge in a hazardous area.

4. Stand to the side of the hatch when opening to permit wind to blow gas away from face.

5. Measure temperature. Suspend thermometer in oil tank. Thermometer should be 12 in. or more from tank shell and must be immersed in oil for 5 minutes.

Use an ASTM-approved, wood-back or corrosion-resistant metal cup case. If atmospheric temperature differs by more than 20°F from that of the liquid in the tank, the cup case should be given at least two preliminary immersions. Empty the cup case after each immersion.

Rapidly withdraw the thermometer and read and record the temperature to the nearest 1°F.

Note: The number of temperature measurements varies with the depth of the liquid.¹

*The original chapter on this topic in the 1962 edition was taken from API Standard 2500.

In a tank containing more than 15 ft of liquid, three measurements should be taken: (1) 3 ft below the top surface of the liquid; (2) middle of the liquid; and (3) 3 ft above bottom of the liquid.

In a tank containing 10 to 15 ft of liquid, two measurements should be taken: (1) 3 ft below the top surface of liquid; and (2) 3 ft above the bottom surface of liquid.

In a tank containing less than 10 ft of liquid, one measurement should be taken in the middle of the liquid.

For tanks over 10 ft high with a capacity of less than 5,000 bbl, one measurement in the middle of the liquid should be taken.

6. With a thief, take sample(s) for basic sediment and water (BS&W) centrifuge test.

Note: The number of samples to be taken for BS&W determination varies.²

In tanks larger than 1,000-bbl capacity that contain more than 15 ft of liquid, equal-volume samples should be taken (1) 6 in. below the top of the liquid, (2) at the middle of the liquid, and (3) at the outlet connection of the merchantable oil, in the order named. This method also may be used in tanks up to and including a capacity of 1,000 bbl.

In a tank larger than 1,000-bbl capacity that contains more than 10 ft and up to 15 ft of liquid, equal-volume samples should be taken (1) 6 in. below the top surface of the liquid and (2) at the outlet connection of the merchantable oil, in the order named. This method may be used on tanks up to and including a capacity of 1,000 bbl.

In a tank larger than 1,000-bbl capacity that contains 10 ft or less liquid, one sample may be taken in the middle of the column of liquid.

7. Place BS&W composite sample in sample container. Sample should be a blend of the upper, middle, and lower (if three samples were required) containing equal parts from the samples taken.

8. Seal sample container. In the lower 48 states, with the exception of California, the sample is ready to be tested for BS&W as described below in Step 17. In California, the container should be labeled and delivered to the laboratory for BS&W determination.

9. With a thief, take sample for gravity determination.³ The sample should be taken midway between oil surface and pipeline connection. Hang the thief in the hatch. Remove bubbles. Place hydrometer in oil sample.

10. Determine and record sample temperature to nearest 0.5°F. Hydrometer must float away from wall of cylinder; temperature of surrounding media should not change more than 5°F.

Depress hydrometer two scale divisions and release.

Read hydrometer to nearest 0.05°API on scale at which surface of liquid cuts scale.

11. Read and record sample temperature to nearest 0.5°F. Repeat gravity reading if temperature of sample before and after reading of gravity has changed more than 1°F. Apply any relevant correction to observed hydrometer reading (correction scale on bulb) to nearest 0.1°API. Record the mean temperature reading observed before and after final hydrometer reading to nearest 1°F.

Note: Hydrometer scale readings at temperatures other than calibration temperatures (60°F) should not be considered more than scale readings since the hydrometer bulb changes with temperature.

12. Convert relevant corrected value to standard temperatures. Use Table 5A* for crude oils.

13. Take bottom thief sample for BS&W height. Lower the clean, dry thief slowly into the oil to the desired depth, trip thief and raise slowly to avoid agitation. When sample is taken, the top of the thief must be two inches above the bottom of the pipeline connections.

14. Determine and record BS&W height in the tank. Pour remaining thief sample over a test glass until contamination appears. Measure and record (as the BS&W height) the distance from the bottom of the thief to the top of the contamination in the thief. If BS&W height is less than 4 in. from the bottom of the pipeline connection, do not run the tank.

15. Gauge the tank.⁴ Do not gauge a boiling or foaming tank. Use steel innage tape with innage plumb bob. Always make contact between gauge line and hatch while running tape into tank.

Gauge the tank only at the reference point on the gauging hatch. On tanks of 1,000-bbl capacity or less, read to the nearest ¼ in. On tanks of 1,000 bbl or more, read to the nearest ⅛ in.

Record the reading immediately. Repeat the above until two identical gauges are obtained.

16. Saturate solvent with water.⁵ Toluene is approved solvent. It is flammable and toxic. Care should be taken when using toluene.

Fill a 1-qt or 1-L glass bottle with a screw top with 700 to 800 mL toluene. Add 25 mL of either distilled or tap water. Screw cap on. Shake vigorously for 30 seconds. Loosen cap.

Place bottle in bath for 30 minutes. Maintain bath at a constant temperature of 140°F ± 5°F.

Remove, tighten cap and shake vigorously for 30 seconds. Repeat three times.

Allow bottle of water/toluene mixture to sit in bath for 48 hr before using. Be sure no free water is left in bottle.

17. Shake sample container until sample is well mixed.

Fill each of two 203-mm [8-in.] cone-shaped centrifuge tubes with 50 mL of sample.

Use pipette to add 50 mL of toluene. Toluene should be water saturated at 140°F. Read top of meniscus at both the 50 and 100 mL marks.

Add 0.2 mL demulsifier if necessary for clean break in oil/water contact.

Stopper the tube tightly. Invert tube 10 times to ensure that oil and solvent are uniformly mixed.

18. Loosen stopper slightly. Immerse tube to the 100 mL mark in bath for 15 minutes. Bath must maintain 140°F ± 5°F; by contract agreement the bath temperature may be 120°F ± 5°F.

Remove tube from bath and tighten stopper. Invert tube 10 times to ensure that oil and solvent are uniformly mixed.

19. Place tubes in trunnion cups on opposite sides of centrifuge. Spin for 10 minutes while maintaining minimum relative centrifuge force of 600.

Following spinning, read and record the combined volume of water and sediment at the bottom of each tube. Read to the nearest 0.05 mL for oil from 0.1 to 1

* See API Manual, Chap. 11.1, Vol. 1 (1980) listed on Page 17-5.

mL graduation. Read to nearest 0.1 mL above 1 mL graduation. Estimate to nearest 0.025 mL below 0.1-mL graduation.

Return tube to centrifuge without agitation. Spin for 10 minutes at same rate. Repeat this operation until the combined volume of water and sediment remains constant on two consecutive readings.

20. Record final volume of water and sediment in each tube. The sum of the two admissible readings is the percentage by volume of water and sediment in the sample.

After the tank has been run, the following closing data should be obtained.

21. Closing oil temperature: no closing temperature is necessary on tanks of 5,000 bbl or less; on tanks 5,000 bbl or more, always read to the nearest 1°F.

22. Obtain closing gauge reading at the same point and in the same manner as the opening gauge reading.

23. Obtain bottom thief. If BS&W level is lower than the opening gauge, report to supervisor.

Abstract of API Manual

Publications and Distribution Section, American Petroleum Inst., 2101 L St. NW, Washington, DC 20037.

Since the *API Manual of Petroleum Measurement Standards* is the industry's standard on this subject and since the manual is quite long, this chapter is a reference to the API manual.

The following table of contents of the API manual lists the chapter titles, the API stock number, and a short abstract of the content of each chapter. These chapters can be ordered from the API.

API Chap. 1—Vocabulary

First edition (April 1977).

The words and terms used throughout the entire *Manual of Petroleum Measurement Standards* are defined and described in this vocabulary.

API Chap. 2—Tank Calibration

Measurement and Calibration of Upright Cylindrical Tanks. *API Publication 852-25500, API Standard 2550, first edition (Oct. 1965).* This standard describes the procedures for calibrating upright cylindrical tanks larger than a barrel or drum. It is presented in two parts. Part I (Secs. 8 through 41) outlines procedures for making necessary measurements to determine total and incremental tank volumes; Part II (Secs. 42 through 58) presents the recommended procedure for computing volumes.

Measurement and Calibration of Horizontal Tanks. *API Publication 852-25510, API Standard 2551, first edition (Oct. 1965).* This standard describes external measurement procedures for calibrating horizontal aboveground stationary tanks larger than a barrel or drum. It is presented in two parts.

Part I (Secs. 7 through 21) includes procedures for the measurement of horizontal, and tilted, cylindrical aboveground tanks with various types of heads; descriptions of tank-measuring equipment and procedures for the calibration of that equipment for which calibration is required; and suggestions for the orderly and complete recording of field measurement data, including tank measurement record forms.

Part II (Secs. 22 through 44) includes procedures for calculating the incremental tank capacities from the field data, suitable for the preparation of incremental capacity gauge tables. Typical examples of calculations are included in Appendix I, as are convenient tables of shape factors for determining contained liquid volume in horizontal cylinders and in formed heads at any liquid depth.

Measurement and Calibration of Spheres and Spheroids. *API Publication 852-25520, API Standard 2552, first edition (Oct. 1965).* This standard describes the procedures for calibrating spheres and spheroids that are used as liquid containers. It is presented in two parts. Part I (Secs. 2 through 10) outlines the procedures for the measurement and calibration of spherical tanks; Part II (Secs. 11 through 20) outlines the procedures for the measurement and calibration of spheroidal tanks.

Measurement and Calibration of Barges. *API Publication 852-25530, API Standard 2553, first edition (Oct. 1966).* This standard describes procedures for calibrating barge tanks. It is presented in two parts.

Part I (Secs. 7 through 9) includes procedures for determining the required field measurement data, description of tank measurement equipment, and suggestions for the orderly and complete recording of field data.

Part II (Secs. 10 through 13) includes procedures for calculating the total and incremental tank capacities from the field data, suitable for preparation of the capacity gauge table. Typical examples of calculations are included in Appendix II.

Measurement and Calibration of Tank Cars. *API Publication 852-25540, API Standard 2554, first edition (Oct. 1965).* This standard describes the procedures for calibrating tank cars. It is presented in two parts: Part I (Secs. 2 through 21) outlines procedures for nonpressure-type tank cars; Part II (Secs. 22 through 31) outlines procedures for pressure type tank cars.

Method for Liquid Calibration of Tanks. *API Publication 852-25550, API Standard 2555 (Sept. 1966).* This standard describes the procedure for calibrating tanks, or portions of tanks, larger than a barrel or drum by introducing or withdrawing measured quantities of liquid.

Correcting Gauge Tables for Incrustation. *API Publication 852-25560, API RP 2556, first edition (Aug. 1968); supersedes supplement No. 1 to API Standard 2500.* This recommended practice defines incrustation, describes the materials involved and recommends methods to correct the observed volume gauged.

API Chap. 3—Tank Gauging

Method of Gauging Petroleum and Petroleum Products. *API Publication 852-25450, API Standard 2545 (Oct. 1965).* This standard describes the procedures for gauging crude petroleum and its liquid products in various types of tanks, containers, and carriers. Secs. 3 through 58 are applicable for measuring quantities of liquids having Reid vapor pressure (Rvp) under 40 psig;

Secs. 59 through 64 are applicable for measuring liquefied petroleum gases and other products having Rvp of 40 psig or more. The determination of temperature, API gravity, and sediment and water are not within the scope of this standard; however, brief descriptions of portable equipment used for this purpose are included in Secs. 8 and 9.

API Chap. 4—Proving Systems *API Publication 852-2315, first edition (May 1978).*

This publication serves as a guide for the design, installation, calibration and operation of meter proving systems. All types of proving systems commonly used by the petroleum industry are covered, including field standards, pipe provers, tank provers, master meter provers, meter proving, and analysis of sphere position repeatability.

Proving systems covered in former API Standards 1101, 2531, 2533, and 2534 (*Measurement of Petroleum Liquid Hydrocarbons by Positive Displacement Meter; Mechanical Displacement Meter Provers; Metering Viscous Hydrocarbons; and Measurement of Liquid Hydrocarbons by Turbine Meter Systems*) are combined in this publication, which supersedes the former standards.

This publication is intended primarily for use in the U.S. and, therefore, is related to the standards, specifications, and procedures of the (U.S.) Natl. Bureau of Standards (NBS). When it is desired to use the publication in other countries, the appropriate national standards organizations and their specifications and procedures apply.

API Chap. 5—Metering

Sec. 1—Foreword, General Considerations, and Scope of Chap. 5—Metering. *API Publication 852-30101, first edition (Nov. 1976).* This is an overall introduction to Chap. 5, Metering.

Sec. 2—Measurement of Liquid Hydrocarbons by Displacement Meter Systems. *API Publication 852-30102, first edition (Jan. 1977).* This section specifies the characteristics of displacement meters and gives rules for systematically applying appropriate consideration to the nature of the liquids to be measured, to the installation of a metering system, and to the selection, performance, operation, and maintenance of the same. It does not apply to two-phase fluids. Special precautions should be taken when used in mass measurement systems.

Sec. 3—Turbine Meters. *API Publication 852-30103, first edition (July 1976).* This section specifies the characteristics of turbine meters and gives rules for applying appropriate considerations to the nature of the liquids to be measured, to the installation of a metering system using a turbine meter, and to the performance, operation, and maintenance of the same in liquid hydrocarbon service.

Sec. 4—Instrumentation or Accessory Equipment for Liquid Hydrocarbon Metering Systems. *API Publication 852-30104, first edition (July 1976).* This publication serves as a guide for the instrumentation of liquid

hydrocarbon meters to obtain optimal accuracy and service life of metering systems. Selection of any piece of accessory equipment described herein depends on the function, design, purpose, and manner in which a measurement installation is to be used.

The application of this publication is limited to instrumentation by accessory equipment made essentially to enhance the usage of liquid hydrocarbon meters. Thus, all valves, manifolding, vents, etc. are not included. Thermometers, hydrometers, and pressure gauges are discussed but only so far as certain minimum requirements must be met.

Sec. 5—Fidelity and Security of Flow Measurement Pulsed-Data Transmission Systems. *API Publication 852-30105, first edition (June 1982).* This chapter provides a guide to the selection, operation, and maintenance of pulsed-data, cabled transmission systems for fluid metering systems to provide the desired level of fidelity and security of transmitted data.

API Chap. 6—Metering Assemblies

Sec. 1—LACT Systems. *API Publication 852-30121, first edition (Feb. 1981).* This chapter serves as a guide for the design, installation, calibration, and operation of lease automatic custody transfer (LACT) systems.

Sec. 5—Metering Systems for Loading and Unloading Marine Bulk Carriers. *API Publication 852-30125, first edition (July 1980).* This section deals with the operation and special arrangements of meters, provers, manifolding, instrumentation, and accessory equipment used for measurement in loading and unloading marine bulk carriers.

The information provided in this section is applicable to shore-to-carrier and carrier-to-shore measurement of crude oils and refined products. These procedures are not intended to apply to hydrocarbons and other materials such as liquefied petroleum gas (LPG) or liquefied natural gas (LNG), which require specialized measurement and handling equipment.

Sec. 6—Pipeline Metering Systems. *API Publication 852-30126, first edition (Aug. 1981).* This section provides guidelines for the selection of the type and size of meter(s) to be used to measure pipeline oil movements. Types of accessories and instruments that may be desirable are specified, and the relative advantages and disadvantages of three methods of proving meters (by tank prover, by pipe prover, and by master meter) are discussed. This section also includes discussions on obtaining the best operating results from a pipeline meter station.

Sec. 7—Metering Viscous Hydrocarbons. *API Publication 852-30127, first edition (Jan. 1981).* This section serves as a guide for the design, installation, operation, and proving of meters and their auxiliary equipment used to meter viscous hydrocarbons.

Measurement of Petroleum Liquid Hydrocarbons by Positive Displacement Meter. *API Publication 852-11010, API Standard 1101, first edition (Aug. 1960).* This section covers the installation of positive

displacement meters, their auxiliary proving equipment, and other accessories. All types of meter installations must meet certain fundamental requirements. These include accurate proving facilities; adequate protective devices, such as strainers, relief valves, and air or vapor eliminators; and dependable pressure and flow controls. A further fundamental installation requirement is that physical conditions during operations and proving should be identical.

API Chap. 7—Temperature Determination

This chapter is in preparation. It will cover the sampling, reading, averaging, and rounding of the temperature of liquid hydrocarbons in both the static and dynamic modes of measurement for volumetric purposes.

The following API standard now covers the subject of temperature determination.

Method of Measuring the Temperature of Petroleum and Petroleum Products. *API Publication 852-25430, API Standard 2543 (Oct. 1965).* This standard describes the thermometer assemblies and temperature levels used in various tanks and carriers of petroleum.

API Chap. 8—Sampling

Sec. 1—Manual Sampling of Petroleum and Petroleum Products. *API Publication 852-30161 (ASTM D 4057), first edition (Oct. 1981).* This section covers the procedures for obtaining representative samples of stocks or shipments of uniform petroleum products, except electrical insulating oils and fluid power hydraulic fluids. Sampling crude petroleum and nonuniform petroleum stocks and shipments also are covered, although the representative nature of these sampling methods is in doubt.

API Chap. 9—Density Determination

Sec. 1—Hydrometer Test Method for Density, Relative Density (Specific Gravity), or API Gravity of Crude Petroleum and Liquid Petroleum Products.

API Publication 852-30181 (ASTM D 1298), first edition (June 1981). This section describes the methods and practices relating to the determination of the density, relative density, or API gravity of crude petroleum and liquid petroleum products by using the hydrometer method (laboratory determination).

Sec. 2—Pressure Hydrometer Test Method for Density or Relative Density. *API Publication 852-30182, first edition (April 1982).* This section provides a guide for determining the density, relative density (specific gravity), or API gravity of light hydrocarbons, including liquefied petroleum products, using a pressure hydrometer.

API Chap. 10—Sediment and Water

Sec. 1—Determination of Sediment in Crude Oils and Fuel Oils by the Extraction Method. *API Publication 852-30201, first edition (April 1981).* This section specifies a method for the determination of sediment in crude oils and fuel oils by extraction with toluene.

Sec. 2—Determination of Water in Crude Oil by the Distillation Method. *API Publication 852-30202, first*

edition (April 1981). This publication specifies a method for the determination of water in crude oil.

Sec. 3—Determination of Water and Sediment in Crude Oil by the Centrifuge Method (Laboratory Procedure). *API Publication 852-30203, first edition (April 1981).* This method describes the laboratory determination of water and sediment in crude oil by means of the centrifuge procedure. This centrifuge method is not entirely satisfactory. The amount of water detected is almost always lower than the actual water content. When a highly accurate value is required, the revised procedures for water by distillation (API Chap. 10.2) and sediment by extraction (API Chap. 10.1) must be used.

API Chap. 11—Physical Properties Data

Chap. 11 includes the physical data that have direct application to volumetric measurement of liquid hydrocarbons. It is presented in table form, in equations relating volume to temperature and pressure, computer subroutines, magnetic tape, and microfilm.

Chap. 11.1, "Volume Correction Factors, 1980," (ASTM D 1250) (IP 200) is available on magnetic tape and includes a paper edition of Vol. X. [*API Publication 852-27150, first edition (Aug. 1980).*] The tape is nine-track, 1,600 bites/in., EBCDIC, unlabeled, fixed block and requires a 32-bit or higher machine. Chap. 11.1 is also available as a FORTRAN card deck (includes paper edition of Vol. X) [*API Publication 852-27151, first edition (Aug. 1980).*] and on microfiche (includes paper edition of Vol. X) [*API Publication 852-27152, first edition (Aug. 1980).*]

The following is a list of tables and computer subroutines to found in Chap. 11.1 through 11.3.

Chap. 11.1, Vol. I, 1980. *ASTM publication (ASTM D 1250).* (*ASTM publications can be ordered from ASTM, 1916 Race St., Philadelphia, PA 19103.*) Table 5A—Generalized Crude Oils, Correction of Observed API Gravity to API Gravity at 60°F.

Table 6A—Generalized Crude Oils, Correction of Volume to 60°F Against API Gravity at 60°F.

Chap. 11.1, Vol. II, 1980. *API Publication 852-27015, first edition (Aug. 1980).* Table 5B—Generalized Products, Correction of Observed API Gravity to API Gravity at 60°F.

Table 6B—Generalized Products, Correction of Volume to 60°F Against API Gravity at 60°F.

Chap. 11.1, Vol. III, 1980. *ASTM publication (ASTM D 1250).* Table 6C—Volume Correction Factors for Individual and Special Applications, Volume Correction to 60°F Against Thermal Expansion Coefficients at 60°F.

Chap. 11.1, Volume IV, 1980. *API Publication 852-27045, first edition (Aug. 1980).* Table 23A—Generalized Crude Oils, Correction of Observed Relative Density to Relative Density at 60/60°F.

Table 24A—Generalized Crude Oils, Correction of Volume to 60°F Against Relative Density 60/60°F.

Chap. 11.1, Vol. V, 1980. *API Publication 852-27060, first edition (Aug. 1980).* Table 23B—Generalized Pro-

ducts, Correction of Observed Relative Density to Relative Density at 60/60°F.

Table 24B—Generalized Products, Correction of Volume to 60°F Against Relative Density 60/60°F.

Chap. 11.1, Vol. VI, 1980. *API Publication 852-27085, first edition (Aug. 1980).* Table 24C—Volume Correction Factors for Individual and Special Applications, Volume Correction to 60°F Against Thermal Expansion Coefficients at 60°F.

Chap. 11.1, Vol. VII, 1980. *API Publication 852-27100, first edition (Aug. 1980).* Table 53A—Generalized Crude Oils, Correction of Observed Density to Density at 15°C.

Table 54A—Generalized Crude Oils, Correction of Volume to 15°C Against Density of 15°C.

Chap. 11.1, Vol. VIII, 1980. *API Publication 852-27115, first edition (Aug. 1980).* Table 53B—Generalized Products, Correction of Observed Density to Density at 15°C.

Table 54B—Generalized Products, Correction of Volume to 15°C Against Density at 15°C.

Chap. 11.1, Vol. IX, 1980. *API Publication 852-27130, first edition (Aug. 1980).* Table 54C—Volume Correction Factors for Individual and Special Applications, Volume Corrections to 15°C Against Thermal Expansion Coefficients at 15°C.

Chap. 11.1, Vol. X, 1980. *API Publication 852-27145, first edition (Aug. 1980).* This volume gives the background, development, and computer documentation for all tables listed in Chap. 11.1 Vol. I through Vol. IX.

Chap. 11.1, Vol. XI, 1982, "Petroleum Measurement Subsidiary." *ASTM Publication (ASTM D 1250).*

Table 6D—Generalized Lubricating Oils, Correction of Volume to 60°F Against API Gravity at 60°F.

Chap. 11.1, Vol. XIV, 1982. *API Publication 852-27200, first edition (Jan. 1982).* Table 53D—Generalized Lubricating Oils, Correction of Observed Density to Density at 15°C.

Table 54D—Generalized Lubricating Oils, Correction of Volume to 15°C Against Density at 15°C.

Chap. 11.1.77, Extrapolation of Table 6A to -50°F, Volume Reduction Factors, 1976. *API Publication 852-25393.* This chapter is a computer printout of Subroutine Table 6 in extrapolated form.

Standard Tables for Positive Displacement Meter Prover Tanks, 1966. *API Publication 852-25410, API Standard.* These tables provide multipliers for converting to 60°F the volumes of petroleum and petroleum products measured at temperatures between 0 and 125°F in insulated, mild steel prover tanks for positive displacement meters.

Chap. 11.3.2.1, Ethylene Density. *API Publication 852-25650, first edition (1974).* This chapter is a computer subroutine and includes subordinate subroutines "rubin" and "taint" on one FORTRAN IV card deck. It

will produce either a density (lbm/cu ft) or a compressibility factor for vapor-phase ethylene over the temperature range of 65 to 167°F and the pressure range of 200 to 2,100 psia.

Chap. 11.3.3.1, Propane Compressibility Table. *API Publication 852-25654, first edition (1974).* This FORTRAN IV subroutine is applicable to liquid-phase propane in the following ranges: relative density, 0.500 to 0.510; temperature, -20 to 120°F; saturation pressure to 1,500 psia. The subroutine computes the following two values: average compressibility per psi (this factor would be applied in the same manner as compressibilities in the current API Standard 1101) and the ratio of volume at flowing temperature and pressure to volume at flowing temperature and saturation pressure.

Chap. 11.3.3.2, Propylene Compressibility Table. *API Publication 852-25656, first edition (1974).* This FORTRAN IV subroutine is applicable to liquid-phase propylene in the following ranges: temperature, 30 to 165°F; and saturation pressure to 1,600 psia. The subroutine computes the following two values: density in lbm/cu ft at flowing temperature and pressure, and the ratio of density at flowing conditions to density at 60°F and saturation pressure.

API Chap. 12—Calculation of Petroleum Quantities

Sec. 2—Calculation of Liquid Petroleum Quantities Measured by Turbine or Displacement Meters. *API Publication 852-30302, first edition (Sept. 1981).* This publication defines the various terms (words or symbols) employed in the calculation of metered petroleum quantities. Where two or more terms customarily are employed in the oil industry for the same thing, this publication selects what should become the new standard term—for example, “run tickets,” “receipt and delivery tickets,” and the like are herein simply “measurement tickets.”

The publication also specifies the equations that allow the values of correction factors to be computed. Rules for sequence, rounding, and significant figures to be employed in a calculation are given. In addition, some tables, convenient for manual as well as computer calculations, are provided.

Field Manual, Sec. 2—Instructions for Calculating Liquid Petroleum Quantities Measured by Turbine or Displacement Meters. *API Publication 852-30303, first edition (Sept. 1981).* This document is the user's field manual. It is addressed to those who need instructions without explanations as to why a particular course of action is necessary to achieve the same answer from the same data, regardless of who or what does the computing.

The user's field manual is an instruction document. Those who wish or need to know more about the background to a set of instructions should obtain Chap. 12, Sec. 2, which is an instruction and explanation document.

API Interim Chap. 13—Measurement Control

Charts and Statistical Methods for Petroleum Metering Systems. *API Publication 852-25342, API Standard*

2534, Appendix B, first edition (March 1970). The more accurate petroleum measurement becomes, the more its practitioners stand in need of statistical methods to express residual uncertainties. This chapter covers the application of statistical methods to petroleum measurement and sampling. Chap. 13 is in preparation.

API Chap. 14—Natural Gas Fluids Measurement

Sec. 1—Measuring, Sampling, Testing, and Base Conditions for Natural Gas Fluids. *API Publication 852-30341, third edition (March 1975).* This chapter presents recommended practices that cover the production, transportation, and custody transfer of natural gas and the products recovered excluding LNG.

Sec. 3—Orifice Metering of Natural Gas. *API Publication 852-30343, first edition (Sept. 1981).* This standard provides guidance on the measurement of natural gas flow. It provides the standards for construction and installation of orifice plates and associated fittings and instructions for computing the flow of natural gas through orifice meters. Also included are the necessary tables providing the basic factors to apply to adjust for expansion, Reynolds number, temperature, pressure, specific gravity, and supercompressibility.

Sec. 5—Calculation of Gross Heating Value, Specific Gravity, and Compressibility of Natural Gas Mixtures From Compositional Analysis. *API Publication 852-30345, first edition (Jan. 1981).* This publication outlines a procedure for calculating from compositional analysis the following properties of natural gas mixtures: heating value, specific gravity, and compressibility factor.

Sec. 6—Installing and Proving Density Meters Used To Measure Hydrocarbon Liquid with Densities Between 0.3 and 0.7 g/cm³ at 15.56°C [60°F] and Saturation Vapor Pressure. *API Publication 852-30346, first edition (Sept. 1979).* This publication provides a method for installation and accurately proving density meters that measure light hydrocarbons used in static or dynamic conditions.

API Chap. 15—Guidelines for the Use of the Intl. System of Units (SI) in the Petroleum and Allied Industries. *API Publication 852-25640, second edition (Dec. 1980).*

This publication specifies the API preferred units for quantities involved in petroleum industry measurements and indicates factors for conversion of quantities expressed in customary units to the API-preferred metric units. The quantities that comprise the tables are grouped into convenient categories related to their use. They were chosen to meet the needs of the many and varied aspects of the petroleum industry but also should be useful in other, similar process industries. Chap. 58 of this edition of *Petroleum Engineering Handbook* is the *SPE Metric Standard*.

API Chap. 16—Measurement of Petroleum by Weight (in preparation)

The purpose of this chapter is to provide references to model regulations promulgated by the National Con-

ference of Weights and Measures regarding commercial weighing, tolerances, and other technical requirements, and to describe the recognized practices of the petroleum industry when products are handled on a weight basis.

API Chap. 17—Marine Measurement

This chapter provides guidelines that suggest the actions to be taken in measuring and reporting quantities of crude oil or petroleum product marine transfers by shore terminal operators, vessel personnel, and other parties involved in cargo transfer measurement and accountability operations.

Sec. 1—Guidelines for Marine Cargo Inspection. *API Publication 852-30401, first edition (April 1982).* This chapter provides guidelines to encourage uniform marine cargo inspection practices and to simplify the making of contracts that can be interpreted clearly and executed between parties.

Edward R. Sauve, Chevron Corp.

Introduction

Offshore petroleum operations emerged in the 20th century and brought new dimensions of challenge and excitement to oil exploration and production. When a structure taller than a 100-story building is launched from a barge, or when a small city is built and placed offshore in 2 years, those involved deserve their feelings of pride and accomplishment.

In nearly every corner of the globe, thousands of offshore installations with payloads from 5 to 50,000 tons are producing gas and oil today in water depths from 10 to 1,000 ft. Although subjected to winds and waves up to hurricane intensity, earthquakes, sheet ice, severe tides and currents, or shifting foundations, surprisingly few structures have succumbed to the environment despite the difficulty in predicting environmental forces, equipment failure, or reservoir behavior.

This chapter can only scratch the surface of offshore operations; detailed procedures for design and construction of structures, equipment, and facilities would require volumes. Furthermore, such volumes would be obsolete before they were published. Because there is no concise reference or set of references, this chapter describes the fundamentals of standard practice in several disciplines and offers guidance for the selection of appropriate offshore codes of practice and technical references.

Historical Review

In 1859, Col. Edwin Drake drilled and completed the first known oil well near a small town in Pennsylvania. This well, which was drilled with cable tools, started the modern petroleum industry. Drilling methods and tools remained in their infancy for more than 40 years, until hydraulic rotary drilling techniques were first used to drill

the Spindletop well in 1901. By then, the petroleum industry was already moving offshore.

In 1897, near Summerland, CA, H.L. Williams extended an onshore oil field into the Santa Barbara Channel by drilling a submarine well from a pier. This first offshore well was drilled just 38 years after Col. Drake's well. Five years later, more than 150 offshore wells were producing oil. Production from the California piers continues even today.

From this start, offshore drilling actually turned inland with activity in the Great Lakes, Caddo Lake in Louisiana, and Lake Maracaibo in Venezuela. Initially, wells were drilled from shore-connected piers and later from wooden single-well platforms. During this period of inland offshore drilling, platform technology remained basic. The one step forward was the change from wooden platforms to concrete structures in Lake Maracaibo.

In the late 1920's, steel production piers that extended a quarter of a mile into the ocean at Rincon and Elwood, CA, were built and new high-producing wells stimulated exploration activity. In 1932, a small company called Indian Petroleum Corp. determined that there was a likely prospect about ½ mile from shore. Instead of building a monumentally long pier, they decided to build a portion of a pier with steel piles and crossmembers. Adding a deck and barging in a derrick completed the installation. By Sept. 1932, the 60×90-ft "steel island" was completed in 38 ft of water with a 25-ft air gap. This first open-seas offshore platform supported a standard 122-ft steel derrick and associated rotary drilling equipment. Successful drilling with largely unsuccessful results was carried on intermittently on the "steel island" until 1939, when the third well was completed on the pump at 40 B/D.

In Jan. 1940, a Pacific storm destroyed the steel island. During the subsequent cleanup, divers were used for the first time to remove well casing and to set abandonment plugs.¹

*Deceased

Meanwhile, the first offshore field was discovered in the Gulf of Mexico in 1938. A well was drilled to 9,000 ft off the coast of Texas in 1941. With the start of World War II, however, offshore activities came to a halt. Activity did not resume until 1945 when the State of Louisiana held its first offshore lease sale.

At the end of the war, surplus Navy ships and barges became available to the oil industry. At first, Navy landing craft (LST's) were converted into tenders to support drilling operations on offshore platforms. By installing mud systems and electrical generation equipment, and by storing consumables on the tender, engineers reduced drilling platform payloads by a factor of 10.

The development of tender-supported platform rigs pointed the way toward mobile exploratory rigs that could move on and off location, thereby eliminating the cost of fixed drilling platforms. During the late 1940's and early 1950's, a number of mobile rigs were developed in rapid succession.

First was the posted barge, which consisted of a submersible barge with the drilling rig mounted on steel columns. The barge was sunk on location with the drilling rig clear of the water. Next came the submersible, with large vertical columns that provided enough buoyancy to transport the drilling rig while floating. These rigs were sunk on location with the drilling rig and deck remaining above water. Finally came the jackup rig. This rig consisted of a barge hull fitted with vertical legs that could be jacked down until they contacted the ocean floor, thus raising the barge, which supported the drilling rig, clear of the water. While the bottom-supported drilling rigs were being developed for the shallow waters of the Gulf of Mexico, floating drilling vessels and techniques were being developed for offshore California. There, water depths in excess of 500 ft were found inside the 3-mile limit.

Civil and structural engineers were largely responsible for the development of submersible and jackup rigs, but naval architects and marine engineers were called on to convert military ships for the drilling industry. Mechanical engineers from the oil fields designed the specialized subsea and shipboard drilling equipment.

The first floating drilling vessels were converted mine sweepers with A-frames over the side for handling pipe and jet bits. The pipe was jetted into the ocean floor, and core barrels were dropped through the pipe to get cores from the bottom of the hole. Next, Navy patrol boats were converted into drillships with "over-the-side" masts and rotary tables. The first rotary floating drilling vessel went into service in 1953 and was capable of drilling in 400 ft of water to depths of 3,000 ft.

The adverse motion characteristics of these ship-shaped vessels, combined with the "over the side" rotary table, encouraged offshore drillers and engineers to find ways to reduce vessel motions. In 1955, innovative drilling engineers moved the drilling rig from over the side to the center of the ship to reduce the effects of vessel motion. A center well, or moon pool, was installed vertically through the hull, and the drilling rig was mounted over it. This breakthrough led the way to modern-day drilling vessels. Technological advances in subsea systems, vessel station-keeping systems, moored and dynamic positioning, motion compensators, control systems, and navigation systems have all contributed to the success of

drillships during the past 30 years. They will be discussed in more detail later in this chapter.

While ship-shaped vessels were being developed for California waters, a different approach to improving vessel stability was taken in Gulf of Mexico waters. The semi-submersible, or column-stabilized drilling vessel, was developed by addition of buoyant hulls to a submersible so that it could drill while floating instead of sitting on the seafloor. These rigs exhibited superior motion characteristics and now are used extensively in such rough-water areas as the North Sea and off the east coast of Canada.

While mobile drilling rigs were being developed into today's sophisticated drilling systems, platform technology was keeping pace. In 1947, the first platform "out of sight of land" was built off the coast of Louisiana in 20 ft of water. From then until the 1970's, the gulf coast dominated offshore petroleum activity with the installation of more than 5,000 offshore drilling or drilling/producing structures. During the 1970's, the North Sea captured most of the offshore attention with the advent of huge payload requirements, and concrete gravity structures competed with the steel "template." Eighteen concrete structures have been installed in water depths from 240 to 540 ft with payloads up to 40,000 tons.

Meanwhile, steel-structure technology competed successfully for smaller payloads in the North Sea and regained favor as deeper U.S. waters were explored. In 1976, "Hondo," a pile-supported two-piece jacket, was installed in 850 ft of water off the coast of California. In 1978, "Cognac" was installed in three pieces in 1,025 ft of water in the Gulf of Mexico. Single-piece structures became viable for deeper water as launch barges and transportation technology developed. "Garden Banks" was installed in one piece in 680 ft of water in the Gulf of Mexico in 1976. "Cerveza," in 935 ft, and "Liguera," in 915 ft, were installed in the gulf in 1981 and 1982. Designs for steel jackets for up to 1,200 ft of water are in the final design stages for placement in the Santa Barbara Channel and the Gulf of Mexico.

Many other specialty structures have been installed. In 1966, a steel gravity-oil-storage structure was placed in service in the Gulf of Mexico. Three 500,000-bbl steel storage domes that resemble inverted champagne glasses were installed in the Arabian Gulf in 1969, 1971, and 1972. Buoyant articulated columns were installed in the North Sea in the 1970's to serve as tanker mooring devices for loading out crude oil. Tankers and drilling vessels have been moored by various means to support gas/water/oil separation facilities and to provide temporary oil storage. Breast mooring and single-point mooring systems have been installed in water depths exceeding 100 ft to accommodate a supertanker's draft. A steel gravity structure with storage capacity of 1 million bbl of oil and a deck payload of 30,000 tons has been installed in the North Sea as an alternative to the concrete structures. A guyed tower was installed in 1,000 ft of water in the Gulf of Mexico in 1983. A tension-leg platform, the commonly favored concept for water depths of more than 1,200 ft, was installed in 485 ft of water in the North Sea in 1984. Each of these special-purpose structures represents an advance in ocean engineering technology and forward-thinking business management to support untried ideas.

Progress is not always the result of new ideas or concepts but often a step-by-step improvement in existing technology. For example, the skirt pile that is currently part of most steel deepwater structures was first implemented in 1955, but the idea had been patented in the 19th century. The North Sea gravity structure had a precedent in a gravity platform constructed offshore in California more than 30 years ago. The guyed tower was patented before the turn of the century. The tension-leg platform was invented during World War II as a seadrome or floating airport. Current improvements in computerized design, transportation, and installation equipment, coupled with an ever-increasing need for new oil supplies, is the driving force for technological advance.

During the evolution of offshore platforms, the new ocean engineering discipline also evolved. Ocean engineers are versed in structural engineering, soil mechanics, the hydrodynamic effects of waves and currents, structural dynamics, statistical analysis methods, and reliability analysis techniques.

The equipment, methods, and techniques for completing, producing, and maintaining wells on the ocean floor have also undergone tremendous advancements since the first subsea wells were completed in the late 1950's. Early subsea Christmas trees were made up of the same conventional valves and flanges as trees for land wells. The one concession to underwater operations was fail-safe hydraulic actuators on remote-control valves. These early trees were usually diver-installed and connected by Bowlines to shore. One company developed a swimming hydraulic wrench that was fitted with television cameras and maneuvering thrusters. This system, integrated into the wellhead system, was successful to a degree. It was the first attempt to eliminate divers from subsea operations. Over the past 25 years, there has been a continuous effort to reduce dependency on divers, but divers are still a very important part of the offshore oil industry.

Complex multiwell systems have been installed on the ocean floor. Single-well completions have been made in 1,300 ft of water. Control systems that involve hydraulic, electronic multiplex, and acoustic signal transmission systems are now common. Unmanned, remotely operated vehicles now are being developed that will become an integral part of the subsea completion system. Much has been accomplished in the past 25 years, but with exploratory drilling being done in 6,500 ft of water, even more remains to be done in this area of subsea completions.

The search for offshore oil and gas reserves has directed the petroleum industry to the ice-covered waters of the Arctic. In 1963, the first commercial oil field was discovered in the upper Cook Inlet of Alaska. For the first time, ice driven by extreme tidal currents produced loads on the production facilities *far* in excess of other environmental forces. By the end of 1968, 14 platforms were producing oil and gas from the inlet.

The onshore oilfield discoveries of Prudhoe Bay in 1968 and Kuparuk in 1969 established the Alaska North Slope as an oil province. In 1977, construction of the Trans-Alaska Pipeline System was completed, and oil began flowing directly to the ice-free port of Valdez. This development has inspired extensive exploration activity in the Arctic offshore continental shelves of the U.S. and Canada.

Fig. 18.1— Typical floating drilling arrangement.

The industry has constructed 26 sand and gravel islands for exploratory drilling in water depths to 100 ft since 1972. Several caisson-retaining systems have been implemented to speed construction and to reduce the fill requirements for the islands. Beyond 100 ft, drillships have been used, but they operate only during the ice-free summer season. In 1983, a floating conical drilling unit was deployed in the Canadian Beaufort Sea. The unit is capable of resisting early winter ice loads, hence extending the drilling season to 6 months a year.

At the current time, at least four major Arctic marine projects are in the planning phases: the Arctic Pilot Project in the Canadian Arctic Islands, the Arctic Marine Hydrocarbon Production Project in the Canadian Beaufort Sea, the Endicott Development nearshore U.S. Beaufort Sea, and the Hibernia Development off the east coast of Canada. Permanent production platforms, subsea pipelines, icebreaking tankers, supply vessels, and evacuation systems are a few of the facilities being developed.

In summary, though the offshore industry has come a long way since the wooden pier days of Summerland, the technological requirements have barely been addressed.

Offshore Drilling

The Introduction brought us quickly from the very early days of the oil industry to today's jackup drilling units, semisubmersibles, and drillships. This section will discuss the planning, preparation, and equipment necessary to conduct a typical floating drilling operation (see Fig. 18.1). Focus will be primarily on floating drilling because operations from jackups, submersibles, and platforms generally follow land drilling practices. The last portion of the section will be devoted to special considerations, such as deepwater and high-current drilling and considerations for cold and hostile environmental conditions. For a general discussion of the technology of offshore drilling, completion, and production, see Ref. 2.

Planning and Preparations

Site Conditions and Considerations. The culmination of the sometimes arduous and complex task of geologic evaluation of a potential offshore play is for the exploration geologist to put a finger on the map and say "drill

here." This decision sets in motion a series of actions that will eventually lead to the drilling of an offshore well.

The first major step is to select a rig to drill the well. Because all rigs have specific operating criteria and limits, however, certain data must be known about the drillsite and surrounding area. Basic rig selection criteria consist of water depth, expected environmental conditions during the forecasted drilling period (wind, waves, current profile, and climatological conditions), distance from nearest dock facility, and availability of consumable supplies (such as drilling mud, cement, pipe, rental tools, and spare parts).

Water Depth. A rough idea of the water depth is an important criterion for rig selection. If the water depth does not exceed approximately 350 ft, any of the three major rig types can be considered. Jackups can handle a water depth range from their shallow draft limit of 20 to 30 ft to a maximum depth of 350 ft. The maximum depth limitation is a function of other environmental constraints, such as wind, wave, and current conditions at the site. Severe conditions tend to lower the jackup rig's maximum water-depth capacity.

Drillship water depths range from approximately 100 to 8,000 ft with today's technology. The shallow side is limited by clearance between the bottom of the hull and the subsea blowout preventer (BOP) equipment. Maximum water-depth limits occur because of riser-system limitations and other constraints that will be discussed later.

Semisubmersible water depths range from approximately 150 to 8,000 ft. The semisubmersible must stay in slightly deeper water than a ship because of the clearance between the submerged hull (60 to 90 ft below the water surface during normal drilling operations) and the subsea BOP equipment. Until 1978, semisubmersible maximum water depth was limited by the practical depth of conventional mooring systems—approximately 2,200 ft. One dynamically positioned semisubmersible that required no conventional mooring system, thus extending the design working depth to 8,000 ft, was commissioned in 1978. Today, several dynamically positioned semisubmersibles are under construction or in service.

The industry water-depth record currently stands at 6,848 ft for a well drilled off the U.S. east coast during the summer 1983.

Expected Environmental Conditions. Wind, waves, and current are all important site-specific data to help in rig selection and in determination of vessel heading, mooring pattern, mooring line tensions, riser tensions, subsea equipment selection, and equipment operational limits.

Wind, wave, current, and climatological data are generally the responsibility of an oceanographic consulting firm or your own company's oceanographer. Many sources of environmental data are available—the marine climatic atlas, ship observations, U.S. Navy publications, privately funded oceanographic studies, and university-sponsored research. Converting these data into useful site-specific wind, wave, and current information is the scientific specialty of oceanography.

The oceanographer must have specified coordinates of the location and the time of the year (with some cushion on both ends) in which operations are expected. With that, he can develop the expected wind, wave, and current conditions for the location. For an exploratory location, the oceanographer may provide environmental data for oper-

ational weather, seasonal one-year storm, and seasonal 10-year storm. With that information, the drilling engineer and technical support staff can accomplish several tasks necessary in planning the well.

1. A preliminary rig selection can be made based on water depth, wind, wave, and current information.

2. A preliminary estimate of vessel heading can be determined. Before a final heading is specified, however, local knowledge of the area should be considered. Local conditions—such as swell, tide-generated currents, and rapidly changing wind directions—frequently can affect the optimum vessel heading significantly. The primary objective of optimum vessel heading is to minimize vessel motion (primarily pitch, roll, and heave) while keeping the vessel's mooring line forces within acceptable limits and providing a lee side (calm-water side) for supply and crew boats to tie up.

3. To assist in vessel selection, a vessel motion or downtime analysis can be run. Computer programs that compare a particular vessel's motion characteristics with the predicted wind and waves are available. The result indicates vessel motion. The resulting motion can be compared with a previously established set of acceptable operating limits (by computer analysis or manually) to determine an approximate downtime to be expected. This analytical tool is most useful in comparing two rigs for a particular location.

4. After the vessel is selected, mooring and riser analyses can be run to determine whether the vessel is adequately equipped for the location. In addition, both mooring and riser operating tensions can be determined. Both are necessary after the rig arrives on location. Typically, the mooring system is analyzed with a one-year seasonal storm to determine what operating tensions should be pulled on the anchor lines. A 10-year storm can be analyzed to determine the level of proof test to pull on each mooring line. With reasonable risk considered, if each line can withstand a 10-year storm proof test, normal operations should be safe without the fear of slipping an anchor or breaking a mooring line. Drilling riser top tensions are developed to minimize ball-joint angles and riser sag while keeping riser-pipe stresses within acceptable limits.

For jackup rig evaluation, comparing water depth, current, wind, and tides with the maximum recommended criteria established by the rig designer is extremely important. In water depths nearing the rig's maximum capability, strong current or other environmental factors may reduce the acceptable water depth.

Soil or foundation competency at the site must be known for jackup operations also. At an exploratory location with unknown soil consistency, soil borings generally will be required before the rig's arrival on location. They are useful in determining depth of leg penetration and to ensure that the soil can adequately support the rig.

Logistics Considerations. Logistics must also be considered in rig selection. Remote locations require substantially more planning and preparation than do locations adjacent to established bases and supplies. Consideration must be given to (1) frequency of consumables supply; (2) distance from supply base (length of boat run); (3) number of people the rig can accommodate; (4) availability of spare parts; and (5) shipment delays caused by customs regulations.

Floating rigs' (ships and semisubmersibles) variable deck-load capacity must be considered and compared with frequency of consumable supplies required. Ships, as an example, have much greater variable deck-load capacity than semisubmersible drilling rigs (15,000 vs. 3,000 tons). If the location is in an extremely rough environment, however, the semisubmersible is more stable in rough seas than the ship. Trade-offs and compromises are necessary ingredients in rig selection.

Availability of pipe, mud, fuel, water, and other consumables must be carefully determined during the planning effort. Helicopters to transport personnel and light equipment in routine and emergency situations are a necessary part of most floating drilling operations. Those located within a few minutes of the coastline and support bases are sometimes exceptions.

Climatological conditions have a major effect on helicopter operations. Fog and impaired visibility conditions will ground flight operations and, depending on their extent, can have a major effect on the resupply of consumables, transportation of crews to and from support bases, and overall rig operations. Floating ice, low temperature, and high currents offer special considerations that are discussed at the end of the Offshore Drilling section of this chapter.

Seismic and Other Location Studies. Preparation to drill an exploratory location will include running and evaluating a suite of location surveys. Site surveys generally are run by seismic companies specializing in prespud site studies. These companies will conduct the surveys, evaluate the data, and prepare formal reports that present the data that will be useful in selecting the exact location, in preparing the mooring plan, and in determining how the top hole will be drilled.

For exploratory drilling in federal offshore waters, the U.S. Mineral Management Service issued a set of guidelines that require certain surveys to be performed and analyzed before it will issue a permit to drill. These guidelines cover studies on shallow geological hazards, culture and archaeology, and biology.

The operator or lease holder must cover a minimum prescribed grid of traverse lines in carrying out these studies. In addition, certain minimum instrumentation is required to be run during the surveys. These include sparker, uniboom, sub-bottom profiler, side-scan sonar, and fathometer for surveys of shallow geological hazards. If the drilling equipment is to be on board a floating vessel, no bottom sampling is required. If a bottom-setting jack-up barge is to be used, then a bottom sample or core must be obtained. Side-scan-sonar, magnetometer, and fathometer are required for cultural and archaeological surveys. For biological surveys, box-core samples of hard-bottom areas and ocean-floor photography or TV view of hard-bottom areas are required.

The shallow-hazard surveys are required for all sites. The grid must be at least 8,000 ft on a side, centered on the proposed location, and surveyed on 1,000-R grid lines. The cultural surveys need to be run only in waters of less than 400-ft depth. The biological surveys must be run in areas where endangered species exist or hard-bottom sediments might be disturbed. Navigation and location of the survey grid during the water-borne surveys must be accurate to within $50 \pm$ ft.

Fig. 18.2— Jackup rig.

Rig-Selection Considerations

Rig-selection criteria and rig types were discussed briefly earlier. In this section, we will discuss the differences in four rigs that are used for offshore drilling: jackups, submersibles, semisubmersibles, and ships. We will also consider drilling equipment, mooring systems, and procedure manuals.

Rig types. Jackup rigs (see Fig. 18.2) consist of barge-shaped hulls with three or four (sometimes more) structural or tubular legs. Jackups must be towed to location or loaded on specially built ships for major moves. Ship transportation of jackups is becoming more frequent as new special transport vessels become available. Ship transport is considerably faster for long moves (6 to 8 vs. 2 to 3 knots) and much less risky. Loading and offloading the jackup requires a calm-water site at both ends of the move. Once the jackup is in its "jacked-up" position, drilling proceeds in a way similar to land or platform operations. However, several subtle differences should be mentioned.

First, water conditions must be relatively calm—generally less than 6- to 7-ft waves—before the rig can jack its hull out of the water. Major concerns are impact and lateral loading on the legs just as it comes in contact with the ocean floor. If the rig is rolling and pitching beyond specified limits, the jacking operation must be suspended until calmer conditions prevail. The same logic applies when the rig is jacking down.

Second, once the rig is jacked up to working position with a safe air gap between the ocean surface and the underside of the hull, primary concerns are lateral loading on the legs and scouring around the leg mats caused by current. Excessive current can cause troublesome vibration, and scouring can lead to foundation failure. Both conditions are monitored closely, and corrective actions are taken when necessary.

Fig. 18.3— Submersible rig

Third, the drilling operation is similar to a land operation after the outer casing is driven or drilled and cemented in place. Surface BOP and conventional drilling equipment are used.

Fourth, the casing extending from the ocean floor to the rig is a structural member and should be analyzed before installation. Wall thickness and strength of the pipe should be specified (and will vary if a mudline suspension system is used) to ensure that it will withstand the lateral loads of the current and the axial loads of the surface BOP and successive casing strings.

Submersible rigs (see Fig. 18.3) are limited to shallow-water drilling. Once the rig is on location and ballasted to sit on the ocean floor, drilling operations proceed as on a land site. Foundation considerations are as important here as in jackup operations. Logistics and supply considerations are common to all offshore operations, so jackups and submersibles can be just as severely hampered by fog and bad weather as floating drilling rigs.

Semisubmersible rigs (see Fig. 18.4) evolved from submersibles. Some semisubmersibles can operate when resting on the ocean floor or in their normal semisubmerged

Fig. 18.4— Semisubmersible rig

Fig. 18.5— Drillships.

position. The major advantage of a semisubmersible is that it provides a stable floating drilling platform. Roll, pitch, and heave are minimized because minimum structure is exposed to the water plane. The rig's main disadvantage is that variable deck-load capacity is limited by its reserve buoyancy or the amount of watertight volume above the water line. A semisubmersible with four 50-ft-diameter columns breaking the water plane displaces about 62 tons of seawater for each foot of displacement of the column. An equivalent 400-ft-long by 60-ft-wide ship displaces 756 tons for each foot of hull displacement. Because semisubmersibles are sensitive to variations in deck load, they are outfitted with extensive ballasting systems that are capable of shifting ballast rapidly to maintain proper trim and of deballasting or ballasting as cargo is loaded or offloaded. The semisubmersible is highly regarded as the year-round drilling vessel for the open-sea environment because it is very stable in pitch, roll, and heave.³

Drillships (see Fig. 18.5) are noted for their mobility and high storage capacity. Drillships have a definite advantage over semisubmersibles because of their size and speed. Most drillships are designed to pass through the major canals of the world, thereby substantially reducing the distance between oceans. The distance from the Gulf of Mexico to the U.S. west coast by the way of the Panama Canal is 4,500 miles. The distance around South America to the U.S. west coast (the route a semisubmersible must travel because it is too large to pass through the Panama Canal) is 15,000 miles. The cost of moving the ship to the west coast is generally much less than that of moving a semisubmersible because of time savings (less day rate) and distance savings (less fuel). Ships generally can travel at a higher speed than a semisubmersible (12 to 13 vs. 8 to 9 knots) for even more time savings. As pointed out in the semisubmersible discussion, the drillship can carry a much larger variable deck load, which offers the advantage of less frequent resupply.

Fig. 18.6— Vessel-motion terminology.

The very nature of drillships (long, narrow hulls with large water planes), however, dictates their sensitivity to sea conditions in pitch, roll, and heave. Operations can be carried out with minimum weather downtime, however, by working drillships in protected waters at seasons when conditions are best for open-sea drilling. Clearly, the biggest disadvantage of a drillship working in severe environments is its motion characteristics, especially in pitch, roll, and heave.³

Motion Characteristics. To compare the advantage of one drilling vessel over another, their relative motion characteristics must be considered carefully. Vessel motions for ships and semisubmersibles can be analyzed by determining the rig's response in the six degrees of freedom (pitch, roll, heave, yaw, surge, and sway) relative to the uniform waves (see Fig. 18.6). All vessels should have a set of motion-response curves. The curves generally are obtained for each rig configuration in a model basin. Each hull shape has a unique set of curves. Roll and heave generally control the limiting operation. With curves like those shown in Figs. 18.7 and 18.8, vessel motion in roll and heave can be determined for a particular set of wave data representing the drilling period. Ocean waves represent a spectrum of wave heights and wave periods. Computer programs are available to calculate vessel motion by entering wave data and the rig's motion curves. The result will be a motion history of that particular rig for a specific drilling period.

Performance Evaluation. The next step is to compare the performance of the two rigs. One performance yardstick is the weather-related downtime the rigs will suffer under the same environmental conditions. Downtime analysis can be particularly useful when comparing available drilling vessels for a one-well project or a complete drilling program. While one vessel may appear to be more

Fig. 18.7—Vessel response—roll.

Fig. 18.8—Vessel response—heave.

economical because it has a lower day rate, it may cost more to complete the job because of weather-related downtime.

The key to weather-related downtime is identifying the maximum limit in degrees of roll, feet of heave, degrees of pitch, etc., that can be tolerated during each discrete operation of floating drilling. The maximum level may be based on equipment operating limits, safety considerations, work efficiency, potential for damage, or other factors. Although such a limit is seldom concise, it can be a fair comparison to evaluate relative rig performance. Implementing an operating limit by shutting down an operation on the rig is completely a judgment call with many variables to be considered on the spot. Each rig should have its own set of operating limits established from experience with the rig or from experience of the rig operating personnel. Table 18.1 is an example of limiting vessel motions for most floating drilling operations.

With the appropriate operating limits, the percent of the time each applies, and the rig's motion history, weather-related downtime can be calculated. A number of papers have been published on downtime analysis. Various techniques (both manual and computer-aided analyses) can be applied to calculate weather-related downtime.⁴

TABLE 18.1—DRILLING VESSEL OPERATING LIMITS

Operation	Heave Limit		Roll Limit (deg.)	Time Criterion Applied Per Well (%)
	ft	m		
Anchoring, running riser, landing BOP	6	1.8	3	10
Running casing, coring, well testing	10	3.0	3	40
Drilling, tripping, logging	12	3.6	6	30
Circulate and condition mud	20	6.1	10	20

An additional item normally not included in the motion-related operating limits is wind. High winds frequently result in shutdown because the rig crane cannot safely handle casing or riser. This is a valid input to the rig's overall performance and should be included in the final downtime comparison. Occurrences other than severe weather also cause operating downtime. Equipment breakdown and repair downtime (sometimes the result of severe weather, but not always) must be determined from experience and operating history with a particular rig or company. This increment of downtime is unpredictable and difficult to estimate.

Mooring Systems (Stationkeeping). Once the engineers are satisfied that a particular rig or group of rigs is capable of handling the environment of a specified offshore location, other equipment systems must be evaluated and compared.

Mooring equipment provided to keep the rig on location is of major significance. Major questions to be answered regarding mooring equipment include the following: (1) is the mooring line (chain, wire, or a combination of chain and wire) strong enough to withstand the loads during the strongest anticipated storm; (2) does the rig have sufficient wire or chain on board or available for the water depth at the specified location; (3) do the anchor handling or supply boats that are being considered have adequate pennant-wire-handling equipment on board (lengths must be greater than the water depth and sufficiently strong to handle the 30- to 40-ton anchors and can approach 2.5 to 3 in. diameter); (4) does the vessel have adequate instrumentation to monitor mooring-line loads; and (5) does the rig have adequate chain-locker capacity to hold the desired amount of chain, or must part or all of the chain be stored on supply boats? (Vessels that don't carry their own chain have greater in-transit deck-load capability but normally will require longer to moor up because of the additional chain-handling requirements.)

Fig. 18.9—Optimum vessel position.

These questions must be answered to specify an adequate mooring system properly. Mooring analysis, which is necessary to answer several of the questions, will be discussed later in this section.

Adequate stationkeeping (keeping the vessel within acceptable limits on the location) is a result of a properly designed and operated mooring system. Why is stationkeeping important? Ideally, the vessel should be located directly over the well. However, wind and current forces can cause the vessel to take an offset downstream from the wellhead location. Waves cause the vessel to oscillate around that offset position.

It is important to keep the vessel reasonably close to the wellhead position for several reasons: (1) the subsea drilling equipment can accommodate angular offsets of up to 10° , but beyond that the equipment mechanically locks up; (2) drillpipe that is rotating in the ball joint at

Fig. 18.10—Typical spread mooring patterns.

the top of the BOP can cause rapid and excessive wear if the angular offset exceeds 1 to 2° for an extended length of time; (3) excessive vessel offset can cause increased riser sag, compounding both the ball-joint offset and the wear problems. Proper monitoring of the ball-joint angle and adjustment of the mooring system will result in a vessel offset upstream of the current and wind that will minimize the lower ball-joint angle. Optimum vessel offset would yield a zero ball-joint angle (see Fig. 18.9).

There are many variations in mooring patterns. Differently shaped vessels will require different mooring patterns (see Fig. 18.10).

One criterion in mooring-system design is that the restoring forces should be able to withstand nearly the same storm conditions from any direction.⁵ The mooring pattern is designed to fit the vessel and particular environmental conditions anticipated at the site.

Fig. 18.11—Typical catenary configuration.

The restoring forces are generated by the mooring line. Environmental loads acting on a vessel displace it horizontally until an equal and opposite horizontal force (restoring force) is developed by the anchor and mooring lines. As the vessel is displaced, tension in the anchor line increases because of additional line being lifted off the ocean floor and because the vertical component of anchor line tension, which increases as line is lifted off-bottom, is affected by the angle in the anchor line at the vessel (see Fig. 18.11).

Vertical or uplifting forces on the anchor are zero as long as line remains on bottom. A properly designed and operated mooring system should always have line remaining on bottom during maximum storm conditions. If all the line comes off-bottom, the chances of dislodging an anchor are high.

With a spread mooring system, vessel excursion in moderate weather conditions can be restricted to 2 to 3% of water depth by pulling initial operating tensions in each line. Fig. 18.12 shows the nonlinear behavior of horizontal force (horizontal component of line tension) and vessel displacement for a typical spread mooring. If the vessel

Fig. 18.12—Single-line catenary horizontal force vs. horizontal displacement.

had two opposing mooring lines and could pull tension on each line initially, vessel displacement could be greatly reduced for the same environmental loads because the line would operate in a much "stiffer" region of its horizontal force vs. displacement curve.

Initial operating tension, however, does affect the maximum line tension that will be required in maximum storm weather. The same environmental loads on the vessel are produced during maximum storm weather regardless of the value of initial operating tension. This force must be balanced by one or more mooring lines. This restoring force is in addition to most of the horizontal components of the initial tension in the line. The vessel will probably not be displaced enough to reduce the initial tension in the leeward lines completely. In actual operations, leeward lines can be slacked off during maximum storm weather to reduce maximum line tension and vessel offset. In general, the higher the initial tension, the higher the maximum line tension during maximum storm conditions. Too little initial tension, however, will result in unacceptable vessel offset during operating weather conditions. Table 18.2 identifies desirable stationkeeping criteria.

Dynamic positioning is another method of stationkeeping where no mooring lines are used. These systems require acoustic positioning beacons, multiple thrusters on the vessel, and an on-board computer system and are primarily for deepwater drilling. Dynamic positioning will be discussed briefly in the last section, Special Considerations.

Drilling-Equipment Considerations. Rig-selection considerations should include a review of the vessel's drilling equipment. Much of the drilling equipment found on board floating drilling vessels is identical or similar to equipment on land drilling rigs. This discussion will be limited to equipment unique to floating drilling.

Fig. 18.13 identifies the major components of the subsea drilling system and related shipboard systems. The figure shows some of the components of the drilling system that have been developed to accommodate vessel motion and water depth. The components to be explained

TABLE 18.2—DESIRABLE CRITERIA OF STATIONKEEPING

Operational:	Drilling operations can be carried out
Minimal weather	That which results in $\leq 3^\circ$ lower ball-joint angle, generally
Maximum vessel excursion	2 to 3% of water depth
Nonoperational, But Riser-Connected:	Seasonal 1-year storm
Maximum weather condition	$\frac{1}{3}$ breaking strength
Maximum line tension	500 ft
Minimum line remaining on bottom	That which results in $\leq 5^\circ$ lower ball-joint angle, generally
Maximum vessel excursion	5 to 6% of water depth
Riser-Disconnected:	Seasonal 10-year storm
Weather conditions	$\frac{1}{2}$ breaking strength
Maximum line tension	100 ft
Minimum line remaining on bottom	

are the BOP, the flex joint, riser, riser slip joint, riser and guideline tensioners, drillstring motion compensator, guidelines, and control system.

BOP. The subsea BOP stack is a major change from land or platform drilling operations. Drilling riser, extended kill and choke lines, remote hydraulic and electrohydraulic control systems, and subsea wellhead equipment are all product modifications needed because the BOP was relocated on the ocean floor. The well's major pressure-containing components were put on the ocean floor because of the need to compensate for vessel motion.

A BOP stack, whether located on the surface or subsea, is considered a last resort for preventing a well kick from becoming a blowout. Several steps are taken to control unusual well conditions before use of the well shut-in device (BOP). If the previous steps have failed and it becomes necessary to shut the well in, the shut-in equipment must be highly reliable. BOP equipment is designed with reliability as its ultimate criterion. Because of its relative inaccessibility, the subsea BOP requires additional redundancy and reliability.

The BOP stack is a combination of individual BOP's designed to shut in a well under pressure so that formation fluids that have moved into the wellbore can be circulated out while continuous control of the well is maintained.

A description of the BOP stack components is included below (see Fig. 18.14).

Ram Preventers. The massive steel rams have rubber seals, and are hydraulically actuated to seal off the wellbore. Pipe rams seal the annulus around the drillpipe and are designed so that an entire string of drillpipe and collars can be suspended from a pipe joint landed on a ram. The ram seals must be the correct size to seal; 3-in. seals cannot be used for 5-in. drillpipe. Conventionally, three pipe rams are used. A fourth ram, a blind-shear ram, is used to seal over the open hole and to shear drillpipe when necessary. Shearing pipe is, of course, one of the last resorts in an emergency situation.⁵ Variable-bore rams are an option that is offered for tapered drillstrings.

Annular Preventers. Annular preventers are comprised of specially designed, reinforced rubber elements that can seal around any tubular or near-tubular objects that will go through the BOP's. They will also seal over the open hole and can pass drillpipe tool joints without severely

Fig. 18.13—Floating drilling system.

Fig. 18.14— BOP stack

damaging the sealing element. Annular preventers are actuated by an annular piston that squeezes the seal into the bore. The piston area is large relative to the other functions on the stack and, except for initial closure, should be operated at pressures lower than the other stack functions. This decreases the possibility of extruding the rubber seal out of the preventer.⁵ Frequently, two annular preventers are used. One normally will be located above the upper hydraulic connector so that it can be retrieved with the riser.

Hydraulic Connectors.³ Hydraulic connectors provide the main pressure seal between the wellhead housing and the BOP and between the top of the BOP and the lower marine riser package (LMRP—usually contains the top annular preventer, flex joint, control system, and crossover to the bottom riser joint). The high-pressure wellhead housing is the male portion of the connector. It will be a mandrel or a hub type. The connector is the female portion and consists of a series of hydraulic cylinders that actuate locking dogs into grooves machined into the wellhead housing or collet fingers that clamp over the wellhead housing hub. Both types of connectors use metal-ring seals. This provides continuous metal-to-metal sealing up through the BOP.

Kill-and-Choke Valves. These valves are the subsea shutoff of the high-pressure kill and choke (K&C) lines that run from the BOP's to the choke manifold on the rig. K&C valves are hydraulically controlled from the surface and are designed to close by spring action when opening pressure is released. Some valves close hydraulically

in addition to the spring or fail-safe close feature. Two valves in each line should always be used for redundancy. They should be located as close to the stack as possible for mechanical protection.⁵

Unitized BOP Stack. The unitized BOP stack that consists of two hydraulic connectors, three or four ram preventers, one or two annular preventers, four K&C valves, one flex joint, and a control system is generally handled in one or two pieces on board the rig. The complete assembly can weigh from 200,000 to 400,000 lbm and stand 25 to 30 ft high.³

Handling and moving the BOP stack from its storage position to the moonpool and back presents unique problems. Generally, either special overhead cranes or hydraulically actuated carts are used to move the stacks.

BOP maintenance is extremely important. The only time available for routine maintenance is between locations. On short field moves, this can present problems. Land BOP systems are frequently broken down and sent to the shop for maintenance between wells, but that is virtually impossible to do without causing major delays on a floating drilling rig. A few rigs are equipped with backup BOP stacks to minimize the chance of major delay.

BOP testing is done in two steps. The stack must be completely function-tested (each of the 30 to 40 hydraulic functions actuated to verify that each works) before running. It must also be completely pressure-tested before it leaves the deck. Each pressure-containing component (rams, annulars, and K&C valves) must be tested to a pressure specified by the operator. API RP 53 on BOP's⁶ identifies testing procedures as a minimum safe guideline. After the BOP has been run and latched on to the subsea wellhead, it must again be pressure-tested. Following procedures defined by regulatory agencies, periodic function and pressure-testing must be done on the BOP equipment during the course of a well. A complete deck and subsea BOP testing checklist simplifies frequent testing requirements.

Flex Joints.³ A flex joint is installed between the lower end of the riser and the BOP stack. This joint essentially acts as a pinned connection to minimize bending stresses in the riser as the drilling vessel is moved by wind, wave, and current action.

The first flex joints were made from bag-type annular BOP's fitted over a mandrel flanged to the top of the BOP stack. The rubber element in the preventer was inflated against the mandrel to a pressure high enough to keep drilling fluid in the riser from leaking past it. This type of flex joint, which was not positively locked to the BOP, worked fine in shallow waters (200 ft or less) where tension was not pulled on the riser.

The next flex joints were the pressure-balanced ball joints. These joints came into existence when operations moved into deeper waters and it became necessary to pull tension in the riser through the ball joint into the BOP itself. With this positive pull upward on the ball joint, it was necessary to provide a pressurized oil pad between the male and female halves of the ball joint to minimize wear. Pressurized oil was provided through a line from the surface and was contained between upper and lower O-ring seals within the ball joint. The balancing pressure on the ball joint was determined by dividing the tension pulled through the ball joint by the projected horizontal area between the ball-joint seals.

Steel-laminated elastomers now are replacing ball joints as riser flex joints. These joints are longer-lived and require less maintenance than the pressurized ball joints. They also eliminate the need for the pressure source and hydraulic lines.

Some operators also require the installation of a flex joint between the upper end of the riser and the slip joint. Pressurized ball joints and elastomeric joints have been used successfully in this application. Most flex joints are designed for an angular travel of $\pm 10^\circ$ for a total included angle of 20° .

Slip Joints.³ All floating drilling vessels, ship-shaped or semisubmersible, heave up and down as swells go by. A slip joint is the link between the riser fastened to the bottom of the ocean and the heaving drilling vessel. The slip joint, similar in action to a trombone, consists of an inner and an outer barrel. The outer barrel is connected to the riser and the inner barrel to the ship. As the ship heaves up and down, the inner barrel strokes in and out of the outer barrel. A pair of inflatable rubber elements mounted on the upper end of the outer barrel serve as the seal between the barrels to prevent loss of drilling fluid. The second seal is for redundancy.

Riser Tensioner. For a drilling riser to survive, two things must happen.³ First, the drilling vessel must be kept within prescribed limits as it moves about in surge and sway. Second, the riser must be tensioned properly so that it will not sag and ultimately be overstressed in bending.

The controlling criterion is not vessel position relative to the well on the ocean floor, but the angle between the axis of the lower end of the riser and the vertical axis of the BOP stack. This angle is called the lower riser angle. During drilling, this angle should be kept at less than 3° . A greater angle will cause the rotating drillpipe to cut into the flex joint and BOP stack. In extreme cases, lost circulation has resulted from a worn-through flex joint. In normal drilling, the riser angle is kept to less than 1° . If it exceeds 3° , drilling is stopped until the vessel can be repositioned.

To keep the lower riser angle as near 0° as possible in areas where ocean current is a factor, the drilling vessel may have to be located up-current from the well.

If the drilling vessel is located up-current, as shown in Fig. 18.9, but inadequate tension is pulled on the riser, the riser could sag, as denoted by the dotted line. If the drilling vessel is moving about and there is heavy drilling fluid in the riser, the angle at the flex joint could exceed 10° and put bending stresses in the riser. If this situation is not corrected, the riser ultimately will fail.

Hydropneumatic tensioning units were developed to keep constant tension pulled on the riser. Determination of the tension required is a complex problem in which water depth, riser size, mud weight, ocean current, vessel motion, and sea conditions must be considered. A number of computer programs, both time and frequency domain, have been developed to determine the tension needed. Many oil companies that operate offshore have their own riser programs or have access to them. These programs give the riser tension required and the desired vessel offset.

The tensioner system works on the principle that displacement of a relatively small amount of hydraulic fluid against a large pressurized volume of air results in a very

Fig. 18.15—Riser tensioner unit.

small change in the hydraulic pressure. Variation in tension on the riser can be kept to less than 5% by proper design.

The tensioning unit (see Fig. 18.15) consists of a series of large air storage tanks that are connected to the air or gas side of an accumulator that serves as the interface between the air and hydraulic systems. The tensioner is a cylinder/piston arrangement that has wire-rope sheaves mounted on the lower end of the cylinder and on the upper end of the piston rod that extends out of the cylinder. A wire rope that is dead-ended on a storage reel is reeved through the sheaves over alignment sheaves and is attached to the outer barrel of the slip joint. As the drilling vessel heaves up, it pulls on the line, which pulls the piston into the cylinder, displacing fluid into the accumulator against the large volume of air. The air is precharged to give the desired tension. Similarly, when the vessel moves down, the gas pressure displaces hydraulic fluid against the piston, extending the piston rod and maintaining a constant pull on the riser.

Guideline tensioning systems, developed to keep constant tension in the guidelines, operate in much the same manner as the riser tensioners. The only difference is that they are smaller because less tension is required on the guidelines.

Drillstring Motion Compensators. Without drillstring motion compensation,³ the drill bit would be constantly lifting off and banging down into the bottom of the hole as the drilling vessel heaves up and down. Weight control on the bit under these conditions without some type of motion compensation is next to impossible. Bumper subs (trombone-type slip joints) in the drillstring above the drill collars were used initially to provide some relief from vessel motion. However, with bumper subs, once the drillstring was in the hole, the weight on the bit (WOB) (weight of the drill collars) was fixed and could be changed

Fig. 18.16—Drillstring motion compensator.

only by pulling the drilling assembly and changing the number of drill collars. Another disadvantage was that the early bumper subs were not hydraulically balanced. Mud pressure in the drillstring that was higher than the external pressure in the drillpipe/hole annulus, as when jet bits are used, caused the bumper subs to “pump” open and to become as stiff as the drillpipe, making them ineffective.

Balanced bumper subs that have the internal pressure routed to both sides of the stroking member were invented to solve this problem. These solved one problem and created another. When working in sandy drilling fluids, the balanced bumper subs’ seals wore out after relatively short runs, making it necessary to come out of the hole with “green” bits to replace the worn-out, leaking subs. Because of their short lives, the worn-out bumper subs were repaired on board, which required an inventory of spare parts and personnel trained in their repair.

These considerations led to development of drillstring motion compensators (see Fig. 18.16). These hydropneumatic units are installed either between the traveling blocks and the hook or in the crown block at the top of the derrick. These units have been successful for both drilling-bit weight control and running and landing heavy subsea equipment (such as 400,000-lbm BOP stacks). They are common on most drilling vessels today.

Drillstring motion compensators are similar to riser tensioners in the way they function—i.e., a small volume of hydraulic fluid is displaced against a large volume of pressurized gas. The weight of the drillstring is supported on a vertical piston inside a cylinder that is connected to the rig blocks. The piston is supported by pressurized hydraulic fluid between the piston and cylinder. As the vessel heaves up, the piston is pulled down into the cylinder, displacing hydraulic fluid into a gas-charged accumula-

tor. When the vessel heaves down, the piston is forced up by the pressurized hydraulic fluid from the accumulator. The gas side of the accumulator is connected to large-volume gas bottles. The small volume of fluid displaced by the piston against the large volume of gas gives a low compression ratio. This means that there is very little change in the gas pressure and the hydraulic pressure, resulting in an almost constant WOB.

At the start of drilling, the gas pressure is adjusted so that it will barely support the weight of the drillstring. WOB is increased simply by reducing the gas pressure. This transfers weight from the drillstring motion compensator to the bit. As a hole is made, the blocks are lowered to keep the compensator at midstroke of the piston. To reduce the WOB, the gas pressure is increased. Large air bottles are kept charged with high-pressure air for this purpose.

Re-Entry Systems. Re-entering a 3-ft-diameter hole in the ocean floor in shallow waters without too much current, say less than half a knot, isn’t too difficult.³ If that same hole is put under half a mile of water in an area with 1- to 2-knot currents, the problem obviously is more difficult.

Almost from the beginning of floating drilling, wire-rope guidelines have been used to guide drillstrings, casing, BOP stacks, and riser pipe into or onto subsea wells. In most instances, the guidelines are anchored to the ocean floor by the temporary guidebase. In some cases, when the hole for the structural pile is spudded without a temporary guidebase, the mud pumps were run at full capacity as the bit entered the ocean bottom. This washed a large conical hole in the ocean floor that, with luck, could be re-entered without guidelines. However, under these conditions, when the structural casing and the permanent guidebase are run, the guidelines are attached to the permanent guidebase for subsequent re-entry operations.

With the advent of dynamically positioned drillships, guidelineless re-entry systems were developed. These systems still had temporary and permanent guidebases; however, instead of using guidelines and guideposts, they were fitted with guidecones that provided a large target for the tools or casing being run. TV cameras were run through the drillpipe, casing, riser, or BOP stack (depending on what was being run) to provide guidance into the hole or back onto the BOP stack. Combinations of TV and sonar also have been used for re-entry guidance. With the dynamic-positioning system, the driller can take control of the drilling vessel from his station and position it as required for re-entry. Re-entry by means of these systems has been made in waters as deep as 6,800 ft.

Marine Risers. The first floating-drilling systems did not use marine risers for mud returns.³ Hoses that were connected below a rotating packer mounted on top of the BOP stack brought mud returns back to the drilling vessel. The rotating packers, which sealed around the drillpipe, were very short-lived and allowed drilling fluid to leak into the ocean when they failed. It was the failure of rotating packers that led to development of today’s marine risers.

As may be seen in Fig. 8.14, the marine riser extends from the BOP stack on the ocean floor up to the drilling vessel. The marine riser, in the parlance of land drilling, is just a very long pitcher nipple. In addition to serving

as a pitcher nipple or mud-return conduit, the marine riser serves another useful purpose: it guides the drillstring through the BOP's and into the hole being drilled in the ocean floor.

The riser joints can be ordered in any length desired, but the length normally is determined by the geometry of the drillship. Normal riser joints are 50 ft long, and at least one riser made of 75-ft joints is in service.

In the beginning, riser couplings were simply threaded collars. Cross threading of couplings being made up on a moving vessel led to the development of clamp-type couplings, piloted union-type couplings, and finally the radially driven dog-and-groove couplings. Riser couplings now being developed for waters in excess of 7,000 ft are of a piloted-bolted type.

As drilling entered deeper waters and drilling vessels ran out of space to install more and more riser tensioners, it became necessary to reduce the weight of the riser by adding buoyancy material. Syntactic foam was used first. Later, air cans were installed around the riser joints to make them air buoyant. Both types of buoyancy are now in everyday use. The cost of the dense syntactic foam that is required for deeper waters is offset by the cost of high-pressure air compressors for air-buoyancy risers. Air-buoyant risers do have one advantage over the foam riser package: the air in the buoyancy cans can be dumped so that the riser will plumb bob vertically below the drilling vessel and not tend to drift off with the current.

For ultradeep waters (deeper than about 10,000 ft), free-standing risers are visualized. Work done in conjunction with the Natl. Science Foundation's proposed Advanced Ocean Drilling Program indicates that to provide the means for rapid disconnect of the drilling vessel from the well, it will be necessary to establish a disconnect point in the riser at about 1,000 ft below the ocean surface. To support the riser vertically below the disconnect point after a disconnect, 10-ft-diameter buoyancy cans will be fitted to an appropriate number of riser joints. The disconnect point will include shear rams to cut the drillpipe if an emergency disconnect becomes necessary. This intermediate disconnect point is essential because it is estimated that pulling 10,000 ft of riser could take from 7 to 10 days, well outside our weather-forecasting capability.

K&C Systems. On land rigs, the K&C outlets³ on the BOP stack are plugged directly into the K&C manifolds on the rig floor. In floating drilling, where the BOP's may be from several hundred to several thousand feet below the rig floor, K&C lines must be provided to bridge the water depth.

In the early days in relatively shallow waters, high-pressure hoses were connected to the BOP stack and, as the stack was lowered, were paid off hose reels. When the stack was landed on the wellhead, the hoses were connected to the K&C manifolds. As water depths became greater, the hose reels became too large for convenient use, and another way to bridge the water depth had to be found. This was done first by installing guide funnels at about 15-ft intervals along the length of the riser as it was run. These funnels were lined up with receptacles immediately above the K&C valves on the BOP stack. With the riser in place, screwed-pipe K&C lines were run down through the guide funnels and stabbed into the receptacles on the stack. Their upper ends were connected into the K&C manifolds.

This system, while functionally satisfactory, was time-consuming to run and test, so another method was developed. This method was to make the K&C lines integral with the riser. The tops of the K&C joints were fitted with a female seal pocket filled with chevron packing, and the lower end fitted with a male seal nipple. When the riser was run, the seal nipples dropped vertically into the female seal assembly. No rotation or screwing was required. The joints were held together by the riser couplings.

Some manufacturers of flexible high-pressure pipe now are proposing to provide long K&C lines that would be stored on reels and paid out with the BOP stack when it is run down to the ocean floor. On the larger vessels now in service, there is space for the large hose reels required.

Control Systems. The simplest way to operate an actuator in a hydraulic control system is to connect hydraulic lines from a pressure source through control valves directly to the actuator.³ Some actuators require two lines to complete the control cycle; others, such as spring-return fail-safe actuators, require only one line.

Subsea BOP's were controlled this way during the start of floating drilling. An early stack consisting of a hydraulically actuated connector top and bottom, K&C valves, four ram preventers, an annular preventer, and a pressure-balanced ball joint would require as many as 17 control hoses. These hoses, bundled together, were stored on a large hose reel. All hoses first were connected directly to their function on the stack, then pressure- and function-tested before the stack was run. Improperly tagged hoses led to many hours of troubleshooting to get the stack to work properly. This time-consuming job had to be done each time the stack was run.

Eventually, male and female multifunction stab plates were developed that reduced some of the hookup time, but the same problem of larger hose reels in deeper waters resulted. In addition, as BOP's became more complex, as many as 30 to 40 hoses were included in the hose bundles, doubling and tripling their size. To solve the problem of large hose reels, multihose bundles, and their slower actuator response times in deeper waters, two new types of control systems were developed: the piloted all-hydraulic control system and the direct-wired electrohydraulic control system.

Backup Control Systems. In spite of the best-laid plans and even with two control pods providing 100% redundancy, problems or failures still occur in the most modern control systems. It is desirable to have reliable backup systems if the primary controls fail. This has led to development of two types of backup control systems: the acoustic control system and the last-chance hydraulic stab system.³

The acoustic backup system uses acoustic signals through the water as the control link between the drilling vessel and the BOP stack on the ocean floor. Energy to power the acoustic signal receiver and to position control valves is provided by dry-cell batteries. Hydraulic energy to power selected functions on the BOP stack comes from accumulators mounted on the BOP stack. These accumulators are kept charged because they are part of the normal control system. Typical functions are to close shear rams, to close pipe rams, and to disconnect the riser at the lower marine-riser package.

An acoustic transmitter located on a surface vessel, drilling vessel, work boat, or other vessel is used to send

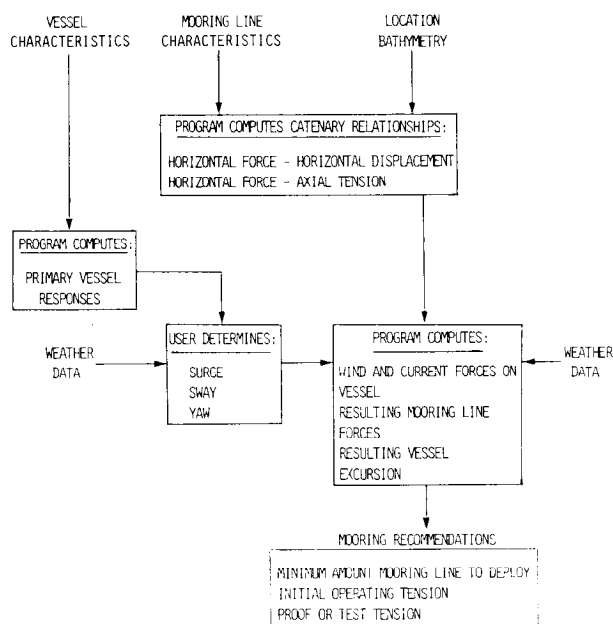

Fig. 18.17—Mooring analysis method.

a signal that is coded for the desired function, down to the receiver on the BOP stack. This signal is interpreted and the proper control valve is actuated, directing hydraulic fluid from the accumulators to the desired function. Acoustic backup systems now are installed on most deep-water drillships. Solid-propellant gas generators also have been tested successfully as backup subsea energy sources.

The last-chance hydraulic stab system provides the means for actuating several selected functions when all else has failed. A hydraulic stab that is ported to accommodate the desired functions is run down to the BOP stack on drillpipe. It may be guided down guidelines or directed by sonar or TV. Hydraulic hoses are connected to the stab and are run in with the drillpipe as the stab is lowered down to the receptacle on the stack. Once the stab is in place, control is accomplished by pressuring up the appropriate hydraulic line. The stab also can retrieve the lower-marine-riser package or the complete BOP stack in the event of a failed riser. The stab receptacle is connected with shear bolts to a mounting plate on the lower-marine-riser package. The receptacle also is attached to the lower-marine-riser package with a heavy wire-rope bridle. The stab contains a connector that, when lowered into the receptacle, latches the stab to the receptacle. To retrieve the lower-marine-riser package, for example, the stab is run in on drillpipe and is stabbed and latched into the receptacle. After the lower-marine-riser-package disconnect is actuated, the drillpipe is picked up, the shear bolts sheared, and the load transferred to the wire-rope bridle. The piece then is recovered by pulling the drillpipe.

Extended-Water-Depth Capability. Occasionally, a drilling vessel is considered that has a maximum-water-depth capability just short of the wellsite water depth (1,300-ft water depth with a 1,000-ft capacity rig as an example). To ensure that the rig is adequate for the location, consider additional riser availability and storage space; additional riser tension (or added buoyancy); lengthened control hoses and TV cable; additional guideline length; mooring system adequacy (mooring lines and

pennant wire); size of control hose reels (large enough to hold additional hose; ease of installing larger ones); size of guideline winch drums (large enough to handle additional line); and substructure strength (enough to support the added tension requirement).

Generally, the added water depth can be accommodated, but each rig and each site should be considered separately.

Operating Manuals and Emergency Procedures

Rig selection considerations should include a review of each drilling vessel's operations manual and emergency procedures plan. The operations manual will include drilling operations and equipment-handling procedures. Normal operating limits for discrete drilling operations will be specified. The emergency procedures plan should cover detailed responses and courses of action to be followed during marine emergencies, well emergencies, and bad weather situations. Disconnect and hang-off procedures must be identified, and special equipment should be on board to accomplish the suspension under adverse conditions. An agreement on well-control procedures should be reached between the drilling contractor and the oil company personnel. The drilling contractor personnel will implement the procedure, so if it is different from their previous procedures, additional training should be conducted.

Mooring and Riser Analyses

Mooring Analysis. Mooring systems and the objectives of station-keeping have been discussed briefly. The concept of the catenary and horizontal restoring force were mentioned. Combining these forces with the wellsite water depth, physical description of the rig's mooring equipment, and environmental data is the task of a mooring analysis. Several commercial computer programs are available to perform mooring analysis. Some companies have developed their own programs. Mooring-analysis methods are documented in numerous articles and papers. Two are referenced at the end of the Floating Drilling section. In addition, API RP 2P discusses mooring analyses.⁷

Fig. 18.17 describes the basic procedure followed in mooring analysis. Combining vessel characteristics and mooring-equipment specifics with bathymetry and weather data yields the length of mooring line to deploy, the initial operating tension, and the proof or test tension. The results can be obtained for a number of mooring configurations to determine which is optimum or simply to verify a recommended configuration.

Riser Analysis. Marine or drilling risers were described earlier. Accurate performance of drilling risers can be determined only by analysis. In floating drilling operations, the riser behaves as a string. It gains all of its structural integrity from tension. The single most important parameter in operation of the system, therefore, is riser top tension. Insufficient top tension can result in operational problems associated with large ball-joint angles and, if low enough, buckling of the riser pipe body. Overtensioning, however, produces high stresses in the riser that can result in a shortening of its life because of fatigue cracking. For each combination of environmental conditions, mud weight, riser weight, and vessel offset, there is an optimum range of riser top tension.

Commercial programs are available to do riser analysis. As with mooring analysis, some companies have developed their own programs. API RP 2Q addresses riser design⁸ and API RP 2K discusses riser use and maintenance.⁹ Papers written on riser-analysis procedures are referenced at the end of the Floating Drilling section. The following discussion covers riser-analysis criteria and operational considerations, but not details of the complex analysis.

The items considered in riser analysis are riser stress, ball-joint angle, top tension, riser top angle, tensioner line angle, sheave friction, and riser pipe collapse.

Riser Pipe Stress. Static and dynamic stresses in riser pipe are calculated by the riser-analysis program. Static loads are caused by the riser weight, mud weight, current-induced hydrodynamic forces, the applied top tension, and deflection of the top of the riser. Deflection of the top of the riser is caused by vessel offset. Dynamic loads result from wave-induced water-particle motion and vessel surge/sway motion. Wave-induced surge/sway motion produces dynamic riser deflections and hydrodynamic forces because of the relative motion of the riser and the water.

The criteria for acceptable static and dynamic stress levels is shown in Fig. 18.18. For purely static loads (no dynamic load applied), stresses up to 50% of the pipe-material yield strength are allowed for normal operations and stresses up to 67% of yield strength for limited or emergency operations. These allowable stresses have factors of safety of 2.0 and 1.5, respectively. For purely dynamic stresses, the allowables have been reduced to 25% of the pipe-material yield strength and 25% of the pipe-material ultimate strength because of fatigue considerations. Combined static and dynamic stress states must fall within the recommended range indicated on the graph. High stresses occur in the pipe-to-connector weld and at the base of the groove in the connector pin. These two areas should be inspected frequently.

Ball Joint Angle. To minimize wear by the drillpipe, the angle of approach of the riser to the BOP stack should be kept as small as possible. Problems are minimized if this angle is maintained to less than 1°—a goal readily attainable in a mild environment. With moderate to severe environments, establishing an allowable ball-joint angle of 3° is a compromise between wear problems and the application of criteria too restrictive to permit economical drilling operations.

The lower ball-joint angle is affected by many variables. Of these, rig personnel can readily adjust only riser top tension and vessel position. The rig's riser-angle indicator should be monitored continuously and the vessel position and/or riser tension adjusted accordingly. Changing the vessel location relative to the wellhead is the best method of minimizing ball-joint angle. The lower ball-joint (flex-joint) angle is the most important operating criterion to maintain.

Top Tension. For long-term operations, it is not desirable to work riser-tensioner systems at more than about 75% of their rated capacity. To do so will result in premature failure, generally in the tensioner lines. Tension requirements can be reduced by the use of buoyancy.

Sufficient tension/buoyancy should be specified to prevent drastic consequences should one tensioner fail. After ball-joint angle, this criterion is the most restrictive

Fig. 18.18—Recommended stress ranges.

on tension requirements. When operating at the recommended tension, failure of one tensioner should not cause increases in ball-joint angle past 3°, and stress should remain in the recommended range for normal operations (see Fig. 18.18).

Minimum operating tension should always be sufficient for emergency disconnect. An overpull at the lower-marine-riser package connector of about 50,000 lbf is recommended to ensure that the lower-marine-riser package and riser will retract sufficiently to clear the top of the BOP.

Increasing riser top tension within the specified range can reduce bottom ball-joint angle. Increased tension beyond the maximum recommended, however, will significantly increase pipe stresses and have very little effect on decreasing ball-joint angle. At that point, the vessel must be moved to correct excessive ball-joint angle.

Riser Top Angle. Although the lower ball-joint angle is the most critical, the top angle must also be controlled. Tensions selected for drilling operations include a top angle of less than 4°.

Tensioner Line Angle and Sheave Friction. Variation in tensioner line angle generally has very little effect on riser tension. Sheave friction, however, may be substantial in some systems. If so, its effect should be compensated for in the tensioner control system so that the desired tension is maintained on the top of the riser.

Riser Pipe Collapse. Riser-pipe material strength and wall thickness should be sufficient to prevent collapse owing to seawater hydrostatic pressure when the riser is completely void. Reduction in collapse strength because of axial loading and bending stress should be included. In general, collapse considerations become important in water depths greater than 800 ft.

The objective of riser analysis is to specify recommended top tensions that keep the system within safe working limits under all anticipated conditions, as described in Table 18.3.

Field Operations

With the major planning and preparation completed, we will now discuss the sequential steps of drilling a well from a floating vessel. The sequence of events in this description is not necessarily followed for every well drilled from a floating vessel, but it is a method that has worked in the past and will work in the future.

TABLE 18.3—RECOMMENDED OPERATING LIMIT

Ball-Joint Angle Range	Comments
0 to 1°	Maintain ball-joint angle within these limits, if at all possible.
1 to 3°	Maximum limit for normal operations. Preferably should be in this range only temporarily.
3° and increasing	Start drillpipe hang-off procedure.
5° and increasing	Drillpipe hung off. Start riser disconnect procedure.

Establishing Location

The location has been plotted on the map, the seismic work reviewed, and the drilling program written. Materials have been delivered (especially subsea wellhead equipment, 30- and 20-in. pipe), and it is time to survey the location. Surveys must be accurate for several reasons. Locations near lease boundaries must be accurately placed from a legal or ownership viewpoint. Well location relative to seismic mapping is critical. If the rig has moved off location, getting back on location requires good survey data.

Today's techniques can provide accuracy within 10 ft. In well-established areas—such as around the perimeters of the U.S., Canada, and in the North Sea—radio triangulation systems are used. In remote areas, satellite navigation (SAT NAV) systems, with receivers located on the floating vessels, are used. SAT NAV systems are accurate to within 3 ft. Depending on the well location relative to available satellites, however, it will take multiple satellite passes and approximately 24 hours to achieve that accuracy. The site may be marked with a buoy or the rig may be surveyed indirectly. Once on location with the mooring system set and tested, drilling is ready to begin. See Fig. 18.19 for the sequence of operations.

Spudding The Well

Step 1 in drilling from a floating vessel is to lower the temporary guidebase to the ocean floor.³ The temporary guidebase is generally 12 by 12 ft and is outfitted with a bull's-eye that is observed by TV for levelness determination. This base is run on drillpipe connected to it with a J-tool or hydraulic connector. Four wire-rope guidelines are attached to the subbase before it is lowered. The base may be loaded with weighted rotary mud so that necessary tension can be pulled in the guidelines when drilling equipment is lowered to the ocean floor. With the base on bottom, the drillpipe running string is marked at the kelly bushing, averaging out the vessel heave, so that the water depth may be determined by measuring the pipe when it is pulled. This measurement, corrected for tide, is the water depth from the kelly bushing to the ocean floor that is used in all subsequent drilling, logging, casing, and testing operations.

Step 2 consists of running the drilling assembly—the bit, drill collars, bumper subs, and drillpipe—down the guidelines, through the temporary guidebase, and into the ocean floor to drill the hole for the structural casing. This hole must be drilled carefully to ensure that it is kept within 1° of vertical because it later will control how vertical the BOP stack will be when it is landed on the wellhead.

Several single shots should be taken while this hole is drilled. When drilling is completed, heavy mud is spotted in the hole to prevent sloughing or caving in. This hole generally has a 36-in. diameter and is 100 to 200 ft deep. The structural casing probably will be 30 in. in diameter with a ¾- or 1-in.-thick wall. It is called structural casing because it serves as a foundation to provide lateral support for the BOP's during subsequent drilling operations. In addition to drilling a hole for the structural casing, it may be driven or jetted in. In these instances, some drillers elect not to use the temporary guidebase.

Running 30-in. Casing

In Step 3, the structural casing (with the permanent guidebase attached and the guidelines threaded through the guideposts) is run down the guidelines into the hole.³ Care must be taken while the 30-in. casing is run to ensure that it is filled with water. Should this be overlooked, it is possible to collapse the 30-in. casing. It is run on, and cemented through, the drillpipe lowering string. Cement returns are taken on the ocean floor and may be observed on TV. To ensure a good cement job for this critical casing string, the cement may be overdisplaced by as much as 100%.

In Step 4, hole is drilled for the conductor casing. If the soil the structural casing was set in is competent, a riser is run and latched into the permanent guidebase, and drilling returns are taken on the drilling vessel. Riser top tension should be sufficient only to minimize lower ball-joint angle. Too much top tension could result in pulling the 30-in. casing out of the ground. If the soil is not competent, the riser is not run and returns are taken on the ocean floor. If the riser were used with incompetent soil, the hydrostatic head of the drilling fluid could break down the soil at the shoe of structural casing, resulting in lost circulation. The conductor hole may range in depth from 298 to 499 ft. The size of conductor casing commonly used has a 20-in. OD. If the riser has been used, it is pulled before the conductor is run.

Running 20-in. Casing

In Step 5, the 20-in. conductor is run down the guidelines on drillpipe, landed in the housing on the structural casing, and cemented back to the ocean floor.³ The top of the 20-in. conductor is fitted with a 16¾- or 18½-in. high-pressure wellhead housing prepared internally to receive subsequent casing strings. The size of the casing head is determined by the size of the BOP's on the drilling vessel. The external profile on the upper end of the casing head is prepared to match the type of wellhead connector installed on the BOP stack. A metal-on-metal seal ring provides the pressure seal between the connector and wellhead.

Running the BOP

Step 6 consists of function- and pressure-testing the BOP stack on the deck, then running it down the guidelines and latching it to the casing head.³ The BOP's, which can weigh as much as 400,000 lbm and range in height from 30 to 40 ft, normally are run on the drilling riser. Depending on water depth, running the BOP stack can be a short or long procedure (from a few hours to several days). Each riser joint must be carefully inspected as it

STEP 6 BOP'S INSTALLED READY TO DRILL TO T.D.

Fig. 18.19—Floating drilling—subsea systems.

Fig. 18.20— Dynamically positioned drillship.

is run. Each riser connection must be checked for correct makeup. The total weight of the BOP is supported by each connection. Integral K&C lines (and hydraulic supply line if it is hard-piped) should be pressure-tested every second or third joint to avoid an unnecessary pulling of the BOP for leak repair. In addition to careful riser inspection, riser handling tools and the riser spider should be inspected for cracks or damage. The riser handling tool supports the total weight of the BOP and riser each time another joint is added to the string. The top of the riser is fitted with a slip joint to accommodate vessel heave and offset. The slip joint lands in a diverter housing immediately under the rotary table. Riser tensioning lines are connected to the slip-joint barrel so that tension can be applied to the riser when the stack is landed on the wellhead. Once in place, the stack is function- and pressure-tested, and all is ready to begin drilling to total depth (TD). As hole is drilled, additional casing strings may be run through the riser and BOP's. Periodic BOP testing after the first casing string is landed in the wellhead housing must be done carefully. A leaking casing-hanger-seal assembly could collapse the casing if test pressure exceeds casing-collapse pressure. API RP 53⁶ includes testing guidelines. If the well is to be put on production, the tubing string also is run through the BOP's and hung off in the casing head.

Drillstem Testing

Drillstem testing (DST) requires specific equipment not normally installed on floating vessels. An inside-the-BOP production tree includes redundant master valves and a surface-actuated hydraulic latch for emergency disconnect, high-pressure piping and valves from the choke manifold to production-equipment area, test trap with metering equipment, storage tanks with transfer pumps, and a flare boom. This equipment requires considerable space. Storage-tank location may require beefing up the local deck structure. Flare booms require special foun-

dations. Installation and operation of production well-test equipment requires planning and significant rig-up time.

The BOP production tree space-out is critical. The tree lands in the subsea wellhead housing, and BOP pipe rams seal the casing tubing annulus. The tree height, including the emergency disconnect mandrel, must not extend above the bottom of the blind shear ram. In case of emergency disconnect, the blind-shear-ram area must be clear for shut-in.

DST is a critical operation. It must be conducted under carefully controlled conditions. If H_2S is possible in the production, special precautions are necessary. Local regulations and API RP 49 cover H_2S requirements.¹⁰

Plug and Abandonment

If the decision is made to abandon the well, it must be plugged first. Local regulations dictate plugging details. Abandonment plugging generally consists of laying cement plugs in the wellbore at specified intervals to just below the ocean floor. The plugs are pressure tested as they are installed.

Next, the subsea wellhead and bases must be recovered. This is accomplished by cutting the casing strings approximately 15 ft below the mudline. Cutting can be done with mechanical cutters (tools are available that can cut 13 $\frac{3}{8}$ -in., 20-in., and 30-in. strings in one step) or with explosives. If explosives are used, the rig may have to be moved several hundred feet away from the wellhead, depending on water depth, so that the explosion shock wave won't damage the vessel's hull. Retrieved wellhead equipment and bases can be reconditioned and reused.

Special Considerations

Deepwater Drilling

Maximum water depths continue to extend. During 1983, a well was drilled in approximately 6,800 ft of water off the U.S. east coast. Locations in water depths greater than

Fig. 18.21—Thirty-inch casing with helical strakes.

2,000 ft should be considered deep water. Mooring becomes more difficult, subsea equipment is heavier, collapse under hydrostatic conditions becomes critical, equipment performance under emergency disconnect conditions, and well-control procedures require additional considerations.

The major differences in shallow vs. deepwater floating drilling equipment are station-keeping (moored vs. dynamic positioning), riser design (material strength vs. buoyancy needed), BOP control systems (hydraulic vs. multiplex), and backup systems (diver vs. unmanned).

Deepwater operations require longer calm-weather periods and improved weather forecasting to accomplish specific tasks. Running and retrieving BOP's can take just a few hours in shallow water. In deep water, 2 or even 3 days may not be unreasonable. Relatively calm sea conditions are required during that time.

Dynamic-positioning (DP) systems have extended station-keeping capabilities to depths of more than 10,000 ft. DP systems consist of acoustic beacons located on the ocean floor, hydrophones mounted on the vessel's hull, thruster units fore and aft, and an on-board computer system for control. Dynamically positioned drilling vessels are equipped with from 12,000 to 20,000 hp for station-keeping. Increased fuel consumption while operating in the DP mode is a major cost increment in a rig's day rate (see Fig. 18.20).

Cold Environment

A few special cold-weather drilling vessels are available today. However, most rigs operating in cold environments today were not designed with low-temperature steel requirements. Highly loaded or highly stressed components—such as the derrick substructure, lifting subs, riser running tools, riser connectors, and elevators—must be fabricated from steels with low-temperature resistance (Charpy impact values comparable to the temperatures encountered) if they are to function safely. Material specifica-

tions of highly loaded components should be checked and verified before an unknown rig is taken into a low-temperature work situation.

Other cold-weather equipment considerations include quarters, insulation and heating, work-area heating, control-fluid freeze protection, water-system freeze protection, water-tank heating, and superstructure de-icing capability.

The American Bureau of Shipping specifies requirements for ice-class rigs.¹¹ Those specifications include hull strength in the ice zone, thruster or propeller protection from ice chunks, and other specific requirements that must be met before a rig (ship or semisubmersible) can be certified to work in ice areas.

High-Current Drilling

The first concern in drilling high-current locations is station-keeping. Does the mooring system have adequate strength, or the dynamic-positioning system adequate horsepower, to keep the drilling vessel on the location? With the mooring analysis previously discussed or with more sophisticated techniques to evaluate dynamic-positioning station-keeping, we can determine the adequacy of the proposed rig's station-keeping system.

The next concern is possible fatigue failure of 30- and 20-in. casing strings (generally in a connector) owing to vibration. High currents can cause vibrations that induce failure in hours under the right conditions. Any surface current of more than 3 knots should be considered high current. Casing strings of 30 and 20 in. have been fabricated with helical strakes to break up the vortices that cause the severe vibrations (see Fig. 18.21).

Vortex shedding, which causes high-amplitude vibration at 90° to the direction of the current, can create severe problems in drilling risers also. Riser fairings have been developed and used on several occasions to eliminate the troublesome vortex-shedding vibrations successfully (see Fig. 18.22). Special equipment, in addition to

Fig. 18.22—Riser vortex shedding.

strakes and fairing, can be installed on the drilling vessel to allow successful drilling operations in high-current areas. A floating rotary table and a moonpool riser-centralizing system have been developed to accommodate the high loads and high angles imparted on pipes and risers during high-current periods. If current direction is fairly consistent, installing early-warning current-meter strings 2 to 3 miles upstream from the rig can greatly assist in coping with the oncoming current conditions.

Structures

Background and Philosophy

As exploration and production encroaches into deeper water and harsher environments, the challenges of structural design increase. Environmental load predictions, transportation analyses, and installation procedures are as important to understand as the more obvious structural-frame analysis. Seldom is a designer afforded the luxury of optimizing a structure on the basis of in-place stress analysis. More often, the transportation and installation (lasting a few weeks out of perhaps a 20-year structure life) will dictate the major framing patterns. Equally disconcerting to the structural designer is that most of his accomplishment is seen by only a handful of people, especially once it is in place. For the structure's lifetime, it is expected to support drilling and/or production operations, and the operator cares little beyond that.

So the structural engineer's job can be simply defined as getting it designed, built, and in place as quickly and economically as possible, while ensuring functionality and providing for minimal maintenance.

Structure Classification

As indicated in the Historical Review, many types of offshore structures are in service. Some are better suited to certain environmental and operational criteria; some are limited by availability of construction sites; and some are chosen simply by subjective preference of an owner/operator. Selecting a structure type is the first major structural design task after environmental and operational criteria have been defined and might require preliminary design of several concepts before a choice is made.

Template/Jacket. "Template" was derived from the function of the first offshore structures: to serve as a guide for the piles. The piles, after being driven, are cut off

above the template, and the deck is placed on top of the piles. The template is prevented from settling by being welded to the pile tops with a series of rings and gussets. Hence, the template carries no load from the deck but merely hangs from the top of the piles and provides lateral support to them.

Some companies prefer to place packers in the bottom of each template leg and to grout the annular space between the leg and pile from bottom to top. The structure and piles share the axial load from the deck and the compressive and tensile loads from the overturning moment produced by lateral wave loads. The grouted pile also provides additional strength to the tubular joints where horizontal and diagonal bracing are welded to the legs. Drawbacks to this system are the difficulty in ensuring that the grout is adequately placed and of sufficient strength to be counted in the analysis and the additional difficulty in platform removal.

Although both top-hung and grouted structures are loosely called templates, some prefer to call the latter a jacket to distinguish the difference in load path. This path is substantially different for the overturning moment as well as axial loads. The top-hung template requires that moment from lateral wave loads be transmitted up the structure to be resolved into axial pile loads. The grouted jacket has a direct downward load path for shear and moments. The novice designer would do well to learn this distinction early in his career.

When steel structures are designed for deeper water (in excess of 250 ft), pile-leg grouting is prevalent. Deep-water jacket designs are heavily influenced by lateral wave loads that produce high base shear and overturning. Piles placed through the legs of the jacket are not always sufficient to transfer these loads to the soil, so "skirt piles" are added, normally in clusters around the corner legs. This adds a new dimension to the installation procedure. Pile guides are required up to water level, and a removable "follower" must be used during pile-driving operations. Grouting procedures for the skirt sleeve-to-pile must recognize that grout placement and inspection will be done remotely.

Template/Jacket Construction. A typical construction sequence for a template or jacket calls for yard constructing the unit on a pair of skid rails, skidding the structure onto a barge with matching skid rails, towing the barge to location, and launching. After the structure comes to

rest, usually floating horizontally, it is upended by ballasting members at the lower end. Once upright, it is moved onto the final site and lowered to the seabed by continued ballasting.

To date, the maximum water depth feasible for a single-piece jacket appears to be about 1,000 ft. The constraint is a result of construction equipment and facility limitations, although contractors are quick to point out that capability can be extended quickly if the business climate warrants. Meanwhile, an alternative for deeper water is the multipiece structure. These structures are built in either two or three pieces that are launched from separate barges. The pieces can be mated while floating horizontally, like the Hondo¹² platform, or stacked vertically and grouted together with pin piles, like the Cognac¹³ platform. Mating of large structural sections has proved to be expensive and involves added risk over single-piece structures, so plans are under way to extend single-piece construction to water depths beyond 1,000 ft.

Yard facilities are tailored to build structures in the horizontal position. Lifting equipment is huge in both capacity and reach because a deepwater structure might have a base width of more than 200 ft, which would require lifts to be placed to the height of a 20-story building! A structure for 1,200 to 1,500 ft of water could have a base width of more than 300 ft, which is beyond the reach of today's equipment.

Since 1975, several large transportation barges have been built with lengths of more than 600 ft and capacities of 40,000 tons. Such a barge was used to place the single-piece Cerveza¹⁴ platform in 935 ft of water. Several installation contractors now have plans for "super barges" with lengths of 900 to 1,000 ft and the capability of transporting jackets more than 1,500 ft long.

The increased pile loads on deepwater structures have necessitated advancements in pile-placing technology. In 1960, driving a 48-in. pile to 300 ft penetration for an axial capacity of 2,500 tons was a major feat. In 1984, a designer can plan for an 84-in. pile driven to about 400 ft to develop an axial capacity of 15,000 tons. Most of the advancement has come in the area of pile hammers. Hammers can be built to energy levels of 1.2 million ft-lbf, nearly 10 times that of the hammers used in 1960. Also, underwater hammers are becoming more dependable, which has the advantage of eliminating pile guides and followers for skirt piles and saving the energy normally lost through the follower.

Concrete Gravity Structures. As the name implies, these structures have large mat foundations instead of piles and are heavy enough to resist overturning and base shear from lateral wave and wind loads. Whereas steel template/jacket technology was largely a product of the U.S., the concrete gravity structures were European designs. Three reasons are offered for the emergence of these designs: (1) the European countries with offshore oilfields demanded a high percentage of national content—i.e., design and construction money had to be spent within their borders; (2) European design expertise, construction facilities, and construction skills leaned heavily toward concrete and away from steel; and (3) template/jacket technology was not prepared for the huge payloads and severe environment of the North Sea. The first major steel structure met with severe design changes and inadequate

fabrication and transportation facilities and was finally placed with high cost overruns. The high cost overruns of the first steel structures opened the door to concrete structures. Although these structures also ran into severe cost overruns, they had the advantage of not being payload-sensitive.

The concrete structures were necessarily massive to resist overturning. Furthermore, the concrete members were often controlled more from pressure than from axial forces of the deck load. Hence, changes in the payload requirement that occurred during construction and even for years after placement could be accommodated with relative ease. This proved valuable as the prolific North Sea fields were developed and facilities were continually added to existing structures.

Most concrete gravity structures were designed to store crude oil until it could be loaded on a transport tanker. This was required in the early stages of development because building an adequate pipeline network for the North Sea took many years. Only a few of the structures still are used for oil storage, and tanker-loading systems are active only in Norwegian fields where a deep coastal trench has delayed pipelines from coming ashore.

Concrete structures have two basic shapes. The French design generally consists of a large, vertical, cylindrical structure surrounded by a perforated wall. The internal structure is capable of storing oil and supports the center of the deck structure. Typically, the perforated wall has 6.6-ft-diameter holes at 13-ft spacing that allow seawater to flow through as the wave passes, thereby reducing the wave force. The wall ends about 33 ft above the water level, and bracing extends up to support the edges of the deck.

Gravity Platform Construction. Concrete structures are nearly always built vertically. The lower portion of the base is built in a graving dock. The dock is flooded to sea level, thereby floating the base. The gate or dike is removed and the structure is towed to a protected deepwater site in a fjord or firth. The remainder of the structure is built by use of slipform methods and increases in draft as construction continues. If the platform has been designed for 450 ft of water, the draft of the completed substructure might be 300 ft.

Meanwhile, the deck is built, outfitted, and skidded onto one or two barges, depending on the configuration. Substructure and barge-mounted deck are towed to a mating site where water depth exceeds the design depth. The substructure is ballasted until only a few feet are above water. The barge-mounted deck is towed carefully over the substructure, and the substructure is deballasted until it picks the deck off the barges.

After the mating is complete, the platform is deballasted to minimum draft for towing to location. Minimum draft is still deep—perhaps 350 ft—and is limited by platform stability; further deballasting would raise the platform until it became top-heavy and toppled over.

The tow to site is nearly as critical as the mating operation. The tow route must be carefully surveyed, charted, and marked. Deviation from this route could result in stranding the structure on a sand bar or hitting a submerged canyon wall. A fleet of the world's largest tugboats is required to tow the platform safely. Power, steerage, and standby tugs must all respond to the direction of the tow master.

Fig. 18.23— Tension leg platform

Once on site, ballasting will set the structure on bottom, and grouting fills any voids under the base. Offshore construction and hook-up time can be held to a minimum because onshore deck construction should have included commissioning most of the systems.

Guyed Towers

The guyed tower is intended for use in deep water—perhaps 1,000 to 2,000 ft. It applies the principle of “compliance” to wave forces. Wave forces are cyclic in nature, pushing a structure first in the wave direction and then against it. By pinning the structure to the seafloor instead of making it a fixed cantilever, the guylines allow the structure to sway back and forth with the wave force, transmitting only small loads to the foundation. The guyline system holds the tower upright and resists the steady forces from wind and current. Depending on the size and configuration of the guyline system, the tilt an-

gle of the tower can be restrained to 2 or 3°. The Lena platform in the Gulf of Mexico is the only guyed tower built and in service to date. Twenty-four guylines support the structure; their diameter varies between 5 and 5½ in.

The vertical support system resembles the template in that the tower is welded to the top of the piles and hangs in tension. The piles carry the deck load directly and, in addition, the vertical component of the guyline tension.

An additional, undesirable, axial load is caused by the tilting of the tower. The piles on one side compress as the tower tilts, and on the opposite side they stretch. The resulting stress cannot be eliminated, only controlled. The piles are clustered near the center of the tower to reduce the stretching and compressing. The system can be designed successfully by limiting the tilt angle and providing sufficient pile length to absorb the compression.

As the tower tilts, the piles must bend through the tilt angle in a relatively short distance near the mudline. The stress can be controlled in this case by locating the guides properly and determining the stiffness of the soil. The influence of the tilt angle on the pile stresses must be evaluated before the guyline system is sized.

Guyed Tower Construction. The guyed tower is lighter and more slender than a jacket would be for the same depth. Therefore, yard and transportation equipment can handle a guyed tower for depths greater than that for a template. Installation procedures, however, are more complex because of the heavy guyline system and the large piles.

After the tower is upended and set on the seafloor, buoyancy must hold the structure upright until the guylines are installed. A derrick barge is needed for driving piles, placing the deck, and setting equipment modules. This barge normally relies on its own mooring system for station keeping, but in this case, some modification will probably be required to prevent the tangling of mooring lines with guylines. The entire installation sequence must be planned carefully to ensure safety of the structure, guyline system, and floating equipment.

Tension Leg Platform

The tension leg platform (TLP) is another structural system based on the “compliance” principle. The platform is composed of a deck structure and a buoyant hull that is made up of a series of vertical cylindrical columns, horizontal submerged pontoons, and tubular member bracing. The platform is tied to the seabed by a number of tendons that are kept taut by excess buoyancy in the hull. Fig. 18.23 shows a TLP designed for 1,600 ft of water. Four vertical 52-ft-diameter columns are tied together with 28-ft-diameter pontoons, and four tendons at each corner column (16 total) tie the platform to the seafloor foundation template.

To date, the Hutton platform in the North Sea is the only TLP in service. It was placed in only 485 ft of water, although the TLP is considered by many as the most promising structure for water depths from 1,000 to 4,000 ft.

Because the TLP is lightly restrained horizontally, steady forces from wind and current will cause large excursions of about 5 to 10% of water depth. Second-order wave forces, insignificant on fixed platforms or guyed

towers, can cause substantial steady offset and "slow-drift oscillation" at the natural surge period of 60 to 120 seconds.

The tendon system and well system on the TLP are the most structurally critical and set the limits on horizontal excursion. Often containing flex joints or tapered cantilevered pipe sections, these systems require careful analysis both for maximum stress and for fatigue life.

The foundation system is subjected to cyclic loads superimposed on a high tension. This system also requires careful analysis based on the best possible geotechnical data for the site.

TLP Construction. The TLP is structurally similar to the common semisubmersible drilling structure, and most efforts to design it differently or to different standards result in extreme cost and schedule overruns. The size of the TLP is related directly to the payload required and the environment it will withstand. This normally means that the displacement (buoyancy) will be between two and five times that of a semisubmersible. Therefore, many shipyard facilities used for semisubmersible construction will be too small for a TLP.

Two distinctly different construction methods are available. The first is separate construction of the deck and hull, requiring a mating sequence similar to that described for a concrete gravity platform. The second method is single-piece construction where the deck is built onto the hull and equipment placed on the completed platform. The first method offers reduced construction time; the second allows for intermediate structural bracing to support the deck because clearance is not required for a barge. The choice between these two construction methods must be made early in the planning stage to take advantage of the benefits afforded by either concept.

The most difficult and uncertain part of TLP construction is the placement of the seafloor template or templates and the piling. Again, several options are open—a single template for the foundation and well system or separate templates. Tendons may be attached to the template or directly to the piles. Again, each system has advantages and disadvantages, and all aspects of allowable tolerances, seabed levelness, potential for settlement, and preference for separate structural systems should be considered.

Special-Service Structures

Many structures have been built for a specific location or specific purpose and are essentially one of a kind or perhaps one of a select few. Self-floating jackets, steel gravity platforms, tanker-mooring articulated towers, mooring dolphins, and single-well caissons are some special-service structures. Each of these concepts and the innovative effort that went into them deserves a chapter in a book, but unfortunately there is not room here. The author recognizes the effort needed to learn the special hydrodynamics, structural dynamics, stress analysis, and construction methods needed for a unique design. Many unheralded innovative engineers have gone virtually unnoticed because their structure, though successful in the purpose for which it was intended, simply was not needed anywhere else.

Structure Selection

From the preceding discussion, it should be obvious that the chosen structure is not always the one that theoreti-

cally has the least concrete or steel. Construction facilities and skills in the area are important, and often the operator's preference will prevail. Here are some guidelines, though, on the four concepts discussed.

Template/Jackets. Around the U.S., these structures are the norm for water depths from 10 to 1,000 ft. Most U.S. offshore structures have a payload based on less than 50,000 B/D production. These small payloads are conducive to templates and jackets. Future technology might push these structures to 1,500 ft of water; limitations will be based on the structure's natural period and cost.

Concrete Gravity Structures. These structures require deepwater construction sites in protected water. Norway and England have such sites; the U.S. does not. These structures can readily carry the equipment for up to 200,000-B/D production. The North Sea will probably need more structures with these production rates; we hope the U.S. will also. Depth limitation is probably around 700 ft, unless new construction methods are developed.

Guyed Towers. These structures should be good for deep water and heavy payloads. Because deckloads are carried directly by the piles and only indirectly affect the tower and guyline system, heavy payloads should not cause a substantial increase in structure costs.

TLP. These structural systems should be relatively economical for deep water and light payloads. Increased payload directly affects buoyancy requirements, which in turn directly increases waveloads and tendon and foundation requirements. Conversely, deeper water requires only longer tendons. With a design based on realistic understanding, this concept could be extended to a 4,000-ft water depth.

It will be interesting to see how the future will bring about changes.

Structural Design Process

As previously indicated, there are many types of offshore structures, but the following example will be confined to a barge-launched jacket. The considerations and procedures, however, have a parallel in the design and construction of any structure.

Methods for determining environmental loads and for analyzing structures are outlined in API RP 2A, "API Recommended Practice for Planning, Designing, and Constructing Fixed Offshore Platforms." This document is one of a series of recommended practices that are reviewed frequently and reflect the state of the art.

Fig. 18.24 shows a rather large offshore jacket for about 500 ft of water. Drilling and production facilities are assumed to be in modules for placement on top of the module support frame.

The structure must be designed for a variety of conditions, including fabrication, transportation on a barge, launching, upending, placement, and operation. Each condition controls the size of some members. The members controlled by in-service conditions may require several separate analysis procedures to size them adequately.

Field Development Plan. To put the design process in a time frame, Fig. 18.25 shows that portion of a possible field-development program that relates to the jacket,

Fig. 18.24—Jacket members as sized by design conditions.

recognizing that facilities design and construction are parallel. The economic studies are to determine the viability of the program and must include a preliminary design of the jacket to determine a cost estimate. Analysis will probably be limited to a single topside load and the maximum storm wave, using a first guess at water depth, wind speed, wave height, and current velocity.

Environmental Criteria. As the design progresses through two or three of the cycles shown in Fig. 18.25, more exact environmental data will be needed, and the oceanographers probably will be working to firm the data up in parallel with the design. Close coordination between the designer and the oceanographer is critical. The information must be available on time, sufficiently detailed, and in a format compatible with the design procedures.

Storm directionality might determine the orientation of the platform. Because of transportation requirements, a jacket is rarely symmetrical, so it will resist lateral wave loading better along one axis than the other. The pattern of well conductors is often dictated by the reservoir characteristics, however, so aligning the strong axis with the most severe storm direction is not always possible.

In addition to maximum storm criteria, statistical wave data and scatter diagrams are needed for fatigue, transportation, and launch analysis, and for determining weather windows for derrick barges that will be used for pile-driving and lifting modules. This information might point out a substantial seasonal variation in weather statistics that will dictate the time of year for installation. The designer should anticipate the required magnitude and format of environmental data and pass this requirement to the oceanographer early in the project.

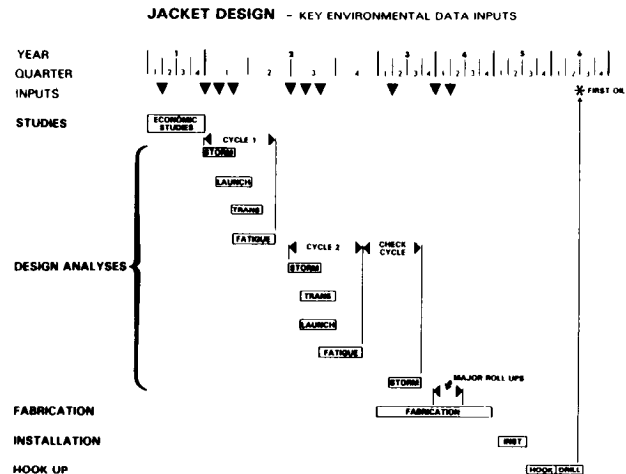

Fig. 18.25—Jacket design—key environmental data inputs.

In-Situ Analyses. The in-situ static procedure in Fig. 18.26 shows the loading systems applied to the jacket. The stiffness analysis assumes these loads to be static, and the results must be combined with the wave data and the natural periods of the structure to derive a dynamic amplification factor. The “combination processor” must combine static and dynamic loads to determine member and joint forces, moments, and displacements. These are then converted to stresses and compared with those permitted by the design codes. If the design is not acceptable, members and joints must be resized and the process repeated.

The linear stiffness analysis usually is adequate for the steel framework, but must be adjusted for the pile/soil interaction that is commonly nonlinear when extreme-event loads are applied. Various linearization techniques or iteration procedures are used to arrive at the correct pile displacement and rotation. This is probably the most difficult and critical area in the analysis because improper stiffness assumptions, either too high or too low, can result in a nonconservative structure.

Transportation and Launch. The approximate location where the structure is to be fabricated must be known to estimate the tow route and duration. Also, the season must be established so that sea-state predictions are appropriate. For Gulf of Mexico structures, tow routes normally are short, and weather forecasts often can cover the entire duration of tow and launch. For the west coast, fabrication might be in the orient, with a tow duration of 6 to 10 weeks. Thus, early construction planning is required for adequate design and analysis.

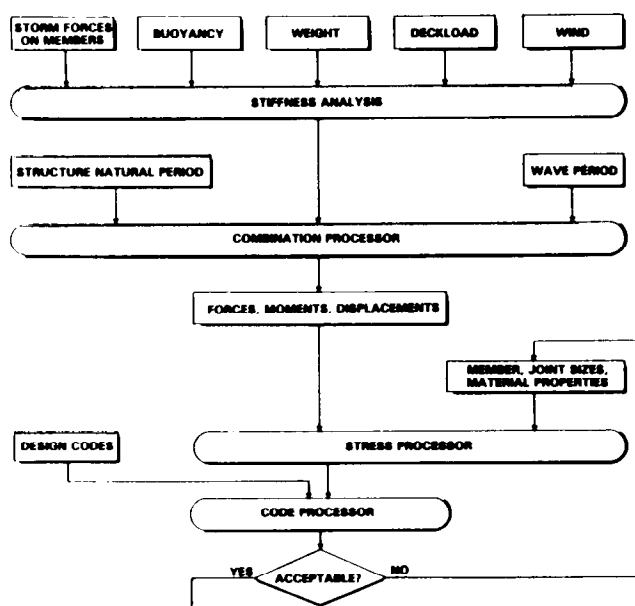

Fig. 18.26—In-situ "static" analysis.

The analysis procedure for both tow and launch is shown in Fig. 18.27. A wave-scatter diagram is used to define significant wave height and period combinations for the various sea states to be encountered. Barge motions can be determined either by analysis or model tests. Member accelerations, dead weight, and tiedown reactions can then be fed into the jacket stiffness analysis to determine stress levels for checking against design-code allowables.

The launch analysis requires a step-by-step simulation of the jacket tipping off the barge on the rocker arms until it is floating freely. Loads and reactions, including hydrodynamic loads on submerged members, must be retained for a stiffness analysis.

Fatigue Analysis. There are two distinct methods of fatigue analysis that are used in industry. The first and most easily understood is the deterministic analysis (shown in Fig. 18.28). This procedure will be described in some depth. The second method is spectral analysis, which involves a statistical prediction of stress magnitude and cycle distribution in each sea state and over the life of the structure. This method is gaining favor in industry but is too complicated to treat adequately in the context of this chapter.

The basic principle of fatigue damage is straightforward, although its accuracy is often debated. It states that for a given stress level, the fatigue damage, F_d , is equal to the number of applied cycles, n , divided by the number of cycles required for failure, N , or $F_d = n/N$. For example, if a steel can withstand 2.5×10^7 cycles at 10 ksi before failure occurs and 6.1×10^6 cycles are applied, then the damage is $F_d = (6.1 \times 10^6) / (2.5 \times 10^7) = 0.244$. This indicates that the member is 24.4% damaged. The common procedure for checking total damage is Miner's rule, which requires that the summation of all damage be less than 1.0. The recommended fatigue curves and al-

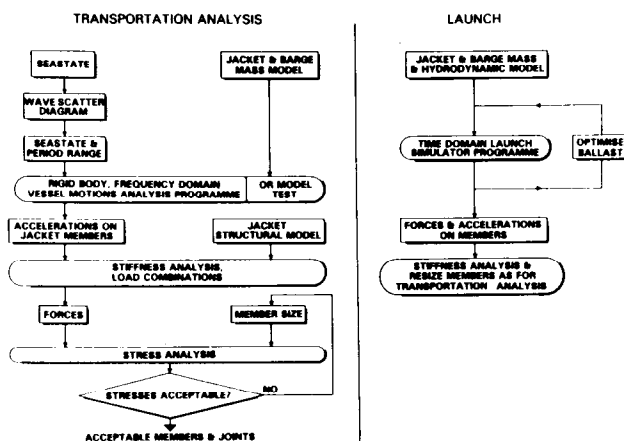

Fig. 18.27—Analysis procedure for tow and launch.

lowable cumulative damage can be found in API RP 2A. The fatigue curves show stress, S , plotted against the number of cycles to failure, N , and are often called $S-N$ curves.

If the natural period of the structure exceeds 3 seconds, API RP 2A recommends that a dynamic amplification factor (DAF) be included in the analysis. The DAF accounts for increased stress because of structural vibration. A complete dynamic analysis may be performed in lieu of using DAF's, but this can become extremely expensive.

Fig. 18.29 shows a spectral fatigue analysis that can be compared to the deterministic analysis in Fig. 18.28. Ref. 13 outlines this procedure.

The previous discussion covers most of the major analyses required for a platform, but don't be misled by the brevity. Between 75 and 100 complete stress analyses usually are required to determine stresses for in-place fatigue. Transportation fatigue might require twice that many. If seismic analyses are included, the total bill for computer time might exceed \$1 million for a thorough final analysis.

Other structures will have unique design and analysis problems. Generally, the same types of analyses are required, but they differ in areas of dynamic response or hydrodynamic loading. Ultimately, the extent and choice of the analysis procedure falls back to engineering judgment, and there is absolutely no substitute for experience.

Offshore Production Operations

Offshore production installations can be either very similar to or radically different from land installations. The purpose of this section is to provide a general overview that will acquaint inexperienced persons with typical designs and requirements for completing and producing wells offshore and describe alternative installations that are currently available to engineers and operators for meeting production objectives under varying conditions.

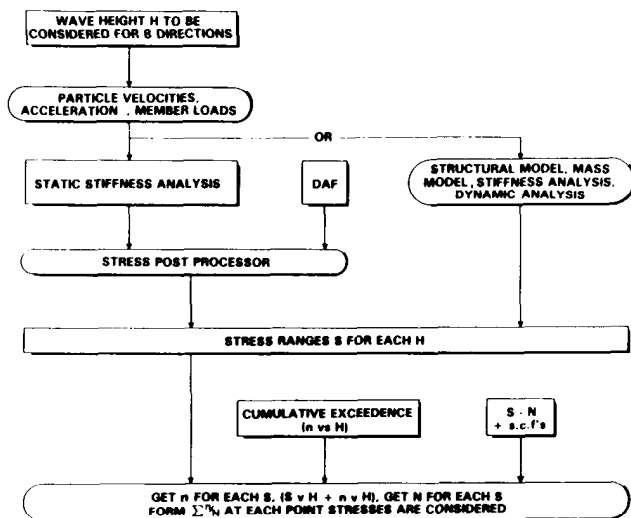

Fig. 18.28—Deterministic procedure analysis.

Platform Production

Well systems and crude-oil and gas process facilities installed on platforms account for more than 99% of current offshore production capacity. A small number of wells are completed on manmade islands. From a design and operating standpoint, these island wells are handled the same as platform wells. Wells that are completed sub-sea number fewer than 300 worldwide and will be discussed separately.

Well Completions. Except for a few innovative installations, wellheads and Christmas trees on platforms are basically the same as for land wells (Fig. 18.30). Control valves, safety valves, and piping outlets are configured the same and use the same or similar components. Some of the valves probably will have pneumatic or hydraulic actuators to facilitate remote and rapid closure in an emergency. Also, some Christmas trees may have composite block valves instead of individual valves flanged together.

The major difference, however, between land and platform well completions is the economic incentive on platforms to reduce equipment weight wherever possible and to minimize space requirements. Simply put, lighter, smaller equipment and more compact installations result in less-expensive platforms. A good example is the use of composite block valves to reduce Christmas-tree size and weight. Another example is the spacing of wellheads as close together as drilling operations will permit, with just enough room for safe and efficient operation of tree valves, control valves, and well-workover equipment. Typically, this means centerline distances of 6 to 10 ft between wellheads.

Where only one drilling rig is on a platform, all the wellheads usually are located in one bay. Larger platforms that are designed to accommodate two drilling rigs may have two well bays (one for each rig) with two or more rows of wells in each bay.

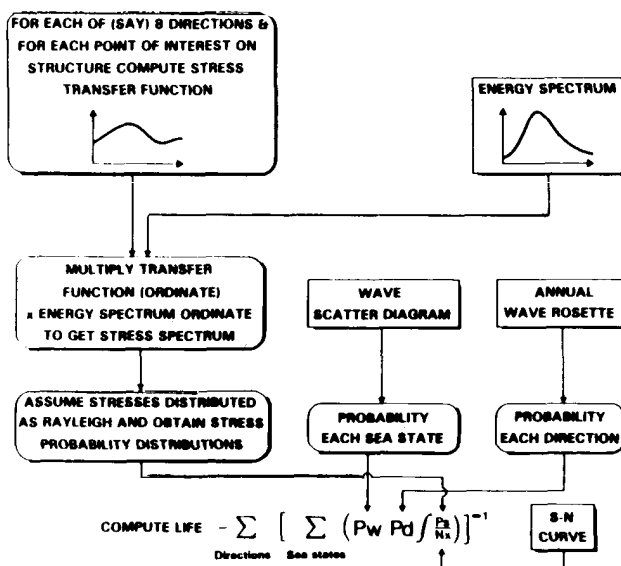

Fig. 18.29—Spectral fatigue analysis procedure.

Process Equipment. The primary function of process equipment, whether on a platform or on land, is to stabilize produced fluids and to prepare them for shipping or disposal. Well production is separated into components of oil, gas, and water (and sometimes condensate). The separated fluids are measured and then either shipped, injected back into the reservoir, or flared.

Differences between the process equipment (oil and gas separators, free-water knockouts, gas scrubbers, pumps, compressors, etc.) installed on a platform and those installed on land are minor (Fig. 18.31). Where possible, consideration is given to using vessels and machinery that are compact and lightweight—e.g., electric motors are commonly used instead of gas engines for driving pumps and compressors. Vertical clearance between decks may impose height limitations and dictate, for example, the use of horizontal instead of vertical separators.

There is a major difference, however, in the way equipment is packaged. If it is to be installed offshore after placement of the platform jacket and decks, process equipment usually is built in modules at a land site. The module assemblies then are barged offshore, lifted onto the platform, and hooked up. This significantly reduces expensive offshore installation and hookup time. In any event, the equipment and its piping, wiring, and controls are installed as compactly as possible. The extra engineering and fabrication costs needed to reduce deck area to an absolute minimum are more than offset by savings in platform structure cost.

Well Servicing and Well Workovers. On relatively small platforms with no more than 5 to 10 wells, it is common practice in some areas to drill all the wells before any of them is placed on production. The drilling rig is removed after the last well is drilled, and future well workovers are performed with a portable workover rig or well-pulling unit. Downhole work that does not require pulling tubing (e.g., replacing safety valves, gas lift valves, or standing valves) normally is accomplished with a wire-line unit.

Fig. 18.30– Platform well bay

On larger platforms with more wells, drilling and production operations generally are carried on concurrently. In this case, well workovers are performed by the drilling rig if it is still on the platform. Depending on the urgency of the workover and on economic considerations, the work typically is scheduled to follow completion of the well that is currently being drilled. Wireline repairs can be performed without interfering with drilling operations unless the two wells involved are too close together for safety considerations.

Even on the largest platforms, drilling rigs normally are removed after all scheduled wells have been drilled. Depending on the number of wells and the amount of downhole work anticipated, a special workover rig may be installed permanently on the platform. An economic comparison between using a portable rig and using a permanently installed rig should be the basis for selection.

Crude-Oil Disposal. In the great majority of cases, crude-oil production is “shipped” from platforms by subsea pipelines. Because most offshore producing areas involve multiple platforms and more than one operating company, the pipelines are generally common carriers.

In the simplest of installations, where a pipeline transports only one type of crude oil from a single platform, an optimum pipeline design and installation can be involved and expensive. Numerous factors must be evaluated, such as seawater temperature, seafloor profile and geologic features, water currents between surface and

seafloor, hazards from commercial fishing equipment and boat anchors, the possible need for a weight coating such as concrete to ensure negative buoyancy, cathodic protection, corrosion-prevention coatings, water depth, the possible need for burial beneath the seafloor, the type of beach crossing that will best protect the pipe and also be environmentally acceptable, the best riser to use at the platform to afford protection from corrosion and physical damage from boats and waves, total length of pipeline, pumping rates and pressures, the need for periodic pigging and inspection, safety shutdowns to prevent or to minimize pollution in the event of failure or accident, and the crude-oil properties and rheology. When crude oil is shipped from more than one platform, a more detailed study of rates and pressures will be required, and if crudes from different reservoirs are being pumped through the same pipeline, a much more detailed study of oil properties and rheology will be necessary.

Depending on pipe diameter, length, need for burial, need for coatings and cathodic protection, water depth, and various construction considerations, an offshore pipeline can be the single most expensive element of an offshore installation, sometimes far exceeding the cost of one or more platforms. In the great majority of cases, however, piping is still the safest, most economical way to transport crude-oil production to a land site.

Occasionally, an offshore oil field is too remote, production rates are too low, or the field is too short-lived to justify a pipeline economically. The alternative is to

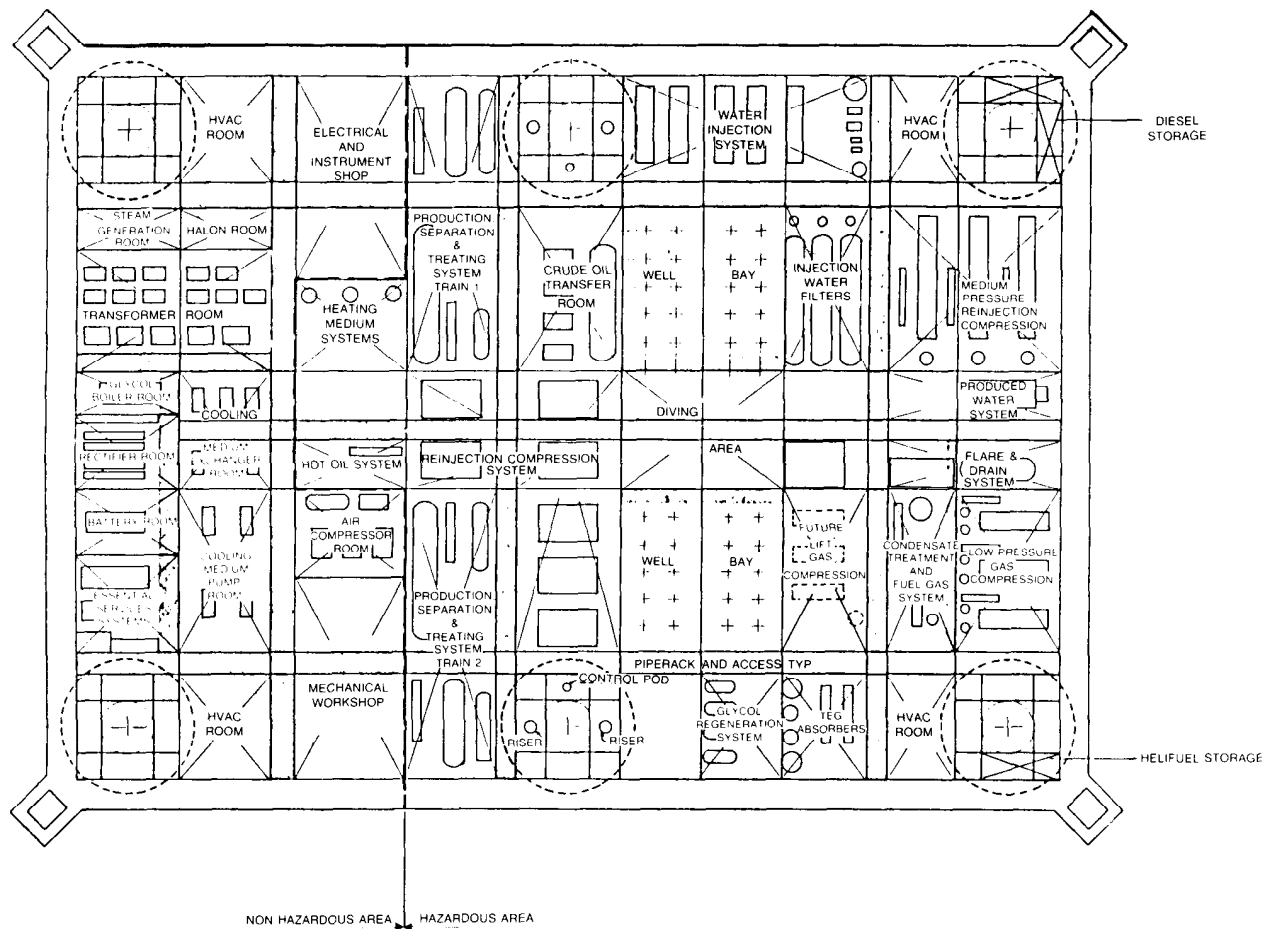

Fig. 18.31—Platform deck layout for process facilities.

ship the oil by tankers. This usually requires some type of loading system installed 1 to 2 miles from the platform, such as a moored buoy or articulated loading tower. A seafloor pipeline connects the loading facility to the platform, and a tanker is moored to the loading facility during the transfer of oil.

The two most important drawbacks of a tanker-loading operation are sensitivity to weather and the need for separate oil storage. Tanker loading is best suited to mild-weather areas to minimize downtime from storms. Oil storage requirements will depend on total field producing rates and reservoir characteristics (can the wells be shut in for short periods without loss in productivity) as well as tanker downtime. This has led to the development of permanently moored storage tankers.

Gas Disposal. Disposition of gas from an offshore production site will depend on a combination of reservoir and economic factors. If well production is primarily oil, the gas may be handled as a byproduct and be disposed of in the most economical way. Piping the gas to a land site for sale and use as fuel is generally preferred if it can be done economically. Injection back into the producing formation is a common alternative. This helps to maintain reservoir pressure and conserves the gas for possible fu-

ture sale. In some areas, gas flaring is still acceptable, but many countries now forbid it except for short test periods and for the disposal of small amounts of residual waste gas.

Water Disposal. Produced water is normally cleaned so that it may be either discharged offshore in accordance with governmental regulations or reinjected. In either case, a combination of mechanical and chemical means may be used to condition the produced water before disposal. Tankage and filtration are used to remove oil and other contaminants from the water. Chemical treatment is common to control bacteria and corrosion in injection wells.

Subsea Completions

Seafloor well completions occupy a very small niche in the offshore petroleum industry, but they attract a lot of attention. Their primary use has been as single satellite wells producing to a nearby platform. They are a means of producing field extremities that cannot be reached by directional drilling from an existing platform and where the economics do not justify the installation of one or more additional platforms. Some multiwell templates and piping manifolds have been installed that go beyond the satellite well concept.

The main benefit of subsea completion efforts is that the petroleum industry and political governments now recognize and accept them as a technically viable means for producing offshore oil and gas wells. This, in turn, means that future installations can be evaluated on the basis of actual field experience and realistic economic considerations. Subsea completions probably will increase in popularity in coming years, especially if significant discoveries are made in deep water where conventional platforms are either extremely expensive or impractical.

Wet vs. Dry. Seafloor installations are made either with the equipment protected by a dry, one-atmosphere pressure chamber (Fig. 18.32) or with the equipment exposed to the sea environment (Figs. 18.33 and 18.34). The dry chambers are large enough for workmen to install and to repair valves, flanges, and control systems in a shirt-sleeve environment. Access is by way of a diving bell lowered from a work boat. Successful installations have been made in water depths greater than 500 ft.

Most subsea completions are of the wet type and require varying amounts of diver intervention during installation and removal of the seafloor equipment. Minor repairs and trouble-shooting can sometimes be accomplished in place, but major equipment or control-system repairs are made above water after the faulty equipment is removed. Running tools operated from a floating drilling or workover rig are used for installation and removal of well completion equipment in much the same way that drilling operations are conducted when running and retrieving a BOP stack for a subsea well. Wet well completions have been made in water depths greater than 1,300 ft, and a satellite system has been constructed in 2,500 ft of water. The latter is designed to use tethered, remotely operated vehicles with manipulators instead of divers for trouble-shooting installation problems and for assisting with repairs.

Single Satellite Wells. Functionally, seafloor well completions are no different than wells on platforms or land. Completions in shallow water where divers are used extensively for installing the equipment may even look like land wells.

In deeper water, however, where diving requires expensive saturation systems for the divers, more reliance is placed on equipment that can be installed and removed with special tools that are run and operated from a floating drilling rig. Hydraulically actuated wellhead connectors are used instead of flanged or clamped connectors. Tubing hangers that can be locked in place and tested remotely are used. Precise equipment systems that can be remotely connected and disconnected and that permit personnel on the drilling rig to test and to function all of the wellhead equipment are required. Hydraulic controls are generally used for this work. The result is a Christmas tree that may be 20 to 40 ft tall when combined with its drilling bases and that may cost several times more than a land tree.

One very important requirement for subsea-well-completion equipment is that it be totally compatible with the drilling equipment that is used in drilling the well (Fig. 18.35). This requires extensive pre-engineering and preplanning between persons responsible for the drilling, completion, and producing operations.

Fig. 18.32—Subsea tree—dry type with diving bell in place.

Fig. 18.33— Subsea tree-wet type.

Multiwell Templates. A seafloor template with guide posts and wellhead receptacles for more than one well is suitable for drilling a number of satellite wells in close proximity to one another. Minor cost savings are realized during drilling operations because the drilling vessel does not have to be moved and reanchored between wells. Any slight adjustment in position can be accomplished by taking in or letting out opposing anchor lines. A major savings in flowlines may be possible by commingling well production at the template and transferring it through one large pipeline instead of individual flowlines. Well testing can still be accomplished by installing one separate flowline with a valve manifold for switching wells. Multiwell templates offer additional opportunities for reduced costs for control systems, gas-lift piping, and water-injection piping. Obviously, potential cost savings will be the greatest with a large number of wells. Multiwell template designs should consider poten-

Fig. 18.34— Exploded view of diverless subsea tree and running tools.

tial hazards from accidentally dropped tool joints or other heavy equipment during drilling operations. This may be a deterrent to producing completed wells until all wells in the template have been drilled. For a large template with many wells, this would have a significant effect on cash flow. A detailed economic analysis of all relevant factors is essential to determine the optimum size and configuration of a multiwell template.

Manifolds. One technique for combining some of the advantages of single satellite wells with the piping savings for multiwell templates is to produce moderately spaced satellite wells to a central, seafloor manifold installation (Fig. 18.36). The manifold would include valves and controls to commingle or test each well selectively and would reduce overall piping- and control-system costs if platform process facilities are located several miles away. Both dry and wet manifolds have been successfully installed and operated.

Fig. 18.35—Sequence drawings for drilling and completing a subsea well and for well re-entry workover.

Flowlines and Control Lines. Subsea satellite wells may be installed with either one or two flowlines, depending on well conditions and operating requirements. The production flowline is usually 2 to 6 in. in diameter. Size is dictated primarily by flow rate, flowline length, and wellhead pressure. A second flowline frequently is installed for communicating with the tubing/casing annulus. This line is effective for monitoring annulus pressure and for circulating kill fluid if needed. It can be hooked up to pump pigs, paraffin scrapers, or through flowline tools. It can also be used as a second production line.

In some cases, a decision to bury flowlines below the

seafloor can be made because of local regulations or obvious hazards. Generally, however, the pros and cons for burial and the overall costs and economics should be evaluated carefully before a decision is made to bury flowlines. If the answer is not clear-cut, leaving the lines unburied is probably best. Unburied lines cost less to install, are less expensive to repair, and are easier to inspect for leaks and damage.

Conventional welded steel pipe is used for most flowlines. It can be protected against external corrosion by either anodes, a corrosion coating, or a combination of both. Cathodic-protection methods should be compat-

Fig. 18.36—Seafloor manifold for satellite subsea wells.

ible with corrosion-prevention designs for equipment at both ends of the flowline (wellhead equipment and usually a platform jacket), as well as other nearby or crossing pipelines.

In recent years, flexible pipe made of laminations of steel wires and other materials has become popular for flowline service. Although the material cost for flexible pipe is usually very high in comparison with conventional pipe, this may be more than offset by savings in the installation cost. Work boats or special-purpose vessels equipped with large-diameter reels can lay long lengths of flexible pipe in short periods of time. Flexible pipe normally does not require a separate coating on the outside, but it may require cathodic protection of the end connections.

All flowlines should be protected from abrasion and physical damage from other crossing pipelines, and expansion loops may be necessary if the installed configuration does not allow for expansion and contraction from temperature changes. Other considerations include possible scour damage or vibration fatigue where bottom currents exist and high stresses where the line bridges low spots on uneven seafloor. Installation methods for flowlines are generally the same as for other subsea pipelines. These are discussed in the Offshore Pipelines section.

Control lines, both hydraulic and electrical, for subsea well completions are discussed in the Electrical, Instrumentation and Control Systems section.

Well Servicing—Wireline vs. Through Flowline. There are two common techniques for performing downhole work on subsea wells when the work tasks do not require removing the Christmas tree and tubing. The most common procedure is to install a workover riser between the surface vessel (drilling or workover rig) and the top of the Christmas tree above the swab valves and to install a wireline lubricator on top of the riser. Conventional wireline tools and equipment can be used to remove and to install safety valves and gas-lift valves, to shift sliding sleeves, or to make temperature and pressure surveys. Vessel heave must be compensated for, but otherwise the procedure is the same as for land and platform wells.

To overcome the delays and high cost associated with wireline work on subsea wells (vessel availability, high daily rates, and weather delays), a procedure for servicing wells remotely from the process platform has been developed. It is called "through flowline" (TFL). It is basically a set of tools that are inserted into the flowline at the platform and hydraulically pumped through the flowline, through 5-ft-radius flowline loops (bends) at the subsea Christmas tree, and down the tubing. A complete hydraulic loop is required between the platform and the well to pump the tools down and back. This means that a second flowline is necessary for work to be performed at or immediately below the wellhead and a second tubing string is required, with controllable communication between the tubing strings downhole to perform work downhole. TFL tools are available to fit common tubing sizes and to perform virtually all the same tasks as wireline tools. Numerous technical papers have been written on TFL tools and techniques.

Gas wells generally are not suitable candidates for TFL servicing because a gas-free hydraulic loop is required

for circulating the tools. A decision favoring either wireline- or TFL-servicing procedures for an oil well should be based on a full evaluation of operating conditions, anticipated downhole service requirements, the availability of trained personnel, and an economic comparison of installed costs and servicing costs.

Well Workovers. Work on subsea wells that requires the tubing to be pulled or is otherwise beyond the scope of wireline or TFL tools is a major undertaking and requires extensive planning and preparation. Unless a special-purpose vessel is available that is suitable for workovers, a semisubmersible or ship-shaped drilling rig must be scheduled and mobilized with a workover riser and running tools specially designed for the Christmas tree and tubing hanger. This equipment is needed in addition to a regular drilling riser and BOP stack, which must have a hydraulic connector that is compatible with the wellhead. Space limitations on some drilling vessels may preclude their use, which further complicates the workover.

Floating Production Facilities

For many years, floating drilling rigs (semisubmersibles, ships, and barges) have conducted drillstem tests and short-term production tests of newly drilled wells. These wells were nearly always drilled for exploratory or delineation purposes. Common practice was to abandon the wells temporarily or permanently after testing. Following the installation of a platform, development wells were then drilled and produced. Because brief production tests frequently provided insufficient reservoir data, and because delaying well production until platforms could be fabricated and installed resulted in poor cash flow, the concept of floating production facilities (FPF's) was developed. This concept requires some type of floating vessel (ship, barge, or semisubmersible) that is equipped for processing crude-oil production instead of for drilling. The vessel is either moored in place with multiple anchors, or is connected to some type of single-point mooring (SPM) or articulated tower. Crude-oil production from one or more seafloor wells is produced to the FPF either directly through individual pipe risers or through a seafloor manifold center and multiple-bore riser assembly (Figs. 18.37 through 18.39).

Applications. Two applications for FPF's were mentioned above: long-term production tests and accelerated (early) production. The use for long-term testing nearly always involves only one well and may be for a duration of anywhere from 2 to 3 months to a year or longer. Some reservoirs, particularly limestone as opposed to sandstone, cannot be evaluated from a short-term test, and full field development may be unacceptably risky without extended test data. The simplest FPF installation for production tests is a vessel moored with multiple anchors directly over a seafloor well connected by drillpipe or tubing to a subsea test tree installed in a BOP on the wellhead. A similar installation generally preferred for longer-term testing would use a flexible pipe riser instead of drillpipe or tubing and a conventional subsea Christmas tree instead of a BOP with test tree.

The same installations described above can also be used for early production if only one or two wells are involved. For more wells (up to 5 or 10), a seafloor manifold center

Fig. 18.37—FPF with flexible pipe risers and floating loading hose for two subsea wells.

may be used with a multiple-bore riser and some type of SPM or articulated tower. An SPM or tower has the added advantage of permitting the process vessel to weather-vane into the wind and seas and thus to mitigate the effect of bad weather on process equipment.

A third application for FPF's is permanent process facilities for a small or short-lived oil field where a conventional platform is either uneconomical or marginally

economical. Particularly where reuse of the facility may be a factor, the ease of moving an FPF to a different location or field may have a significant impact on overall economics.

Semisubmersibles vs. Tankers. Most FPF installations have been converted semisubmersible drilling rigs or converted oil tankers. Semisubmersibles are characteristically

Fig. 18.38—FPF with seafloor manifold, composite riser, and seafloor pipeline to loading buoy and tanker.

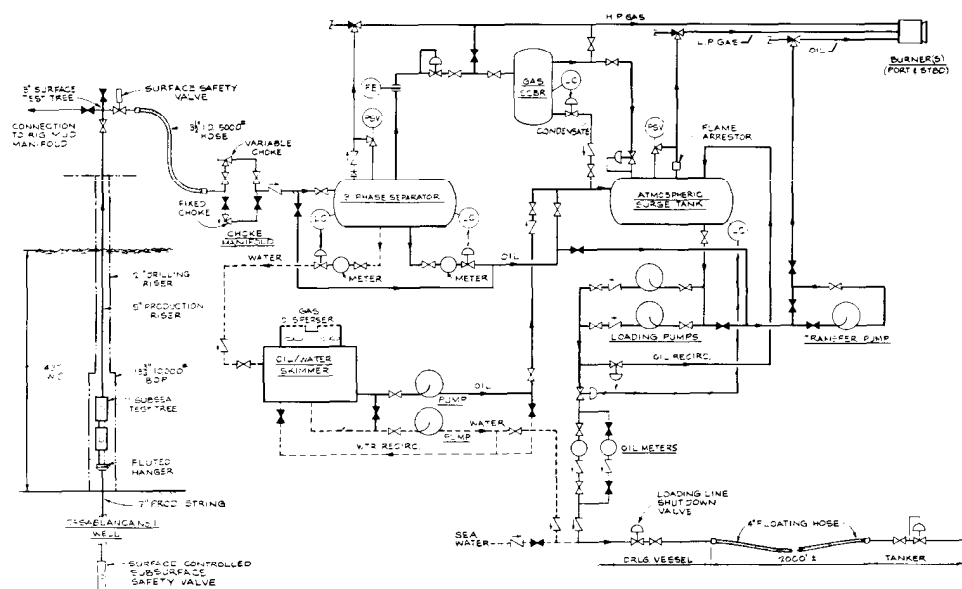

Fig. 18.39—Flow diagram for FPF process equipment for one-well, long-term test.

better suited to severe weather areas such as the North Sea, because of their superior stability. Their main drawback from an operating standpoint is the lack of sufficient oil storage capacity to prevent shutdowns when tanker-loading operations are disrupted. Loading disruptions are not uncommon and can result from either equipment failure or bad weather.

In relatively mild weather areas, converted tankers perform satisfactorily as FPF's, especially when moored to SPM's or loading towers that permit the tanker to weather-vane. Large oil-storage capacity, inherent to tankers, greatly facilitates the scheduling of shuttle tankers to transport the crude oil to refineries or terminals.

The choice between semisubmersibles and tankers for FPF service is heavily influenced by the availability of surplus vessels, the operating conditions, and the geographic area. A careful investigation of the used-vessel market is essential to an economic decision. At the time of this writing, new special-purpose vessels designed specifically for FPF service are being promoted. These include semisubmersibles with some storage capacity to offset that drawback and ship-shaped vessels with anti-roll devices to improve stability. A wide selection of FPF designs and vessels probably will make their use more economically and operationally attractive in coming years.

Disposal of Oil, Gas, and Water. Technically, there is no reason why oil cannot be shipped from an FPF by pipeline. Most installations to date, however, have transported oil with shuttle tankers. Loading operations can be accomplished by a floating hose directly between the FPF and the shuttle tanker. This inexpensive approach is practical in mild weather areas, especially with low production rates. For higher production and transfer rates and for adverse weather conditions, a seafloor pipeline or hose between the FPF and a dedicated loading buoy is safer and generally will result in less downtime.

Water produced with crude oil can be treated and disposed of the same as on a platform. It can be cleaned and

treated for reinjection into the reservoir, or, where local regulations permit, it can be cleaned and discharged into the ocean. Depending on downstream terminal or refinery conditions, shipment of small amounts of water production with the crude oil may be possible.

Small amounts of gas production have to be flared in a typical FPF installation. If flaring is not permitted, or if economics favors reinjection, compressors can be installed for this purpose. Use of FPF's in fields producing large amounts of gas may require additional facilities for gas treating, processing, and disposal.

Offshore Pipelines

The design and installation of subsea pipelines bear only slight resemblance to their counterpart activities on land. Preliminary sizing of lines can be based on general-purpose pressure-drop curves as long as the effects of the ocean environment on fluid rheology are understood. Also, preliminary cost estimates can be made on the basis of either estimating manuals prepared for this purpose or historical data for similar installations. Final pipeline designs, detailed plans, and cost estimates for fabrication and installation, however, are best handled by pipeline contractors or consultants who specialize in this activity.

Flowlines. Flowlines for subsea wells range in size from 2 to 6 in. As indicated previously in the Subsea Completions section, conventional steel pipe is used for most installations. It is readily available and does a good job when protected against corrosion and physical hazards. Flexible pipe made of laminations of steel wires and other materials is now available from several sources and has been used in a number of instances. It is made in a range of pressure ratings and a variety of materials that are suitable for most applications.

Welded flowlines sometimes are made up on the beach and then towed to the point of placement. Towing can be at or near the surface of the water with the pipe supported by buoys or other buoyant material, or it can be just off-bottom by a combination of buoys and chains for

Fig. 18.40—Conventional pipe-lay barge.

buoyancy control. More common methods of installation, however, are either by conventional lay barges (Fig. 18.40) or by reel barges (Fig. 18.41). The former make up straight lengths of pipe on the barge and feed it into the water by way of a curved stinger as the barge is winched along the flowline route. The purpose of the stinger is to control radius of curvature as the pipe is lowered into the water and thus to prevent buckling. Buckling and overtensioning of the pipe as it contacts the seafloor are prevented by maintaining a predetermined amount of tension on the pipe as it leaves the barge and by controlling the forward movement of the barge.

Probably the most popular method of installing flowlines, both conventional steel pipe and flexible pipe, is with special-purpose reel ships or reels mounted on large work boats. Depending on pipe diameter, several miles of pipe can be reeled onto one or more large reels at a shore-mobilization site and then rapidly reeled off at the placement site. The main advantage of this technique is the speed of installation. Fast installation reduces not only the number of offshore construction days but also costly interruptions caused by bad weather. A job that might require a week of offshore construction time with a conventional lay barge is much more susceptible to weather downtime than a job that can be completed in 1 or 2 days with a reel ship.

Flowline connections at platforms generally are made by pulling the line up through a curved conductor pipe called a J tube and then securing the line at the platform deck opening with a flange or clamp. Several procedures are used for connections to subsea wells, depending on Christmas tree configuration and whether the flowline in-

stallation starts at the tree (a first-end connection) or ends at the tree (a second-end connection). Most tree connections have been a pull-in type, where the flowline is first laid on the seafloor and then pulled into a receptacle on the tree base with a wire rope. One advantage of this is that it can be performed either on a first-end or second-end connection. A pull-in procedure can also be used as the flowline is being lowered to the seafloor, making a connection at the tree base before laying the flowline on

Reel Capacity

Nominal Pipe Size (Inches)	Approximate Capacity (Feet)	
4	267,000	50.5
6	160,000	30.3
8	104,000	19.7
10	73,000	13.8
12	54,000	10.2
14	45,000	8.5
16	30,000	5.7

Fig. 18.41—Work boat with pipe-laying reels.

Fig. 18.42—J-lay method for installing flowlines away from subsea well (first-end connection).

the seafloor. A procedure particularly applicable to subsea wells in very deep water is the J-lay first-end connection (Fig. 18.42), where the flowline is run vertically to the tree base from the drilling rig, stabbed into a receptacle, and then laid down into a horizontal position as the drilling rig or pipe-lay vessel moves away from the well-site toward the platform. A trunnion-type assembly on the end of the flowline permits the line to be laid down without bending. The mating of the flowline to the Christmas tree is made after the line is fully horizontal.

Many different devices and procedures have been developed for making the actual connection between the Christmas tree and the flowline. In shallow water, divers can install a piping spool with flanges or couplings on each end. Diverless connections usually have some type of hydraulically actuated device that is operated remotely from the drilling rig.

Larger Pipelines. Pipeline diameters from 8 to 36 in. or more are used extensively for the transfer of crude oil and gas from offshore fields to land sites. Installations typically have been made with conventional pipe-lay barges as described previously, but reel barges also are used extensively for the smaller sizes. Both bottom tows and surface tows are used in limited applications where logistics favor them. As discussed previously, a pipeline can be the single most expensive element of an offshore installation, sometimes exceeding the cost of one or more platforms. Numerous factors must be considered when

designing a line and planning its construction to minimize installation difficulties and to ensure satisfactory operation throughout the expected life of the line. Many technical papers and magazine articles have been written about this subject and are excellent sources of further information—e.g., proceedings from the annual Offshore Technology Conference.

Arctic

Production operations in the offshore Arctic regions are within the reach of existing technology. Procedures used onshore and offshore in less hostile regions, however, must be modified to meet the challenges of the harsh climatic conditions in these remote locations.¹⁵

In the last decade, the major areas of industry interest have been the offshore regions of Alaska¹⁶ and Canada. The environmental conditions vary significantly in each of these regions. Major factors that affect normal offshore operations are extremely cold temperatures, fog, gusty winds, short open-water seasons, permafrost, and the persistence of ice. The specific production system that is selected must be tailored to each unique combination of these factors to ensure safe oilfield development.

Environmental Conditions

Ice Characteristics. Sea ice is the principal environmental factor in all of the offshore Arctic areas.¹⁷ The most abundant type of sea ice that is encountered offshore is less than 1 year old. This first-year ice begins to form

during fall and grows to a thickness of 4 to 8 ft during the winter. Sheets of ice close to shore become landfast and remain locked in place throughout the winter. Beyond the landfast zone, the ice is kept in constant motion by wind, currents, and, in some areas, the influence of the Arctic polar pack. This dynamic movement causes shearing and impacting between ice features that produce ridges of ice several miles in length. Ice ridges formed in this manner are called pressure ridges. Localized ridging around a grounded ice feature, the shoreline, or a structure is considered a rubble pile. In areas of extremely cold winter temperatures, the ice blocks within a ridge or rubble pile begin to refreeze into a contiguous feature. Depending on the conditions, the refrozen consolidated thickness could become several times larger than the first-year ice thickness.

Sea ice that survives one or more melt seasons is considered multiyear ice. The predominant source of multiyear ice features is the polar pack. The pack consists primarily of floes 25 to 50 ft thick with embedded ridges 50 to 100 ft deep. During the summer, northerly winds break off portions of the pack and push them toward shore. These multiyear floes are commonly 1,000 to 2,000 ft in diameter.

The other major type of ice is not formed from seawater but is freshwater ice from the glaciers of Northern Canada. In the Arctic Ocean, the glacial fragments are called ice islands. These tabular-shaped features are several thousand feet in diameter and more than 200 ft deep. Because of the enormous size and slow movement rates of these features, they can be tracked for several months before encroachment upon a given area. Most of the areas of interest for oilfield development in the Arctic Ocean are also in relatively shallow water. This shallow bathymetry causes these freshwater ice features to run aground before they are a threat. In the North Atlantic, similar glacial features are called icebergs. Icebergs that weigh more than 50 million tons have been observed in water depths beyond 1,600 ft. Again, the local bathymetry dictates the maximum size iceberg that could encroach upon a given area.

Ice Loading. Ice exerts the predominant forces on Arctic offshore structures. Extensive laboratory and field tests have been conducted on small- and large-scale specimens to determine in-situ strength characteristics for design. From the results of these tests, the mechanical properties of ice are predicted that consider its salinity, temperature, crystallographic structure, and loading rate.

Newly formed sea ice is relatively warm—only a few degrees above seawater temperature—and high in salinity. As the ice sheet grows, the temperature at the surface reduces to the ambient air temperature, while the bottom remains near the seawater temperature. The salt in the crystal structure of the sheet begins to consolidate into brine droplets. These droplets migrate down through the thickness of the sheet, creating drainage channels and lowering the overall salinity. Fresh water, from precipitation or melting snow cover, fills these channels and refreezes, thereby further reducing the salinity. The result is an ice feature with varying strength, strongest at the surface and reducing through the thickness with increasing salinity and warmer temperature. For multiyear ice, this process ap-

proaches equilibrium. The multiyear ice floe is near zero salinity and has a relatively cold temperature through its thickness. This results in an ice strength several times greater than a first-year ice sheet.

Another parameter that influences the strength of sea ice is the loading rate. When ice is loaded at a very slow strain rate, it exhibits a plastic behavior. Loaded rapidly, it behaves as a brittle material. Empirical equations have been developed that relate the ice movement rate and shape of the structure or indenter to the strain in the ice feature.

The shape of the structure is also a primary factor in producing a crushing, buckling, or flexural failure of the ice feature. For narrow structures relative to the ice thickness, crushing is the predominant failure mode. As the width increases, a combination of crushing and buckling of the ice field around the platform results in the development of a rubble pile. This rubble pile will then shield the structure from direct impact of subsequent ice floes and ensure failure of the ice mantle away from the production facility. And finally, sloping-sided structures normally force a flexural ice failure. Because ice flexural strength is 20 to 40% of the crushing strength, an appreciable reduction in ice forces can be achieved when a bending failure is induced.

Waves. The wave conditions in the Arctic are similar to other offshore areas, and the design of structures or islands against wave loading is well established. Nearshore sea states can be defined by determination of the open-water area along the storm route or fetch and the water depth. In the Arctic Ocean, the presence of sea ice and the polar pack limits the open-water fetch for storms to generate and consequently reduces the design wave height. Breaking wave conditions exist in most shallow-water-depth locations and around gravel islands. This diffraction, shoaling, and refraction of the waves produces highly irregular sea states. Because the interaction of the waves and structure is dependent on structural geometry, the forces the design wave exerts on the structure should be determined by model testing or approximated by linear diffraction analysis.

Scour of the foundation around the structure caused by waves must also be considered and appropriate protection methods implemented. The scour protection could consist of rock, sand bags, or precast concrete elements placed around the structure after installation. For artificial islands, this becomes slope protection and can be used to reduce wave and ice run-up by providing an artificially rough surface.

Permafrost. Permafrost is soil at a temperature below 32°F with partially or completely frozen pore water. Drilling and producing operations in areas with permafrost have been well defined from the experience of the Prudhoe Bay field. In most nearshore areas of the Arctic, permafrost has been found at or near the mudline. These soils are very stiff and can make excavation for pipelines or driving of piling nearly impossible. Permafrost normally is soil bonded by ice and is very susceptible to changes in temperature. This can result in significant changes in the soil characteristics and must be considered in the design.

Fig. 18.43A— Protected-slope production island.

Production Structures ¹⁶

Artificial Islands. Artificial islands already are used in many shallow-water areas throughout the world for permanent drilling and producing facilities. The islands that are currently being used for drilling in the Arctic consist of either unretained or retained beach slope systems, as shown in Figs. 18.43A and 18.43B. Because of the short summer construction season and, in some areas, the lack

of island fill material, the quantity of fill required for the island should be minimized. The minimum island working surface is determined by the area required for drilling and production operations. To reduce the quantity of island fill, the steepest side slopes that the mode of construction and fill material will allow should be provided. The minimum side slopes of unretained islands depend on whether the island is constructed by summer dredg-

Fig. 18.43B— Caisson-retained production island

Fig. 18.44—Hole casing programs, Alaska.

ing or winter transport of onshore borrow material over the ice to the desired location. The side slopes for summer dredging are approximately 1:20 (vertical to horizontal), and for winter construction are 1:3. On completion, sandbags or concrete mats are placed on the exposed slopes of the island to prevent ice and wave erosion. Sandbags, stiffer soils for embankments, or caisson units are used on retained islands during construction to reduce the required volume of fill. The caisson units typically consist of vertical walled concrete or steel units. The caissons also provide easy access to the island as a dock for resupply and could be used for storage of consumables or oil.

Artificial islands must be designed to withstand the horizontal forces exerted by ice. The potential failure modes of the island consist of slope instability, bearing failure, or horizontal shearing of the island near the waterline. Each of these failure modes can be predicted by classic geotechnical analysis. The only variable in the analysis is the properties of the island fill material. During winter construction, the fill is delivered to the site at the cold ambient temperature and dumped into the sea. Ice forms on the granular material and inhibits consolidations. As the island surface thaws, considerable settlement may take place. To minimize the effects of thaw settlements, thermal analysis of the freezing and thawing interface should be conducted to determine the proper gradations of fill material.

The design of production facilities placed on an island is similar to that on land. Equipment foundations must be designed and insulated to reduce the potential for frost heaving, pile jacking, and thaw settlements from seasonal thawing and freezing of the island surface and, in some

areas, subsea permafrost. To prevent thaw settlement, an artificial refrigeration system for the fill material could be installed. Placement of equipment and accommodation modules should account for predominant wind, ice movement, and wave directions to ensure safe year-round operations.

The well systems should be vertically drilled through the frost-susceptible island surface and permafrost and then directionally drilled to true vertical depth (TVD). Wells should be spaced close together to minimize the overall size of the island surface and to reduce the effects of thaw subsidence. The casing program should be designed to withstand freeze-back loading during periods of well inactivity and to accommodate differential movement in the tubing string owing to the thermal effects of the drilling fluids. Two casing programs in the Prudhoe Bay field are shown in Fig. 18.44,¹⁸ which shows that both systems incorporate the use of a permafrost cement and provide a safety valve in the production tubing string below the permafrost for emergency shut-in.

Gravity Structures. Various types of gravity structures are being proposed for use in the Arctic. Many of the conventional gravity structures that are used in the North Sea are being adapted for the deepwater and moderate-ice-concentration areas. In the more hostile areas of the high Arctic, vertical- and sloping-sided gravity structures are being proposed. These structures provide the large deck load and space requirements, protection of the wells within tower shafts, and storage of oil. Because of the extreme winter ice conditions in many areas, the production facilities will have to operate 9 months without major resupply.

Fig. 18.45—Vertical-sided structure.

The vertical-sided structures (Fig. 18.45) are proposed for the shallow, nearshore areas in the Arctic. These structures typically are rectangular or hexagonal and are capable of being installed directly on the seabed or subsea berm. Production equipment can be placed directly on the working surface of the top slab or integrated into the hull of the structure. Wells are drilled and produced directly from the deck of the structure. Because of the large width of this concept, the structural integrity of the system is

not sensitive to local discontinuities in the seabed from ice gouges or settlements in the foundation from local degradation of permafrost.

Conical, sloping-sided structures (Fig. 18.46) are being proposed for the deeper-water, dynamic-ice-movement areas. This geometry induces flexural failure of the ice features and is relatively transparent to pack-ice movements. The deck is fully outfitted with processing equipment before it is mated with the structure. Wells are confined to a central moon-pool area in the cylindrical throat. Consumables and oil can be stored in the base.

Fig. 18.46—Arctic mobile drilling structure: sloping-sided structure.

Piled Structures. Piled steel structures have been developed primarily for the Bering Sea area of offshore Alaska. These structures are similar to conventional template or jacket concepts but must be modified to resist annual sheet-ice loading. A typical geometry is shown in Fig. 18.47. The platform concept consists of four or eight main pile legs with intermediate bracing of the legs omitted in the ice-loading zone near the waterline. Well conductors and oil-transport lines are positioned within the legs of the platform for protection from ice loading. This requires close spacing of the wells and, in some cases, completion of the wells at different levels of the deck. Diver-access tubes may also be located in the legs to facilitate the repair and inspection of subsea components of the platform during complete ice coverage.

In most other Arctic areas, pile structures are not practical. Subsea permafrost makes pile installation nearly impossible. The short construction season also does not accommodate the installation, pile driving, and placement of the topside modules in one season. Also, the hookup and commissioning of the production equipment modules would be very expensive in these remote areas.

Transportation Systems

Pipelines. Offshore pipelining is the predominant mode of crude-oil transport proposed for Arctic regions. The pipelines will interconnect platform facilities, mooring

structures, and land-based facilities in much the same manner as in conventional offshore locations. The principal factors affecting the construction and operations of Arctic pipelines are the short open-water seasons, subsea permafrost, scour, and ice gouging of the seafloor.

Pipelines can be placed directly on the seabed in deep water, in trenches in areas susceptible to ice gouging or scour, and on causeways or elevated bridges at shore crossings. In areas of extreme ice gouging, redundant lines may be used to lower the risk of interrupted production.

In deepwater, moderate-ice areas of the Bering Sea, the lines will be laid directly on the seabed by conventional lay-barge methods. The 6- to 9-month open-water season, extreme summer wave conditions, and logistics of operating several hundred miles offshore reduce the efficiency of the construction process. The distance from shore or an offshore loading terminal may also require pump stations along the pipelining route.

Marine pipelines in the Arctic Ocean are considered feasible but will require the greatest challenge to existing technology. The open-water season lasts approximately 1 to 3 months a year. In shallow-water locations, the keels of ice features may gouge the seafloor for several miles in a single ice-movement event. Pipelines must be buried in trenches that are deep enough to ensure no damage. Offshore permafrost may also cause difficulty in obtaining the desired trench depth and may require the use of cutter-suction dredges to remove the ice-rich soil. Once the pipeline is installed, refrigeration of the trench may be required to ensure no subsequent thawing of the permafrost. Nearshore pipelines may also have to be designed for wave-induced erosion or strudel scour. Strudel scour, which is common at the mouth of rivers, is the process in which river-water outwash flows over the nearshore sheet ice and floods down through holes and cracks in the ice. This jet of water could create large, eroded pockets in the seabed and produce long, unsupported spans of pipe.

Marine Terminals and Tankers. Transportation of crude-oil products from many of the remote Arctic oil fields also can be accomplished by offshore terminal and tanker systems. The systems could consist of an interfield pipeline-gathering network with processed crude shipped directly to shore. Once onshore, the crude could be stored until it is loaded onto tankers and shipped to market. Another form of marine terminal system is direct shipment of processed crude from offshore platforms to tankers through single-point mooring systems.

The design, construction, and operation of these systems have been proved in many sub-Arctic areas. However, some of the components must be modified for the cold temperatures and persistence of ice. Loading arms must be designed to ensure that hoses remain elevated above the ice mantle and can accommodate loading of tankers from any location around the terminal. Tanker-mooring systems must be designed for both wave- and ice-loading conditions. Extreme ice areas may require offshore loading directly from fixed platforms or from subsea facilities, making maneuvering and stationkeeping very difficult. Icebreaker assistance vessels may also be required to ensure safe access and departure from the terminal by tankers.

To travel through the offshore Arctic regions, purpose-built icebreaking tankers may be required. The amount

Fig. 18.47—Piled structure.

of hull stiffening will be dictated by the ice conditions for its area of operation. The modifications could range from simply thickening the hull plate to the requirement of an icebreaking bow and turbine-powered propulsion system. Internal bulkhead arrangements should also be arranged to ensure that oil storage tanks are adequately stiffened and not susceptible to direct ice impact.

Special Considerations

Ice Management. A critical support system, unique to the Arctic, is the ice-management system. The key component of this system is instrumentation of the structure, foundation, and ice field around the structure to monitor both local and global ice loading. Other elements of ice management include icebreaker support vessels for tankers or supply boats, tractor-mounted ditch diggers for slotting the ice to reduce loads, and water-pumping units to flood areas around a platform to stabilize ice movement.

Electrical, Instrumentation and Control Systems

Offshore production facilities have the same basic requirements for electric power and control systems as onshore facilities. These are a power source with a reliable distribution system, instrumentation to control and to monitor production operations, and a safety shutdown system tailored for the installation.

Although offshore and onshore installations have similar needs in these areas, the two operations are significantly different in other respects. As pointed out earlier, deck size and payload significantly affect offshore structure costs. Consequently, offshore electrical facilities must

be designed for minimum weight and space while still offering a high degree of flexibility, reliability, access, and maintainability. Because of deck space and layout limitations, hazardous area considerations are more complex and often are governed by different regulatory codes depending on the type of structure, its location, and the responsible governmental agency. Additionally, environmental considerations are much more demanding because of the generally salt-laden atmosphere and the possibility of saltwater washdowns and sea spray.

Several wiring methods are approved for offshore installations, but the method used frequently depends on local practices and personal preferences. There is no single correct method for wiring an offshore installation as long as the appropriate codes are satisfied and the craftsmanship is of average quality or better.

Offshore-production instrumentation and control systems also tend to differ from their onshore counterparts. Offshore oilfield operations are confined to a relatively small spot on the ocean rather than being spread over several acres. Consequently, controls tend to be much more centralized. This trend toward centralization has become more pronounced with increased use of computer-based production-monitoring and control systems.

Safety shutdown systems onshore and offshore are roughly equivalent. However, offshore requirements regarding functionality and reliability are somewhat more stringent because of the greater potential for spills and resultant pollution. Increased concern for personal safety and environmental protection creates a more stringent atmosphere for approval, testing, and inspection by outside agencies, as well as thorough documentation of the entire process and facility by the operator.

Alternative methods of addressing and satisfying these and other considerations peculiar to offshore operations will be discussed. The intent is to lay out the problems, to highlight areas of concern, and to discuss possible solutions, rather than to present specific, detailed engineering methods for design and installation of electrical and/or control systems.

Codes and Regulatory Authorities

Offshore electrical installations are governed by one or more codes and regulations, depending on the type of offshore structure involved and its location. In U.S. waters, electrical designs are governed by local or state electrical codes and in most cases the Natl. Electrical Code.¹⁹ Generally, the installation should be in accord with the more stringent requirements of the applicable codes. The guidelines given in API RP 14F²⁰ provide direction for accepted good practice in accordance with most applicable codes. If the facility falls under U.S. Coast Guard jurisdiction (e.g., TLP's, mobile offshore drilling units and FPF's), all or portions of the electrical system also must be designed, installed, and operated in accordance with the applicable portions of U.S. Coast Guard Regulations 46 CFR Chapter I, Subchapter IA, Mobile Offshore Drilling Units, Part 108 and Subchapter J—Electrical Engineering, Parts 110–113.²¹ Overseas installations frequently fall within the jurisdiction of local/national codes or regulatory agencies. This situation occurs in the North Sea where Lloyds of London or Det norske Veritas frequently are named as certifying authority, and their requirements must be met. If there is no lo-

cal certifying authority, it generally is good practice to design all systems to meet normal U.S. requirements for that type of facility.

Platform Loads

With the exception of the hotel loads that serve accommodations and personnel needs, normal platform loads are not greatly different from the normal assortment of onshore loads. Processes are likely to be concentrated in a single location offshore, and the loads are appropriately higher. Loads usually consist of a mix of transfer pumps, compressors, fans, and heaters as well as utilities (air compressors, sump pumps, fire water pumps, water makers, sewage facilities, etc.). Other typical loads include pumps and gas compressors associated with shipping, artificial lift, secondary recovery, and pressure-maintenance operations. Depending on platform type and production facilities and rates, the loads on any given platform in a field can range from less than 25 kVA to more than 40 MVA.

Layout of Facilities

Considerations that govern layout of offshore electrical facilities are similar to those for land installations, but the options are more restricted because of the space limitations. The primary requisite is to separate to the maximum extent possible the sources of ignition from the process facilities. Electrical equipment should be kept out of hazardous areas when economically feasible. Primary electrical switch gear is frequently grouped in a pressurized, central electrical-equipment room. Remote motor-control centers (MCC's) sometimes are used to reduce the amount of platform wiring. Installing MCC's near load concentrations and supplying the MCC's with high-voltage feeders shortens branch circuits that feed individual loads. Remote MCC's frequently must be purged or pressurized because of their location. The design approach appropriate in each individual case must be based on practicality and economics.

Detailed load analyses must be made early in the design stage. Each analysis must consider both initial and anticipated future load. Results of the analysis should control design of primary power facilities, layouts of conduit or cable ways, switchgear space, and distribution-equipment layouts. Designs must allow for expansion in each of these areas. The designer must carefully consider possible future system expansion and pay particular attention to possible future artificial-lift and water-injection requirements. Hydraulic pumping and electric submersibles can add significantly to the ultimate electrical load. It is important to consider the potential for future changes in facilities as reservoir conditions change and possible increased demand on the electric power system.

Primary Electric Power

Typically, offshore facilities either generate power locally or they are fed by submarine cables. Generated power ranges from 480 to 4,160 V. The higher voltage levels are more prevalent where there are high horsepower loads or where platform drilling rigs are not set up to generate their own power. Very large platforms are sometimes designed with primary power system voltages of up to 13.8 kV.

The primary source of generated power usually consists of one or more brushless synchronous generators with either diesel-engine or turbine prime movers. Turbines may be gas- or diesel-fueled or they may be dual fueled. Dual-fueled turbines generally are set up to run on diesel initially and then to cut over to produced gas as production builds to a stable supply. Turbines offer the advantages of lighter weight and the opportunity for the use of waste heat in oil production processing. Turbine-generator packages, however, are very costly, require more maintenance, and in some cases, may require more deck space than internal-combustion-engine-driven generators of the same capacity. In addition, primarily because of the somewhat limited selection of turbine sizes available, it can be more difficult to match turbine generator packages to the electrical system loads.

The second source of offshore power, submarine cable, offers an efficient means of electrification if adequate sources are located nearby. Depending on the loads and the distances involved, cable-system voltages can range between 480 and 35,000 V. Submarine-power-cable technology is well established. Power cables generally include one or more pairs of small-gauge wires dedicated to telecommunications or telemetry and also are protected with torque-balanced double layers of galvanized armor wires that may be plastic-coated for additional protection. Power cables may be buried, depending on local conditions or regulations. Tubular risers are required at each platform served by submarine cables to protect the cables as they rise from the seabed to the platform deck. The riser generally should be filled with a corrosion-inhibiting fluid to preserve the long-term integrity of the armor wires. When the submarine cables originate on land, they must be buried and suitably protected through the surf zone. Mechanical protection is frequently provided by additional armor or by the installation of heavy-wall pipe through this area.

Secondary/Back-up Power

Essential loads on offshore facilities must remain energized even when the main power source fails. These loads usually fall in the category of navigation lights (ship and aircraft), foghorns, communications, emergency lighting, and possibly some selected hotel loads. In some instances where marine regulatory bodies have jurisdiction, the emergency system may have to be expanded to serve other loads related to the safety of personnel on board.

High-volume oil and gas facilities are frequently designed to shut in completely in the event of power failure, in which case process or shipping loads do not have to be considered in determining backup power loads. Some smaller facilities, such as wellhead platforms, are designed to continue production operations without any electrification other than lighting, navigation lights, and foghorns.

Emergency power generally is derived from onboard generators, storage batteries, or both. The generators usually are small (less than 500 kW) and diesel-engine driven. Diesel engines that are used in emergency service normally are equipped with automatic starters. These engines also are equipped with cooling water and lube-oil heaters to ensure that they will start reliably and instantaneously (within 10 seconds) on loss of primary power.

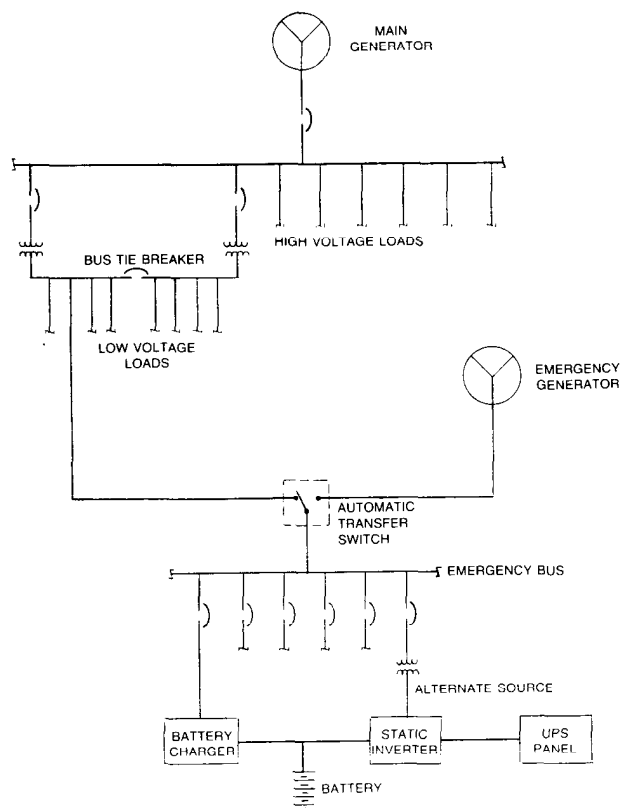

Fig. 18.48—Typical electrical one-line diagram with ups and emergency generator.

Offshore facilities with electronic instrumentation or computer-based monitoring or telemetry systems generally need uninterruptable power supplies (UPS's) to provide reliable, clean power for these loads. A UPS is essential on platforms where some loads are supplied from onboard, solid-state, silicon-controlled rectifiers (SCR's) because of the high level of electrical noise injected into the power system by the SCR's.

The emergency bus typically is tied into the normal power bus through an automatic transfer switch. The emergency bus receives power during normal operation from the main bus. On failure of the primary power, the transfer switch opens the tie between the two buses to isolate the emergency bus and its loads from the remainder of the platform loads. Additional controls automatically start the emergency generator to energize the emergency bus. Normally, no provisions are made for operating the emergency generator in parallel with the main power supply. Interlock circuits should be provided, however, to permit testing the emergency generator offline without energizing the emergency bus.

Typical one-line diagrams for a UPS and an emergency generator bus tie are shown in Fig. 18.48.

Distribution System

Offshore power-distribution systems and associated equipment do not differ substantially from land-based operations. Depending on load sizes, distribution voltages will normally range from 120 to 2,400 V. Distribution systems with 4,160 V and higher are rare except on very

large platforms with high horsepower loads. As with land-based systems, accepted good practice and system capacity determine the maximum allowable horsepower for individual loads and the appropriate supply voltages.

Motor-control centers and switchgear usually are installed inside pressurized or purged enclosures or modules. The pressurizing or purging frequently is required to ensure a nonhazardous operating environment for the electrical equipment so that air-break switching equipment can be used safely. Code requirements for purging are prescribed in the Natl. Electrical Code¹⁹ and Natl. Fire Protection Assn. Bull. NFPA 496.²³ As indicated in the references, interlocks usually are provided either to sound an alarm or to shut down all supplies when a loss of pressurization or purge occurs. Depending on the particular operations involved, a simple alarm may be permissible if shutdown of the process could create a greater hazard than continuing operation during a short-term loss of pressurization or purge protection. Each installation is site-specific and must be considered on its own merits.

System transformers may be installed either indoors or outdoors. Both single- and double-ended line-ups are used offshore, depending on the nature of the operation. Double-ended 100%-capacity supplies with bus tie breakers are frequently used for increased reliability and continuity of service in the event of equipment failures.

Hazardous Areas

The possibility of fire or explosion because of the ignition of leaking gas or liquids is a concern in all producing facilities. The concern is even greater offshore because of the concentration of personnel and facilities in a relatively confined area where fire can be difficult to extinguish and platform evacuation can be a complex problem. The requirements for classifying areas according to their degree of hazard and for selecting equipment for the various areas are covered in API RP 500B²²; Section 500 of the Natl. Electrical Code¹⁹; and USCG Regulations 46 CFR, Chapter I, Subchapter I-A, Part 108 and Subchapter J, "Electrical Engineering," Parts 110-113.²¹ Certifying agencies outside the U.S. have some different rules and categories, but in general, they are no more strict than the U.S. rules for the same situation.

Wiring Methods and Equipment Enclosures

Several wiring methods are applicable to offshore installations, and opinions differ as to whether conduit-and-wire or cable-and-cable-tray systems are best. Each has advantages and disadvantages. If the installation complies with the appropriate procedures as outlined in the Natl. Electrical Code¹⁹ and API RP 14F,²⁰ each method is safe and reliable. Rigid steel conduit and wire systems provide the maximum mechanical integrity, but the conduit and fittings should be coated with plastic (PVC) to eliminate corrosion effectively. PVC-coated fittings and accessories are readily available in most locations. Copper-free aluminum conduit systems have been used successfully in lieu of galvanized steel. Aluminum systems require special wrapping of the conduit wherever steel support clamps are used to prevent setting up corrosion cells where dissimilar metals would come in contact. Overall, conduit systems provide excellent protection for wiring systems, but they have the disadvantage of being bulky and relatively expensive to install, maintain, and modify.

Type MC (metal-clad) cable, which has a corrugated aluminum sheath and an overall PVC jacket, is another preferred system that is frequently used offshore. Armored shipboard cable and type TC tray cable are viable alternatives to MC cable in many instances and are suitable as long as the installation complies with the Natl. Electrical Code.¹⁹ Cable systems are more flexible, quicker to install, and less subject to corrosion than conduit offshore, but they are more subject to mechanical damage.

As with onshore facilities, all electrical equipment installed in locations classified as Class I, Div. 1 must be explosion-proof. Requirements for equipment in Class I, Div. 2 areas are slightly less stringent as long as no arcing contacts are exposed. Electrical equipment in nonhazardous areas generally is chosen for its applicability to the situation. Switches, for instance, generally are provided with explosion-proof enclosures for mechanical protection and durability even if the contacts are enclosed. General-purpose enclosures are normally used in protected areas. Fiberglass enclosures are seldom used in open areas because of their susceptibility to mechanical impact damage.

Explosion-proof motors are required in Div. 1 areas. Fractional horsepower motors in Divs. 1 or 2 areas must be explosion-proof. Otherwise, both Div. 2 and unclassified areas permit the use of totally enclosed fan-cooled (TEFC), totally enclosed nonventilated (TENV), or encapsulated, open drip-proof motors. Choice of enclosure must be based on exposure and service. Motors operating at 2,400 V or higher should be equipped with integral heaters or low-voltage winding heating systems if they are in exposed locations to ensure that the integrity of the insulation resistance is maintained during periods of nonuse. As warm windings cool in the relatively high-humidity offshore atmosphere, moisture is pulled into the windings, giving rise to a high chance of an internal short circuit. Motors of 500 hp or more that have been shut down for an extended period should always be checked with an insulation tester before they are restarted, regardless of whether they have been heated in the interim.

General Instrumentation

The primary guide for the instrumentation of offshore installations is API RP 14C.²⁴ In conjunction with the applicable U.S. OCS Orders,^{25,26} the API guide provides an excellent reference for guidelines in the design of monitoring and control systems for offshore-production facilities. Most offshore installations have local control panels for packaged equipment, such as gas compressors, low-temperature gas separation (LTS) units, and electrical generators. Beyond this, the choice of individual local display/controllers or centralized control rooms with field transmitters and local displays depends on the nature of the facility, the complexity of the operation, economics, and preference of the operator. Most large, modern offshore facilities are planned with centralized controls. The one design principle that must be followed regardless of the overall design philosophy is that all systems should be designed to be fail-safe so that loss of a signal represents an alarm or shutdown condition.

Even when a centralized control room has been provided, continuous remote, closed-loop (analog) control is seldom used. Remote, closed-loop controls usually are

considered only when the process includes complex separation processes, sulfur removal and handling, or gas processing. Most oil/gas handling processes are sufficiently simple and straightforward that local control loops are satisfactory.

Centralized controls can be based on conventional instrument and relay control panels, but advances in electronics have increased the use of programmable controllers and microprocessor-based instrument systems. These advanced system designs have multiplexed monitoring and control systems that frequently offer significant savings in wiring costs and space for a complex installation. They are more compact and much more flexible than conventional control panels.

Offshore instrumentation is very similar to onshore instrumentation. Process controls frequently include a combination of pneumatic, hydraulic, electric, and electronic instrumentation. Process variables that must be monitored and/or controlled include level, pressure, temperature, flow, oil/water interface, and gas/oil interface. In most offshore installations, the considerations in designing instrument systems to accommodate these variables are identical to those for their land-based equivalent. Foam, gas cutting, sand, wax, and H_2S are typical considerations. Radios are used extensively for offshore communications, and radio interference can present some unique problems. Some electronic-based sensors are sensitive to radio-frequency interference and may give false alarms or shutdown signals when high-powered radios are keyed nearby.

Most operators prefer to separate emergency shutdown circuits from alarm and control circuits. Typical examples are high- and low-level shutdowns on tanks or separators, high/low pilots on manifolds, and gas and fire detectors.

Regardless of the level of complexity of an instrument and control system, a conscientious, well-disciplined, and well-documented program of regular testing and maintenance is essential. Offshore instrument systems are not overly complicated, and given adequate maintenance and correct initial installation, every instrument should perform its intended function reliably over the life of the facility.

Safety Systems

Separation of process-related shutdowns from instrument-control loops was mentioned earlier. Process shutdowns generally involve process-related variables that have exceeded preset limits. Other key safety-related systems should be kept separate. These systems are covered in various U.S. Coast Guard Regulations and OCS Orders.²⁶ Examples of these systems are combustible-gas detectors, poisonous-gas sensors, fire detectors, surface-controlled subsurface safety valves (SCSSV's), surface safety valves (SSV's), and emergency shutdowns (ESD's). Proper design and installation of these systems is perhaps the single most critical aspect of offshore instrumentation and control systems. (Safety shut-in systems are covered in more detail in Chap. 3).

Combustible-gas detection systems are required in most offshore operations. They are intended as early warning devices to alert operators to potentially hazardous conditions where none normally exist. Modern systems have catalytic sensing heads whose electrical characteristics depend on the concentration of hydrocarbon gases surround-

ing the sensor. Units are calibrated and have known variations in their electrical output that are based on the gas concentration in the area of the sensor. Gas sensors normally are connected to a central monitoring panel equipped with individual sensor readouts calibrated in percent of lower explosive limit (LEL). Each readout has at least two alarm outputs. Normally, one alarm is set for about 20% LEL and the other for 60% LEL. Some operations/regulations require automatic shut-in at the higher level. Although gas detection technology has improved over the years, malfunctioning caused by poisoning of the sensing heads by contaminants in the air and loss of circulation caused by dirt accumulations on the sensors continues to be a problem.

H_2S gas detectors are essential where sour crude and sour gas is handled or produced because of the extreme toxicity of H_2S . Sensors continue to improve, but reliability and maintenance are continuing problems.

Because of their vulnerability, gas detectors must be installed where they are protected from water spray, drilling mud, and other contaminants; yet they must be in areas where they can adequately monitor the environment. They generally are installed in areas where leaks or accumulations might be expected under abnormal conditions—above gas compressors, in a wellhead or manifold area, over drilling mud pits, or in dead-air spaces—or in areas where a gas build-up could be catastrophic, such as in ventilation system inlets.

Fire-detection systems generally are based on the use of ultraviolet (UV) sensors or fusible plugs. The operating principle of UV sensors is that their sensitivity to the UV radiations from flame provides an alarm output in the presence of UV radiations from open flames. Unfortunately, they also are somewhat sensitive to direct and reflected UV radiation from welding arcs. Because of their extreme sensitivity, most UV fire systems include a brief time delay to minimize false triggering of a fire alarm. The layout of UV sensors at a site is important. Considerable care must be taken in laying out a coverage that considers viewing angles, range, and sensitivity.

Infrared (IR) fire sensors were tried on early offshore platforms, but they had many operating problems. IR sensors are seldom used today, primarily because of difficulties with their calibration and reliability.

Fusible plug fields that consist of pressurized stainless steel or plastic tubing, heat-sensitive solder plugs, and pneumatically held pilot shutdown valves are popular and reliable systems for fire detection. With this system, tubing is run through and around various critical areas of an offshore facility. The tubing runs are segregated by process area or some other criterion. Multiple solder plugs are included within each field. If a fire occurs in that field, the solder plug melts, depressurizing the field and tripping a shutdown valve. The major problem with plug fields is maintenance and accidental shutdown because of leaks.

Overall, a judicious combination of strategically placed UV sensors and fusible plugs forms the optimum fire detection and automatic shut-in system. With such a system, it is possible to shut in production facilities, to blow down pressurized vessels, and to activate the appropriate fire suppression system simultaneously and immediately, thus minimizing fire danger.

SCSSV's should form an integral part of every offshore production system. These valves are installed in the production tubing below the mudline. They are hydraulically actuated and held open during normal operation by pressurized hydraulic fluid in their individual control lines. They are designed to be fail-safe in that they close when a loss of hydraulic pressure occurs. On modern platforms, the SCSSV hydraulic system is generally a separate, centralized, hydraulic power unit dedicated solely to their control. Surface power units and their associated alarms and controls are available as specialty packaged units. Their design and component selections have been developed over the years to the point where it is not cost-effective to try to design alternative units.

Platform wells also are equipped with surface safety valves (SSV's) between the wellhead and the production manifold. The actuators on these valves are designed to be fail-safe closed and can be actuated either hydraulically or pneumatically by the automatic safety shutdown system and/or the manual emergency shutdown.

SCSSV's normally are actuated only in extreme emergency to preserve their integrity. Repairs are expensive. SSV's, on the other hand, usually are activated in almost all platform or process shut-ins. They are simpler devices that are less expensive to repair, more rugged, and more accessible.

Nearly all platforms are equipped with automatically controlled riser shutoff valves on pipelines and flowlines feeding or leaving the platform. The intent of these valves is to allow isolation of the platform from any outside source of flammable fuel in the event of a platform accident. In the case of subsea wells, it frequently is desirable to shut in the wells by simply blocking the flowline rather than operating the subsea valves unnecessarily. The flowline riser valves commonly are operated first in the event of a subsea well shut-in and last on startup to avoid cutting out seafloor valves by closing or opening them unnecessarily against a flowing stream. Riser valves are far more accessible and maintainable than the subsea tree valves.

The final element in any safety system should be the manual ESD. These controls can be either electrically operated solenoids or pneumatically or hydraulically held pilot valves that control various shutdown control circuits around the facility. ESD stations usually are located on boat landings, on helidecks, in process areas, and in control rooms.

Control of Subsea Production Facilities

The mechanics of subsea production systems, such as wells and manifold centers, were covered under Production Facilities. This section presents various operating philosophies and discusses methods of providing remote control of subsea equipment.

Subsea controls should be as simple and straightforward as possible and still meet requirements for operational considerations and the physical layout of the field. System reliability, maintainability, control response times, and the need for feedback of tubing or annulus pressure and valve position to the operator are some of the most important factors that must be considered. Physical aspects of the oilfield—water depth, lateral offset of the subsea equipment from its associated platform, anticipated sea or ice conditions, and the potential for well damage caused

by shut-ins—and the complexity of the subsea facility determine the optimal design of the control system.

Subsea facilities require two separate sets of controls. Production controls provide day-to-day operational control of the subsea equipment. Initial completion and subsequent workover of subsea wells require controls designed specifically for installation/maintenance functions. Completion/workover systems generally provide control over more functions than the associated production system. Production controls normally exclude control over hydraulic connectors, test ports, and vertical access valves.

Reliability/Maintainability

Reliability of a control system can be considered to be the probability that the control will not malfunction in such a manner as to preclude performing an intended function. Reliability usually is quoted over some specified period, such as the intended operating life of a particular project or the planned time between scheduled maintenance. For any system, the probability that the system will fail to perform its intended functions over a given time period is a function of the design, quality of the system components, built-in redundancy, and the quality of manufacture. Regardless of how well a system is designed and built and how short an operating period is considered, there will be a finite probability that it may malfunction during that period.

The likelihood of a failure can be minimized, but it can never be completely eliminated. Consequently, rather than going to great lengths and expense to design a system that "can't fail," it may be more cost-effective to set realistic reliability goals and to concentrate on designing the equipment for maximum maintainability. This approach is aimed at minimizing the effect of a problem instead of trying to avoid the inevitable and generally results in a sound design that maximizes ease of retrieval and reinstallation. How best to implement increased reliability and maintainability should be determined by the incremental cost involved and the benefits to be derived.

Redundancy

A system fault generally results in a well shut-in, and recovery of the control equipment for repair and reinstallation is then required before the well can be returned to production. The ultimate cost of the repairs is reflected in the expense of mobilization for repair, the repair, and subsequent demobilization.

One of the most economic and effective means of increasing system reliability is to include active backup for weaker elements within the basic subsea control module or, in the extreme, to provide a completely redundant module.

This approach may be cost-effective in situations where field conditions could impose severe economic penalties or pose a safety hazard in the event of a control system malfunction. The value of deferred/lost production and the possibility of premature well work necessitated by the shut-in also must be taken into account in evaluating the economics of providing redundancy.

Redundancy does not eliminate the ultimate need for repairs, but it may permit postponing them to take advantage of favorable weather windows, contracting rate trends, or vessel availabilities, all of which can work to

substantially reduce repair costs. In addition, built-in redundancy allows operations personnel to schedule the work on the basis of convenience without incurring unnecessary production losses or potential well damage.

Although potentially economical, redundancy is not free. The decision on the extent to which it should be included in a design must be based on a careful examination of the cost impact on the project and the potential benefits.

Operational Considerations

Many operational factors and operating philosophies must be weighed when the control system for a specific installation is selected. Among the items that should be considered are response-time requirements; potential need for diver or remote-operated vehicle intervention; requirements for feedback regarding subsea valve operation, wellhead pressures, and temperatures; single-well or multiwell completions; use of subsea manifolds, commingling, and application of subsea chokes; type of control fluid; and the type of control-system design.

Response time for opening a tree valve usually is not critical if it is not unreasonably long, particularly with low flow velocities and clean production. Closing times are of considerable concern, however, and closing response may determine the type of control system to be employed. Excessively long closing times are neither desirable nor necessary. From the standpoint of pollution potential in the event of a flowline rupture, closing response times are less critical for water-injection wells than clean-gas wells, which, in turn, are less critical than oil wells.

All other factors being equal, a system that provides discrete control over each subsea valve and allows the operator to verify or to infer valve operations would always be recommended over one that does not. Some type of feedback on valve position is almost mandatory for safe operation of subsea facilities. If there is any concern about wellhead temperature or pressure because of flowline materials or other considerations, the ability to sense this information and to transmit it to the surface can be an overriding consideration in the selection of a control system.

Control Fluids

High-pressure control fluid is the means of converting a control command into subsea valve operation in both all-hydraulic and electrohydraulic control systems. Military-grade, low-viscosity, conventional oil-based hydraulic oil and highly water-based fluids are the two types of fluids in subsea control systems. Oil-based fluids provide the best system performance from the standpoints of lubricity, component wear, internal leakage, corrosion protection, and ultimately, system reliability. Oil can be used only in closed systems, however, because it cannot be discharged into the ocean when a control loop is vented to deactivate a control. Closed systems imply higher costs and, over long distances, slower response times. Oil-based systems can be particularly troublesome in cold climates. Water-based fluids, on the other hand, are inexpensive, are biodegradable (so they can be discharged into the environment), exhibit very low viscosity, and provide the fastest response times.

Unfortunately, water-based fluids also have certain inherent deficiencies. They exhibit lower lubricity, en-

courage higher leak rates, display lower corrosion inhibition, and are subject to biofouling from bacterial growth. All of these shortcomings can be overcome with proper component selection, design, and operating practices. Water-based fluids are used in most subsea and drilling control systems.

The single most important factor with any hydraulic control system, regardless of the type of fluid, is fluid cleanliness. Failure to keep the hydraulic system clean virtually guarantees an early malfunction.

Umbilicals

Platform control of subsea facilities requires a control umbilical between the platform and the subsea facility. The umbilical may consist of multiple hydraulic lines in a common jacket, a composite of hydraulic hoses, power wires, and communication pairs in a common jacket, or separate hydraulic and electrical bundles. The makeup of the umbilical depends entirely on the nature of the control system and the field conditions.

Hydraulic bundles can be fabricated with either stainless steel tubes or elastomeric hoses. Because of the importance of quick response and because hose expansion is a major determining factor in response time, manufacturers have upgraded hoses to the point that their expansion characteristics approach that of steel tubing. Hose and tubing display different installation and operational characteristics, however, and the decision on umbilical design must consider the unique aspects of the materials and specific project requirements.

Protection of control lines laid on the ocean floor is always a concern. One of the principal means of protecting control lines that are not buried is to armor them with galvanized wires applied in two separate, contrahelically wound layers. Because of the cost of armoring the large diameters encountered in most hose bundles, however, they are seldom armored. As armoring costs are reduced with improved technology, armoring of hose bundles may become more common. Hose bundles that are armored usually have a polyethylene bedding jacket under the armor and may have a thin covering over the armor. Some unarmored designs include a small-diameter wire rope molded integrally with the jacket to provide tensile strength and additional weighting. An alternative hose-bundle design makes use of a thick outer urethane jacket in lieu of armor. The high density of urethane provides the necessary negative buoyancy, and it provides excellent abrasion resistance.

A viable alternative to hose bundles uses stainless steel tubes laid side-by-side in a flat configuration. Relatively large-diameter wirelines (ropes) normally are placed on the outside of a flat bundle to provide mechanical protection and resistance to kinking.

The generally accepted practice is to armor subsea electric control cable for mechanical protection, weighting, and tensile strength. Even though it means a substantial reduction in cost, few, if any, unarmored cables have been installed subsea.

Alternative Subsea Control System

There are currently two primary approaches to the control of subsea equipment—all hydraulic and a hybrid of electric and hydraulic (electrohydraulic). Each offers a number of variations with unique advantages, disadvantages, and associated costs that must be considered and

Fig. 18.49—Direct hydraulic subsea control.

evaluated before a system design is finalized. Usually, one design will prove superior to the others for a given situation. Applicability of a given design depends on factors such as water depth, operating environment, offset distances, equipment to be controlled, operating requirements, operating philosophies, reservoir characteristics, and field economics.

The following sections include brief discussions of several basic system designs and their primary advantages and disadvantages. When the final selection is made, trade-offs must be made between simplicity, response time, operability, and costs on a site/project-specific basis.

Direct Hydraulic Control

Direct hydraulic control (Fig. 18.49) is the most straightforward design approach. It uses a single three-way surface control valve—a single, relatively large-diameter, dedicated high-pressure control line between the surface control valve and the subsea tree hydraulic-valve actuator and the valve actuator. When the surface control valve is operated, high-pressure fluid is introduced into the control hose, causing the subsea valve actuator to open the tree valve. When the surface valve is deactivated, the fluid that opened the subsea valve is returned to the surface fluid reservoir. The advantages of this system are simplicity, discrete remote control over each subsea function,

inherent feedback on subsea operations, and minimum cost of the basic control hardware. The disadvantages are slowest response time for a given control-line size, highest control-line costs, and potential problems with corrosion and biofouling of the subsea actuator when a water-based control fluid is used because the fluid is never renewed. System costs are directly proportional to the number of functions controlled and the distance between the control point and the subsea device. This type of system is seldom used with producing wells at offset distances of more than 10,000 ft, or with injection wells at more than 15,000 ft, because of the cost and response-time considerations.

Response time of the direct hydraulic controls for the valve-closing (shut-in) operation over a given distance with a given line size can be improved significantly by installing a subsea dump valve on each tree-valve actuator. This approach also permits the introduction of new control fluid into the control lines because the fluid in the actuators is vented to the ocean whenever a valve is closed. This provides a gradual renewal of control fluid with each valve operation.

The disadvantage of dump valves is that they introduce additional flow-rate/direction-sensitive hydraulic-control elements that require very clean control fluid. This increases subsea hardware cost and markedly reduces the overall system reliability.

Fig. 18.50—Discrete-piloted hydraulic subsea control.

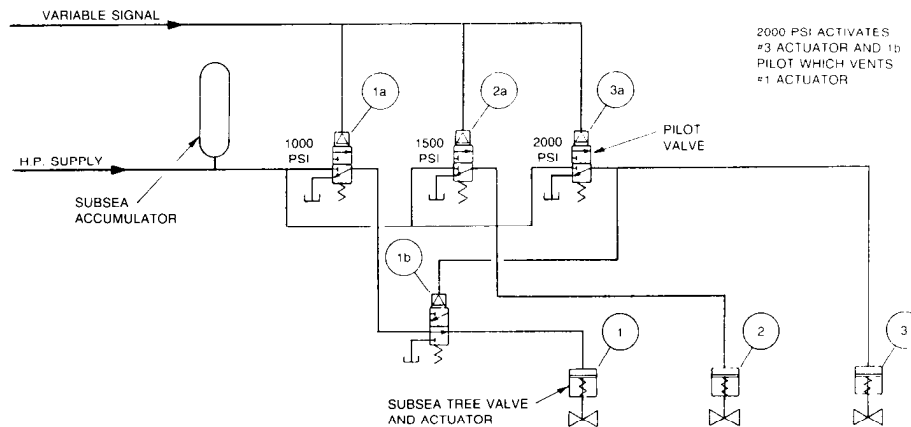

Fig. 18.51—Sequential-piloted hydraulic subsea control.

Discrete-Piloted Hydraulic

Discrete-piloted control (Fig. 18.50) has a single three-way control valve at the surface for each subsea function, a corresponding subsea pilot control valve, and single small-diameter dedicated signal line between the two control valves. A single common high-pressure line provides hydraulic supply from the surface to the tree. When the subsea pilot valve is actuated, it switches high-pressure fluid from the supply line to the subsea valve actuator. When the pilot valve is deactuated, it vents the actuator fluid subsea rather than returning it to the surface.

The advantages of this design are its relative simplicity, discrete remote control over each subsea function, inherent inferred feedback on subsea operations, relatively low-cost hardware, and relatively fast response compared to the direct hydraulic design. The disadvantages are that cost and response time are both proportional to distance just as they are with direct hydraulics, but the effects are significantly less. The pilot lines are dead-ended, but cor-

rosion is not a problem because pilot valves usually are made of stainless alloys. Biofouling, however, can still be a problem.

Sequential-Piloted Hydraulic

Sequential control is similar to discrete-piloted control in that it also has subsea pilot valves that direct high-pressure hydraulic fluid to tree-valve actuators (Fig. 18.51). However, subsea pressure-sensitive pilot valves that are manifolded to a common signal line are used in this design. Rather than discrete control over each individual pilot valve, they are switched in groups according to the signal pressure and the pilot-valve set points. The valves are interconnected so that supply pressure is applied to the subsea tree actuators in a predetermined sequence in response to changes in signal pressure. Up to six combinations of valve operations can be implemented reliably with a single control line and a single supply line. The advantage of this system is its relatively lower cost for

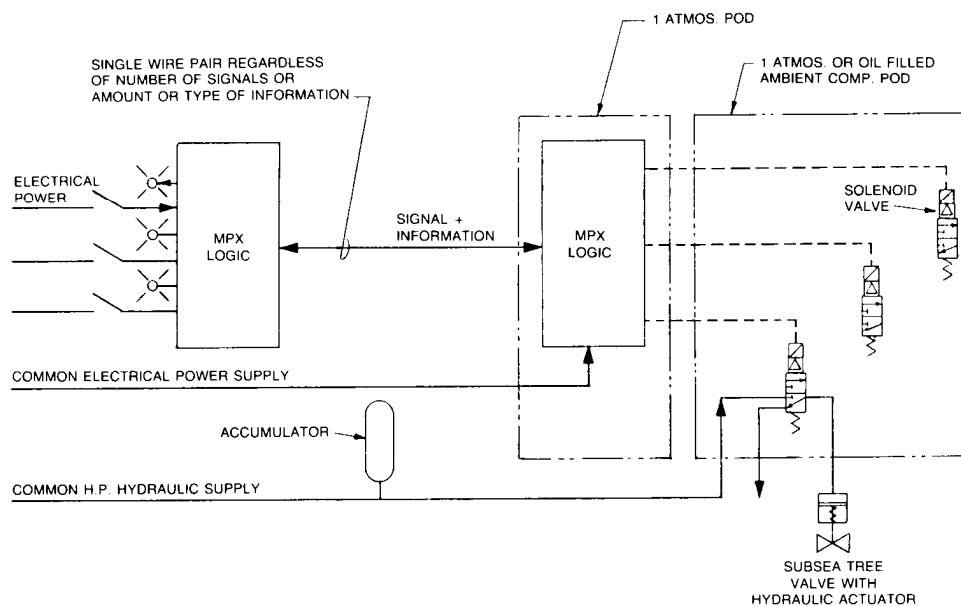

Fig. 18.52—Multiplexed control with hydraulic valve actuators.

hardware and control lines. It has a somewhat slower response than a discrete-piloted hydraulic system, and it is less reliable because it is more complex. The really significant disadvantages, however, are that independent valve control is impossible, there is no ready means of confirming valve operations, and operating sequences must be predetermined before manufacture and installation. Further, the sequence approach offers no means for independent valve control for performing operational tests, troubleshooting or diagnosis, or for changing flow paths through a subsea system in the event of a malfunction.

Multiplexed Electrohydraulic Control

This design (Fig. 18.52) has a single high-pressure hydraulic supply line and an electric cable that, in its simplest form, consists of one pair of signalling wires and one pair of power wires. The limited number of electrical conductors permits the use of inductive couplers rather than the more conventional pin-and-socket connectors. Pin connectors historically have been troublesome in subsea production applications, while inductive couplers have proved to be relatively foolproof. Inductive couplers are easily and reliably remotely mated and unmated subsea, which provides maximum flexibility in hardware layout. Encoding and decoding multiplex logic are provided at the surface and subsea to enable transmission of coded valve-open and valve-close commands and associated status feedback over one pair of single wires. The multiplexed valve commands trigger electric solenoid pilot valves that activate hydraulic-switching valves to direct high-pressure fluid to the tree-valve actuators. The advantages of this system are (1) fastest possible response independent of distance, (2) simplicity of control lines, and (3) total flexibility. With some designs, a totally hydraulic backup system can be included with the multiplexed system at little increase in cost to provide some measure of temporary operability in the event of an electrical failure. The obvious disadvantages of this design are its increased complexity and higher costs.

With a multiplexed electrohydraulic system, a recirculating (closed) subsea hydraulic power unit is also feasible in the control housing. This approach offers the possibility of eliminating the hydraulic supply line if system leakage can be controlled to a very low level. If this design approach is used, some provision still must be made for fluid makeup to account for long-term leakage. The primary advantage is that it allows the use of conventional oil-based hydraulic fluids, thus ensuring maximum life and reliability. The obvious disadvantages are the substantial increase in system complexity and consequent overall lower system reliability.

Chapter 19

Crude Oil Emulsions

H. Vernon Smith, Meridian Corp.

Kenneth E. Arnold, Paragon Engineering Services Inc.

Introduction

Much of the oil produced worldwide is accompanied by water in an emulsion that requires treating. Even in those fields where there is essentially no initial water production, water cuts may increase in time to the point where it is necessary to treat the emulsion. Water content of the untreated oil may vary from a fraction of 1% to over 90%.

To prevent increased transportation costs, water treatment and disposal costs, and deterioration of equipment, purchasers of crude oil limit the basic sediment and water (BS&W) content of the oil they purchase. Limits vary depending on local conditions, practices, and contractual agreements and typically range from 0.2 to 3.0%. BS&W is usually predominantly water but may contain solids. The solids contained in the BS&W come from the producing formation and consist of sand, silt, mud, scale, and precipitates of dissolved solids. These troublesome solids vary widely from producing field to field, zone to zone, and well to well.

Purchasers may also limit the salt content of the oil. Removing water from the stream decreases the salt content. Salt content along with BS&W are the two important crude purchasing requirements.

When water forms a stable emulsion with crude oil and cannot be removed in conventional storage tanks, emulsion-treating methods must be used. The methods, procedures, equipment, and systems generally used in treating crude oil emulsions are considered in this chapter. Space limitation does not permit the rigorous treatment of crude oil emulsions. Many topics and sub-topics exist on which entire chapters can be written. This chapter contains an abbreviated discussion of only a few of the most important and pertinent considerations of crude oil emulsions. More detailed and diversified discussions on crude oil emulsions can be found in the General References at the end of the chapter.

Theories of Emulsions

Definition of an Emulsion

An emulsion is a heterogeneous liquid system consisting of two immiscible liquids with one of the liquids intimately dispersed in the form of droplets in the second liquid. An emulsion is distinguished from a simple dispersion of one liquid in another by the fact that, in an emulsion, the probability of coalescence of droplets on contact with one another is greatly reduced because of the presence of an emulsifier, which inhibits coalescence. Such inhibition is not present in a dispersion.

The stability of the emulsion is controlled by the type and amount of surface-active agents and/or finely divided solids, which commonly act as emulsifying agents or emulsifiers. As shown in Fig. 19.1, these emulsifying agents form interfacial films around the droplets of the dispersed phase and create a barrier that slows down or prevents coalescence of the droplets.

The matrix of an emulsion is called the external or continuous phase. The portion of the emulsion that is in the form of small droplets is called the internal, dispersed, or discontinuous phase. The emulsions considered in this chapter consist of crude oil and water or brine produced with it.

In most emulsions of crude oil and water, the water is finely dispersed in the oil. The spherical form of the water globules is a result of interfacial tension (IFT), which compels them to present the smallest possible surface area to the oil. This is a water-in-oil emulsion and is referred to as a "normal" emulsion. The oil can be dispersed in the water to form an oil-in-water emulsion, which is referred to as an "inverse" or "reverse" emulsion. A typical reverse emulsion is shown in Fig. 19.2.

Emulsions are sometimes interrelated in a more complex form. The emulsion may be either water-in-oil or oil-in-water to begin with, but additional agitation may

Fig. 19.1—Photomicrograph of water-in-oil emulsion. Observe the rigid-appearing film or skin that retards coalescence.

Fig. 19.2—Photomicrograph of reverse emulsion. Uniformly sized oil particles are about 10 μm in diameter and are dispersed in the continuous water phase.

cause it to become multistage. If it is a water-in-oil emulsion initially, a water-in-oil-in-water emulsion can be formed if a small volume of the original water-in-oil emulsion is enveloped in a film of water. It is also possible to form multistage emulsions in an oil continuous phase as shown in Figs. 19.3 and 19.4. This alternating external-phase/internal-phase/external-phase arrangement has been known to exist in eight stages. Multistage emulsions usually add appreciably to the problem of separating the emulsion into oil and water. The more violent the agitation, the more likely multistage emulsions are to form.

How Crude Oil Emulsions Form

The three conditions necessary for the formation of an emulsion are (1) the two liquids forming the emulsion must be immiscible, (2) there must be sufficient agitation to disperse one liquid as droplets in the other, and (3) there must be an emulsifying agent present. Crude oil and water are immiscible. If gently poured into the same container, they will quickly separate. If the oil and water are violently agitated, small drops of water will be dispersed in the continuous oil phase and small drops of oil will be dispersed in the continuous water phase. If left undisturbed, the oil and water will quickly separate into layers of oil and water. If any emulsion is formed, it will be between the oil above and the water below.

When considering crude oil emulsions, we are usually concerned with water-in-oil emulsions because most emulsions are this type. Oil-in-water emulsions are encountered in some heavy oil production, however, such as that

found in areas of Canada, California, Venezuela, and other areas. Oil-in-water emulsions are generally resolved in the same way as water-in-oil emulsions, except electrostatic treaters cannot be used on oil-in-water emulsions.

The agitation necessary to form an emulsion may result from any one or a combination of several sources: (1) the bottomhole pump, (2) flow through the tubing, wellhead, manifold, or flowlines, (3) the surface transfer pump, or (4) pressure drop through chokes, valves, or other surface equipment. The greater the amount of agitation, the smaller the droplets of water dispersed in the oil. Figs. 19.5 through 19.9 show common crude oil emulsions that demonstrate the range of droplet sizes normally encountered. Studies of water-in-oil emulsions have shown that water droplets are of widely varying sizes, ranging from less than 1 to about 1,000 μm . Emulsions that have smaller droplets of water are usually more stable and difficult to treat than those that have larger droplets.

Crude oils vary widely in their emulsifying tendencies. Some may form very stable emulsions that are difficult to separate, while others may not emulsify or may form a loose emulsion that will separate quickly. The presence, amount, and nature of an emulsifying agent determines whether an emulsion will be formed and the stability of that emulsion. If the crude oil and water contain no emulsifying agent, the oil and water may form a dispersion that will separate quickly because of rapid coalescence of the dispersed droplets. On the other hand, if an emulsifying agent is present in the crude oil, a very stable emulsion can be formed.

Fig. 19.3—Photomicrograph of oil-in-water-in-oil emulsion. Oil droplets are shown dispersed in water droplets that are dispersed in the continuous oil phase.

Fig. 19.4—Photomicrograph of multiple-stage emulsion from Rocky Mountain field. The dispersed water phase contains small oil particles.

If an emulsion is not treated, a certain amount of water will separate from the oil by natural coalescence and settling because of the difference in density of oil and water. Unless some form of treatment is used to accomplish complete separation, however, there probably will be a small percentage of water left in the oil even after extended settling. The water that remains in the oil will be in minute droplets that have extremely slow settling velocities. They will be widely dispersed so that there will be little chance for them to collide, coalesce into larger droplets, and settle.

The amount of water that emulsifies with crude oil in most production systems may vary from less than 1 to more than 60% in rare cases. The most common range of emulsified water in light crude oil—i.e., oil above 20° API—is from 5 to 20 vol%. The most common range of emulsified water in crude oil heavier than 20° API is from 10 to 35%.

Emulsifying Agents

Emulsifying agents are surface-active compounds that attach to the water-drop surface and lower the oil/water IFT. When energy is added to the mixture by agitation, the dispersed-phase droplets are broken into smaller droplets. The lower the IFT, the smaller the energy input required for emulsification—i.e., with a given amount of agitation, smaller droplets will form.

There are many theories on the nature of emulsifying agents in crude oil emulsions. Some emulsifiers are thought to be asphaltic in nature. They are barely soluble

Fig. 19.5—Photomicrograph of loose emulsion from western Kansas containing about 30% emulsified water in the form of droplets ranging in diameter from about 60 μm downward.

Fig. 19.6—Photomicrograph of water-in-oil emulsion with dispersed particles of water ranging in size from about 250 to about 1 μm .

Fig. 19.7—Photomicrograph of relatively tight water-in-oil emulsion. Largest water droplets are about 60 μm , medium droplets are about 40 μm , and the smallest ones are about 1 to 20 μm .

Fig. 19.8—Photomicrograph of tight emulsion with the dispersed water particles varying in size from 1 to 20 μm .

in oil and are strongly attracted to the water. They come out of solution and attach themselves to the droplets of water as these droplets are dispersed in the oil. They form thick films that surround the water droplets and prevent the surfaces of the water droplets from contacting, thus preventing coalescence when the droplets collide.

Oil-wet solids—such as sand, silt, shale particles, crystallized paraffin, iron, zinc, aluminum sulfate, calcium carbonate, iron sulfide, and similar materials—that collect at the oil/water interface can act as emulsifiers. Fig. 19.10 shows some of these solids removed from a crude oil emulsion. These substances usually originate in the oil formation but can be formed as the result of an ineffective corrosion-inhibition program.

Many emulsions are prepared for commercial use. An emulsion of kerosene and water is used for spraying fruit trees; soap is used as the emulsifying agent. Eggs supply the emulsifying agent used in the preparation of mayonnaise from vegetable oil and vinegar. These are very stable emulsions.

Most but not all crude oil emulsions are dynamic and transitory. The interfacial energy per unit of area in petroleum emulsions is rather high compared with familiar industrial emulsions. They are therefore thermodynamically unstable in the sense that if the dispersed water coalesced and separated, the total free energy would decrease. Only the presence of an emulsifier film introduces an energy barrier that prevents the “breaking” or separation process from proceeding.

The characteristics of an emulsion change continually from the time of formation to the instant of complete resolution. This occurs because there are numerous types of

Fig. 19.9—Photomicrograph of tight emulsion from Huntington Beach, CA; water content 20%, with the average water droplet diameter less than 5 μm .

adsorbable materials in a given oil. Also, the adsorption rate of the emulsion and permanence of location at the interface may vary as the fluid flows through the process. Furthermore, the emulsion characteristics are changed as the liquid is subjected to changes in temperature, pressure, and degree of agitation.

Prevention of Emulsions

If all water can be excluded from the oil as it is produced and/or if all agitation of well fluids can be prevented, no emulsion will form. Exclusion of water in some wells is difficult or impossible, and the prevention of agitation is almost impossible. Therefore, production of emulsion from many wells must be expected. In some instances, however, emulsification is increased by poor operating practices.

Operating practices that include the production of excess water as a result of poor cementing or reservoir management can increase emulsion-treating problems. In addition, a process design that subjects the oil/water mixture to excess turbulence can result in greater treating problems. Unnecessary turbulence can be caused by over-pumping and poor maintenance of plunger and valves in rod-pumped wells, use of more gas-lift gas than is needed, and pumping the fluid where gravity flow could be used. Some operators use progressive cavity pumps as opposed to reciprocating, gear, or centrifugal pumps to minimize turbulence. Others have found that some centrifugal pumps can actually cause coalescence if they are installed

Fig. 19.10—Photomicrograph showing a collection of inorganic solids removed from an emulsion by filtering and washing. These solids include calcite, silica, iron compounds, obsidian, and black carbonaceous materials.

in the process without a downstream throttling valve. Wherever possible, pressure drop through chokes and control valves should be minimized before oil/water separation.

Color of Emulsions

The color of a crude oil emulsion can vary widely, depending on the oil and water content of the emulsion and the characteristics of the oil and water. The most common color of emulsions is a dark reddish brown. However, any color from light green or yellow to grey or black may be found. "Brightness" is an indicator of the presence of an emulsion. Oil-free water and water-free oil are clear and bright. Emulsions are murky and opaque because of reflection and scattering of light at the oil/water interfaces of the dispersed phase. The greater the total interfacial area between the oil and water, the lighter the color of the emulsion. That is, an emulsion containing many small droplets of water will tend to be lighter than one containing an equal volume of water in larger droplets because the latter has less total interfacial surface area.

Stability of Emulsions

Generally, crude oils with low API gravity (high density) will form a more stable and higher-percentage volume of emulsion than will oils of high API gravity (low density). Asphaltic-based oils have a tendency to emulsify more readily than paraffin-based oils. High-viscosity crude oil

will usually form a more stable emulsion than low-viscosity oil. Emulsions of high-viscosity crude oil usually are very stable and difficult to treat because the viscosity of the oil hinders or prevents movement of the dispersed water droplets and thus retards their coalescence. In addition, high-viscosity/high-density oils usually contain more emulsifiers than lighter oils.

Effect of Emulsion on Viscosity of Fluids

Emulsions are always more viscous than the clean oil contained in the emulsion. The ratio of the viscosity of an emulsion to the viscosity of the clean crude oil in oilfield emulsions depends on the shear rate to which it has been subjected. The authors have found that for many emulsions and the shear rates normally encountered in piping systems, this shear rate can be approximated by the following equation if no other data are available.

$$\mu_e/\mu_o = 1 + 2.5f + 14.1f^2, \dots\dots\dots (1)$$

where

- μ_e = viscosity of emulsion,
- μ_o = viscosity of clean oil, and
- f = fraction of the dispersed phase.

Sampling and Analyzing Crude Oil Emulsions

Purchasers of crude oil have established certain specifications that must be met before they will accept oil from a producer. These specifications limit the amount of BS&W in the oil. The limitations are usually strict, and if the amount of BS&W in the oil exceeds the specified limit, the oil may not be accepted by the purchaser. The seller and buyer must agree on the procedure for sampling and analyzing the oil to provide consistent and mutually acceptable data.

The performance of emulsion-treating units or systems can be observed and studied by the practice of regularly and periodically withdrawing and analyzing samples of the contents at multiple levels in the vessels or multiple points in the systems. This is particularly beneficial in treating emulsions involving viscous oils. Samples of emulsions should be representative of the liquid from which they are taken. Emulsification should not occur when the sample is extracted. Samples obtained at the wellhead, manifold, or oil and gas separator may show a high percentage of emulsion, but the oil and water in the system may actually not be emulsified. This indicates that emulsification occurred because of the turbulence created as the sample was removed from the pressure zone to the sample container.

It is possible to take a sample from a pressure zone without further emulsification of the liquids if the velocity of the discharging liquid is controlled. One method is to use a piece of small-diameter tubing approximately 10 to 15 ft long. One end of the tubing is connected to a bleeder valve on the line or vessel from which the sample is to be extracted, and the other end is connected to the sample container. The bleeder valve should be opened fully and the sample allowed to flow through the small-diameter tubing into the container. The pressure drop from

the line to the container is absorbed by flow through the tubing. Flow through the tubing, however, can cause either coalescence or additional emulsification.

Another method of withdrawing a representative sample of emulsion is to use a sample container initially filled with water. The sample container is equipped with valves at the top and bottom with the top valve connected to the point from which the sample is to be extracted. The top valve of the container is opened first and the container pressured from the line. The valve at the bottom of the container is then opened and the water discharged into the atmosphere as the sample enters the container. There will be no emulsification in the container because there is no pressure drop between the source and sample container to cause turbulence. Once the sample is taken, pressure can be bled off through a third valve with little effect on the sample.

Small centrifuges are used to determine BS&W content of crude oil. The centrifuges may be driven by hand or electric motor. A small measured volume of sample is diluted with solvent and placed in graduated glass containers. These are then inserted into the centrifuge and rotated at high speed for a few minutes. Separation of the oil, water, and solids is accomplished by centrifugal force. The percentages of each constituent can be read directly from the graduated containers in which the sample is centrifuged. The speed used in these small centrifuges varies from 2,000 to 4,000 rev/min.

Methods of taking and analyzing samples of crude oil for custody transfer are included in the *API Manual of Petroleum Measurement Standards*. Also see Chap. 17.

Methods Used in Treating Crude Oil Emulsions

Three basic steps usually are required to separate a crude-oil/water emulsion into bulk phases of oil and water.

Step 1—Destabilization. An emulsion is destabilized by counteracting the stabilizing effect of the emulsifier. The tough skin or film surrounding the dispersed water droplets must be weakened and broken. This is usually accomplished by adding heat and/or a properly selected, interfacially active chemical compound to the emulsion.

Step 2—Coalescence. After the films encasing the dispersed droplets are broken, the dispersed droplets must coalesce into drops large enough to settle out of the continuous phase of oil. Fig. 19.11 shows a small droplet of water breaking through a destabilized emulsion film to coalesce with the bigger drop. This usually is accomplished by imposing a period of moderate agitation or by subjecting the destabilized emulsion to an alternating electric field. This will increase the dispersed droplets contacting rate. Thus coalescence will increase, resulting in larger droplets.

Step 3—Gravity Separation. A quiet period of settling must be provided to allow the coalesced drops to settle out of the oil because of the difference in density between the water and oil. This is accomplished by providing a sufficient residence time and a favorable flow pattern in a tank or vessel that will allow the coalesced drops of water to separate from the oil.

Another way of stating the general emulsion-treating procedure is that to resolve a crude-oil/water emulsion into bulk oil and water three things must be done:

Fig. 19.11—A water-in-oil emulsion with the film or skin surrounding the water droplet in the process of rupturing.

(1) increase the probability of coalescence of dispersed water droplets on contact, (2) make the rate of contact of dispersed water droplets high without creating high shear forces, and then (3) allow the liquids to settle quietly so that they can separate into bulk phases of oil and water. All the incidental variables, such as selection of proper chemical, rate of chemical injection, treating temperature and pressure, oil and emulsion viscosity, flow rate, vessel design, vessel size, and fluid levels, are controlled to execute these three steps in the quickest and most economical manner.

An emulsion-treating unit or system will use one or more of the methods in Table 19.1 to aid in destabilizing, coalescence, and/or settling. Each of these treating methods that can be used to resolve an emulsion is discussed separately.

Heating

The use of heat in treating crude oil emulsions has four basic benefits.

1. Heat reduces the viscosity of the oil, resulting in a greater force during collision of the water droplets. Also, the reduced oil viscosity allows the water droplets to settle more rapidly through the less viscous oil. Fig. 19.12 can be used to estimate crude oil viscosity/temperature relationships. Viscosities vary widely from one crude to another. The curves should be used only in the absence of specific data. If the viscosity of the crude is known at two temperatures, the viscosity at other temperatures can be approximated by a straight line. If the viscosity is known at one temperature, it can be approximated at

other temperatures by drawing a straight line parallel to the others. If the viscosity is unknown at any temperature, the lines on the chart may be used. API Spec. 12L recommends that crude be heated so that its viscosity is below 150 SSV (about 50 cSt) for treating.

2. Heat increases the droplets' molecular movement. This aids in coalescence through increased collision frequency of the dispersed-phase droplets.

3. Heat may deactivate the emulsifier (e.g., dissolving paraffin crystals) or it can enhance the action of treating chemicals, causing the chemical to work faster and more thoroughly to break the film surrounding the droplets of the dispersed phase of the emulsion.

4. Heat may also increase the difference in density between the oil and the water, thus accelerating settling. In general, at temperatures below 180°F, the addition of heat will increase the difference in density. Most light oils are treated below 180°F; thus the effect of heat on gravity is beneficial. For heavy crudes (below 20° API), which normally are treated above 180°F, heat may have a negative effect on difference in density. In special cases, increased heat may cause the density of water to be less than that of oil. This effect is shown in Fig. 19.13.

Heating well fluids is expensive. Adding heat can cause a significant loss of the lower-boiling-point hydrocarbons (light ends). This results in "shrinkage" of the oil, or loss of volume. Because the light ends are boiled off, the remaining liquid has a lower API gravity and thus may have a lower value. Figs. 19.14 and 19.15 illustrate typical gravity and volume losses for 33° API crude vs. temperature. The molecules leaving the oil phase may be vented or compressed and sold with the gas. Even if they are sold with the gas, there probably will be a net loss in income.

The gas liberated when crude oil is treated may also create a problem in the treating equipment if the equipment is not properly designed. In vertical emulsion treaters and gun barrels, some gas may rise through the coalescing section. The liberated gas can create enough turbulence and disturbance to inhibit coalescence. Perhaps more important, the small gas bubbles have an attraction for surface-active material and hence for the water droplets; thus they have a tendency to keep the water droplets from settling and even may cause them to be discharged with the oil.

Fig. 19.12—Approximate viscosity/temperature relationships for crude oil.

Fig. 19.13—Relationship of specific gravity with temperature for three crude oils.

Fuel is required to provide heat, and the cost of fuel must be considered. If the oil is much above ambient temperature when discharged from the treating unit, it can be flowed through a heat exchanger with the incoming well fluid to transfer the heat to the cooler incoming well fluid. This will minimize evaporation losses and reduce fuel cost. It will also increase the vapor pressure of the crude, however, which may be limited by contract.

If properly applied, heating an emulsion can have great beneficial effect on water separation. The most economical emulsion treating may be obtained by use of less heat and a little more chemical, agitation, and/or settling space.

In some geographic areas, emulsion heating requirements vary in accordance with daily and/or seasonal atmospheric temperatures. Emulsions are usually more difficult to treat when it is cool—at night, during a rain, or in winter months when the atmospheric temperatures are lowest. Treatment, especially heating, may not be required in warmer summer months. Where the treating problem is seasonal, some emulsions can be resolved successfully by addition of more chemical demulsifiers during winter months. Study is required to determine the proper economic balance of heat and chemicals.

Crude oil emulsions with similar viscosity ranges do not always require the same type of treating equipment or the same treating temperature. Emulsions produced

Fig. 19.14—API gravity loss vs. temperature for crude oil.

Fig. 19.15—Percent loss by volume vs. temperature for crude oil.

from different wells on the same lease or from the same formation in the same field may require different treating temperatures. For this reason, it is recommended that low treating temperatures be tested so that the lowest practical treating temperature for each emulsion and treating unit or system can be determined by trial.

The heat input and thus the fuel required for treating depends on the temperature rise, amount of water in the oil, and the flow rate. It requires about twice as much energy to heat a given volume of water as it does to heat the same volume of oil. For this reason, it is beneficial to separate free water from the emulsion to be treated. Often this is accomplished in a separate free-water knock-out vessel upstream of the point where heat is added. Sometimes it is accomplished in a separate section of the same vessel.

The required heat input for an insulated vessel (heat loss is assumed to be 10% of heat input) can be approximated from

$$Q = 16\Delta T(0.5q_o\gamma_o + q_w\gamma_w), \quad (2)$$

where

- Q = heat input, Btu/hr,
- ΔT = increase in temperature, °F,
- q_o = oil flow rate, B/D,
- q_w = water flow rate, B/D,
- γ_o = specific gravity of oil, and
- γ_w = specific gravity of water.

Chemical Demulsifiers

Certain chemical compounds are widely used to destabilize and to assist in coalescence of crude oil emulsions. These are referred to as dehydration chemicals or demulsifiers. This treatment method is popular because the

chemicals are easily applied to the emulsion, usually are reasonable in cost, and usually minimize the amount of heat and settling time required.

The chemical counteracts the emulsifying agent, allowing the dispersed droplets of the emulsion to coalesce into larger drops and settle out of the matrix. For demulsifiers to work, they must (1) be injected into the emulsion, (2) intimately mix with the emulsion and migrate to all of the protective films surrounding all of the dispersed droplets, and (3) displace or nullify the effect of the emulsifying agent at the interface. A period of continued moderate agitation of the treated emulsion to produce contact between and coalescence of the dispersed droplets and a quiet settling period must exist to allow separation of the oil and water.

Four actions are required of a chemical demulsifier.

Strong attraction to the oil/water interface. The demulsifier must have ability to migrate rapidly through the oil phase to reach the droplet interface where it must counteract the emulsifying agent.

Flocculation. The demulsifier must have an attraction for water droplets with a similar charge and bring them together. In this way, large clusters of water droplets gather, which look like bunches of fish eggs under a microscope.

Coalescence. After flocculation, the emulsifier film is still continuous. If the emulsifier is weak, the flocculation force may be enough to cause coalescence. This is not true in most cases, and the demulsifier must therefore neutralize the emulsifier and promote rupture of the droplet interface film. This allows coalescence to occur. With the emulsion in a flocculated condition, the film rupture results in growth of water drop size.

Solids Wetting. Iron sulfides, clays, and drilling muds can be made water-wet, causing them to leave the interface and be diffused into the water droplets. Paraffins and

asphaltenes can be dissolved or altered by the demulsifier to make their films less viscous, or they can be made oil-wet so that they will be dispersed in the oil.

The demulsifier selection should be made with all functions of the treating system in mind. If the process is a settling tank, a relatively slow-acting demulsifier can be applied with good results. On the other hand, if the system is an electrostatic process, where some of the flocculation and coalescing action is accomplished by the electric field, there is need for a quick-acting demulsifier. Time for demulsifier action in a vertical emulsion treater normally will be somewhere between that of a settling tank and that of an electrostatic treater.

As field conditions change and/or the treating process is modified, the chemical requirements may change. Seasonal changes may cause paraffin-induced emulsion problems. Well workovers may change solids content, which may alter emulsion stability. So no matter how satisfactory a demulsifier is, it cannot be assumed that it will always be satisfactory over the life of the field.

While the first commercial emulsion-treating chemical was a solution of soap, present-day chemicals are based on highly sophisticated materials. Chemical emulsion breakers are complex organic compounds with surface-active characteristics. The active properties may be derived from any one or a combination of nonionic, cationic, and anionic materials. Within each of these types, compositions are used that will confer various degrees of hydrophobe/hydrophile balance to the chemical as desired. The active components are highly viscous and sometimes even solids. It is necessary to use a carrier that will make handling easier; this carrier is almost without exception an organic solvent. Solvent systems are designed to make emulsion breakers compatible with the crude oil system in which they are used. It is also necessary to omit materials that will interfere with refining processes, such as those that will poison catalysts. Therefore, no organic chlorides, bromides, iodides, fluorides, or compounds of arsenic or lead are used in the manufacture of most emulsion-treating chemicals.

There is no simple designation of specific chemicals to treat specific emulsions. There are, however, certain common demulsifier types that tend to produce a consistent reaction in many water-in-oil emulsions. Some of the demulsifier types are as follows.

Polyglycol esters are characterized by quick brightening of emulsions, but frequently tend toward slow water drop and sludging; they are subject to overtreating problems.

Low-molecular-weight resin derivatives tend toward rapid water drop and fair to good overall demulsification properties; they show some tendency toward overtreatment in high-API-gravity emulsions.

High-molecular-weight resin derivatives generally have a strong wetting tendency and fair brightening and water-drop characteristics; they are always used in combination with other materials.

Sulfonates exhibit fair to good wetting and water-drop performance, some ability to brighten oil, and very little tendency to overtreat, particularly in high-gravity emulsions.

Polymerized oils and esters produce specific characteristics on particular emulsions; they are generally poor for widespread application and are always used in combination with other materials.

Alkanolamine condensates promote water drop in some emulsions and may produce some brightening; they are blended with other materials for overall good performance.

Oxyalkylated phenols are predominantly wetting agents with fair to poor demulsification properties; they are used in blending to improve demulsifier performance.

Polyamine derivatives produce good brightening characteristics and are good blending agents; they are relatively poor in other respects.

There are many specific variations within each of these broad categories. Most demulsifiers used in breaking crude oil emulsions are blends of the above and other compounds. The components selected for a given demulsifier are chosen to provide the necessary actions to achieve complete emulsion treatment. The number of different surface-active materials that can act as emulsifiers in crude oil is large. The possible combinations of these emulsifying agents is almost infinite. Therefore, the number of demulsifiers and their combinations must likewise be numerous to treat the emulsions. The type and composition of the crude oil in the emulsion being treated has more influence on how a certain chemical demulsifier will perform than does the specific category of components included in the treating chemical. For example, a low-molecular-weight resin used in treating an emulsion of 35°API oil may exhibit rapid water drop, but that same chemical, when used in treating an emulsion of 15°API oil, may not cause rapid water drop. This illustrates that demulsifying chemicals must be compounded for each particular emulsion.

Each treating system must be tested and checked to ensure that the chemicals used for treating the water for disposal do not conflict with chemicals used for treating the oil emulsion. One chemical must not react with the other to cause problems, such as stabilizing the oil in the water. Compatibility of the two chemicals must be tested by bottle tests and then by field tests in the actual treating system. Also, compatibility tests should be performed for any other chemicals added to the produced fluids.

Selection of the optimum chemical to use usually starts with bottle tests. A representative sample of fluid is taken and transferred into several test bottles. Several demulsifying chemicals are added to the test bottles in various amounts to determine which chemical will best break the emulsion. Additional tests are made to determine the optimum ratio of chemical to fluid. Several series of tests may be necessary at various ratios and temperatures before a selection can be made. Many factors—such as the color and appearance of the oil, clarity of the water, interface quality, required operating temperature, settling time, and BS&W content—are observed during these bottle tests.

Bottle tests can be made with the samples of emulsion taken at the wellhead, anywhere in the flowline, at the manifold, or at the entrance to the treating system or tank. Well-equipped mobile laboratories are available, so this type of work can be done in the field. These mobile units should be operated by trained technicians who can minimize testing and optimize selection of chemical demulsifiers.

After the bottle tests are made and the best two or three chemicals have been selected, they should be field tested in the treating system to verify that the best chemicals have been selected. Tests should be made in the treating sys-

Fig. 19.16—Chemical distributor for flowlines 10 in. and larger.

tem at various concentrations, operating temperatures, settling times, degrees of mixing, etc., before the final selection is made on the basis of performance and cost. The optimum chemical is one that will provide the clearest, cleanest separation of water from oil at the lowest temperature in the shortest time at the lowest cost per barrel treated and that will not interfere with subsequent deoiling of the water.

The required concentration of demulsifying chemical may be as high as 8 gal/1,000 bbl (about 200 ppm) or as low as 1 gal/5,000 bbl (about 5.0 ppm). This is a range of 40 to 1. The most common range of chemical injection is between 10 and 60 ppm.

Application of heat to an emulsion after a demulsifier has been mixed with it increases effectiveness of the chemical by reducing the viscosity of the emulsion and facilitating more intimate mixing of chemical with emulsion. Chemical reaction at the oil/water interface takes place at a more rapid rate at higher temperatures.

The point of injection of demulsifier chemical into the emulsion is important. The chemical should be injected into the emulsion and mixed with it so that it is evenly and intimately distributed throughout the emulsion when it is heated, coalesced, and settled in the treating system. The demulsifying chemical should be injected in a continuous stream, with the chemical volume directly proportional to the emulsion volume. Certain demulsifiers should not be present in the emulsion during excessively prolonged agitation because the beneficial effect of the demulsifier may be spent or counteracted by the agitation and re-emulsification may occur.

Turbulence accelerates the diffusion of the demulsifier throughout the emulsion and increases the number and intensity of impacts between water droplets. Turbulence must be prolonged for a sufficient time to permit the chemical to reach the interface between the oil and all the dispersed water droplets, but the intensity and duration of the turbulence must be controlled so that it will not cause further emulsification. Turbulence is the dynamic factor that disperses the water in the oil and is a prerequisite

to emulsion formation. A moderate level of controlled turbulence, however, causes the dispersed droplets to collide and coalesce. Usually, this turbulence is provided by normal flow in surface lines, manifolds, and separators and by flow through the emulsion-treating unit or system.

One way of assisting in dispersing the chemical throughout the entire volume of emulsion is to mix a small volume of chemical with a diluent and then to inject and mix the diluted chemical with the emulsion. The larger volume of the mixture may make it possible for the chemical to be more uniformly and intimately mixed with the emulsion.

When flow rates are low (less than 3 ft/sec) or when laminar flow is encountered, the injection of chemical into a coupling welded in the side of the pipe is not recommended. In such cases, an injection quill (which injects the chemical in the stream at a location removed from the wall), a chemical distributor (Fig. 19.16), and/or a kinetic mixer (Fig. 19.17) is recommended. The kinetic mixer consists of a series of staggered, helically convoluted vanes that use the velocity of the fluid to accomplish mixing.

When a tank of wet oil (oil containing more than the permissible amount of water) accumulates, the tank contents can be treated by adding a small proportion of demulsifier, agitating or circulating the tank contents, and then allowing time for the water to settle in the tank. Trailer-mounted units that include a heater, circulating pump, and chemical injector are sometimes used for this method of tank treating. This batch-treatment method normally is used as an emergency measure.

Excessive amounts of treating chemical can result in increased stability of the water-in-oil emulsion or of the oil-in-water emulsion in the produced water, increase the stability or the volume of the interfacial emulsion and/or sludge, or waste money equal to the cost of the excessive volume of chemical over the optimum volume. Also, the cost of handling and injecting the excessive amount of chemical must be considered along with the purchase cost of the chemical. Insufficient treating chemical can fail to

Fig. 19.17—Kinetic (static) mixer for mixing chemical demulsifier with emulsion.

break the emulsion; allow a quick buildup of excessive amounts of emulsion and/or sludge; and result in a need for excessive heat to break the emulsion, a need for excessive settling time to resolve the emulsion, reduced capacity of the treating equipment, excessive water remaining in the crude oil causing accumulation of unsalable oil and the resultant cost of retreating the crude, or more difficulty in removing oil from the produced water.

Agitation

Agitation or turbulence is necessary to form a crude oil emulsion. When turbulence is controlled, however, it can assist in resolving the emulsion. Agitation causes increased collisions of dispersed particles of water and increases the probability that they will coalesce and settle from the emulsion. Caution should be exercised to prevent excessive agitation that will result in further emulsification instead of resolving the emulsion. If the turbulence is kept to moderate Reynolds numbers of 50,000 to 100,000, good coalescing conditions usually should be achieved.

Fig. 19.18—The S. P. Pack™ grows a larger drop size on the inlet separator of a gravity settler.

The flow of emulsions at moderate Reynolds numbers through long pipelines has been shown to cause coalescence and develop droplets that exceed 1,000 μm in diameter. The length of the pipeline required to obtain coalescence can be dramatically decreased by using a defined flow path as in the special flow coalescing device shown in Fig. 19.18.

The demulsification process may be assisted by the use of baffle plates placed inside the treating vessel. Properly designed and located baffle plates can evenly distribute emulsion in a vessel and cause gentle agitation that may bring about collisions of dispersed water particles to aid in coalescing the droplets. Excessive baffling should be avoided because it can cause excessive turbulence, which may result in increased emulsification and impede water-droplet settling. Special baffling in the form of perforated plates properly placed inside treating vessels affords surfaces upon which water droplets in the emulsion may coalesce. As the emulsion flows through the perforations, slight agitation in the form of eddy currents is created, causing coalescence. If the perforations are too small, however, shearing of the water droplets can occur, resulting in a tighter emulsion.

Other designs of baffle plates provide coalescing surfaces for the water droplets, as shown in Fig. 19.19. Flow through the plates is laminar, but directional changes enable the water droplets to contact the plates and coalesce. Such a device may plug easily and become inoperable quickly.

Electrostatic Coalescing

The small water drops dispersed in the crude oil can be coalesced by subjecting the water-in-oil emulsion to a high-voltage electrical field. When a nonconductive liquid (oil) containing a dispersed conductive liquid (water) is subjected to an electrostatic field, the conductive particles or droplets are caused to combine by one of three physical phenomena.

1. The water droplets become polarized and tend to align themselves with the lines of electric force. In so doing, the positive and negative poles of the droplets are brought adjacent to each other. Electrical attraction brings the droplets together and causes them to coalesce.

2. The water droplets are attracted to an electrode because of an induced electric charge. In an AC field, because of inertia, small droplets vibrate a greater distance than larger droplets, promoting coalescence. In a DC field, the droplets tend to collect on the electrodes, forming larger and larger droplets until eventually they settle by gravity.

3. The electric field tends to distort and thus to weaken the film of emulsifier surrounding the water droplets. Water droplets dispersed in oil subjected to a sinusoidal alternating-current field will be elongated along the lines of force as voltage rises during the first half-cycle. As they are relaxed during the low-voltage portion, the surface tension pulls the droplets back toward spherical shape. The same effect is obtained in the next half of the alternating cycle. The weakened film is thus more easily broken when droplets collide.

Whatever the actual mechanism, the electrical field causes the droplets to move about rapidly in random directions, which increases the chances of collision with other droplets. When droplets collide with the proper velocity, coalescence occurs. The greater the voltage gradient, the greater the forces causing coalescence. Experimental data show, however, that at some voltage gradient, the water droplet can be pulled apart and a tighter emulsion can result. For this reason, electrostatic treaters normally are equipped with a mechanism for adjusting the voltage gradient in the field.

If the quantity of water in the oil is large there is a tendency for the formation of a chain of charged water particles, which may form links between the two electrodes, causing short-circuiting. This is referred to as "chaining" and has been observed in emulsions containing 4% or less water. The short-circuit releases a burst of electrical energy that immediately causes this chain of water particles to become steam. The resulting explosions sound like popping popcorn. If chaining occurs, the voltage gradient is too large (i.e., the electrical grids of the electrostatic treater are too close together or the voltage is too high) for the amount of water being handled. Small amounts of gas breaking out of solution may also create sufficient turbulence and impede the coalescing process.

Water-Washing

In some emulsion-treating vessels, separation of liquids

Fig. 19.19—Performax™ plate pack, a special coalescing medium for crude oil emulsions.

and vapors takes place in the inlet diverter, flume, or gas boot located at the top of the vessel. The liquid flows by gravity to the bottom of the vessel through a large conductor pipe or conduit. A spreader plate on the lower end of the conduit spreads the emulsion into many small streams or rivulets that move upward through the water, accomplishing a water-wash. After the emulsion has passed through the water-wash, it flows to the upper portion of the vessel, where the coalesced water droplets settle out of the oil by gravity separation.

If an emulsion is flowed through an excess of the internal phase of the emulsion, the droplets of the internal phase will tend to coalesce with the excess of the internal phase and thus be removed from the continuous phase. This is the principle on which a water-wash operates. The water-wash is more beneficial if the emulsion has been destabilized by addition of a demulsifier and if the water is heated. The effectiveness of a water-wash greatly depends on the ability of the spreader plate or distributor to divide the emulsion into small streams or rivulets and to cause the emulsion to be in maximum intimate contact with the water bath so that the small drops of water can coalesce with the water.

If an emulsion-treating system or unit uses a water-wash, it can be charged with water to facilitate initial operation. Water from the emulsion to be treated should be used if available. If it is not available, extraneous water may be used.

Filtering

A filtering material with the proper size of pore spaces and the proper ratio of pore spaces to total area can be used to filter out the dispersed water droplets of a crude oil emulsion by preferentially wetting the filtering material with oil and keeping it submerged in oil. When used in this manner, the pack is correctly called a "filter" because it filters out the liquid that it prevents from passing through.

When excelsior is used as a filter in an emulsion treating, it is immersed in oil above the oil/water interface level. Excelsior is preferentially wetted by water because of the high affinity the cellulose fibers have for water. If the excelsior is initially wetted by oil, however, the dispersed water droplets in the oil will not normally take possession of the excelsior fibers because the fibers are saturated with oil. If the water droplets do take possession of the excelsior fibers, possession will occur at a slow rate and penetration of the pack by the water will be only partially complete.

Excelsior is wood that is cut into small shreds or fibers. Observed under a microscope, the surfaces of each strand of excelsior bristle with tiny sharp barbs. When emulsion flows through an excelsior pack, these rough surfaces cause distortion of the film surrounding the water droplets, thereby encouraging adherence of the droplets to the strands of excelsior. This results in coalescence of the water droplets into drops large enough to settle out of the oil. Excelsior should be made from pitch-free woods, such as aspen, cottonwood, or poplar. Pine excelsior is not recommended for crude oil emulsion-treating purposes. Excelsior should be used at less than 180°F treating temperature. Higher temperature will delignify and deteriorate the excelsior. It will also make it difficult to remove from the vessel.

Glass wool and other porous materials have been used as filtering material. Glass wool, when the fibers are properly sized and compacted, can serve as a filtering material for filtering water droplets out of a crude oil emulsion. If the glass wool is coated with silicone, its filtering effect will be enhanced because the silicone-coated fibers will be more wettable by oil than untreated glass wool fibers. Glass wool is not widely used for filtering because of its initial expense and its fouling problems.

Porous materials, both plastics and metals, are available that will filter dispersed water droplets from a crude oil emulsion. These porous materials are not widely used because of the difficulty of obtaining and maintaining the proper size pores and because they easily foul and become inoperable.

Treating crude oil emulsions by filtering is not widely used because of the difficulty in obtaining and maintaining the desired filtering effect and because the filtering material is easily plugged by foreign material.

Fibrous Packing

Fibrous coalescing packs are not commonly used in oil treating. They are mentioned for completeness and to differentiate between filtering and coalescence. A coalescing pack is a section or compartment in an emulsion-treating tank or vessel that is packed with a material that is wetted by the water, causing the water to coalesce into larger drops. Separation of two emulsified liquids by use

of a coalescing pack operates on the principle that two immiscible liquids with different surface tensions cannot simultaneously take possession of a given surface. The coalescing pack is wetted with or submerged in water. When the dispersed droplets of water come in contact with the water-wet coalescing material, the water droplets coalesce and adhere to the coalescing surfaces. Oil will pass through the pore spaces of the coalescing material. Separation of the two liquids in a coalescing pack is not caused by filtering but by the greater affinity of the water-wet coalescing material for the water droplets.

The film of oil containing the emulsifying agent surrounding the dispersed water particles must be broken before these droplets will adhere to a coalescing medium. The film is broken with the aid of demulsifying chemicals and/or heat and by repeated contact between the water particles and the surface of the coalescing materials as the emulsion flows through the pack. When this film has been broken, the water particles adhere to the surface of the coalescing material until they combine into drops large enough to settle out of the oil.

Glass wool can be used as coalescing material in emulsion-treating vessels. It will not deteriorate like wood excelsior and will prolong the service life of the coalescing pack. Glass wool fouls rather easily and may cause channeling. Woven wire mesh can also be used but tends to be more expensive than glass wool.

Gravity Settling

Gravity settling is the oldest, simplest, and most widely used method of treating crude oil emulsions. The difference in density of the oil and water causes the water to settle through and out of the oil. Because the water droplets are heavier than the volume of oil they displace, they have a downward gravitational force exerted on them. This force is resisted by a drag force caused by their downward movement through the oil. When the two forces are equal, a constant velocity is reached that can be computed from Stokes' law as

$$v = \frac{1.78 \times 10^{-6} (\Delta\gamma_{ow}) d^2}{\mu_o}, \dots\dots\dots (3)$$

where

v = downward velocity of the water droplet relative to the oil, ft/sec,

d = diameter of the water droplet, μm ,

$\Delta\gamma_{ow}$ = difference in specific gravity between the oil and water, and

μ_o = dynamic viscosity of the oil, cp.

Several conclusions can be drawn from this equation.

1. The larger the size of a water droplet, the greater its downward velocity—i.e., the bigger the droplet size, the less time it takes for the droplet to settle to the bottom of the vessel, and thus the easier it is to treat the oil.

2. The greater the difference in density between the water droplet and the oil, the greater the downward velocity—i.e., the lighter the oil, the easier it is to treat the oil. If the oil gravity were 10°API and the water fresh, the settling velocity would be zero because there is no gravity difference.

3. The higher the temperature, the lower the viscosity of the oil, and thus the greater the downward velocity of the water droplets—i.e., it is easier to treat the oil at high temperatures than at low temperatures (assuming a small effect on gravity difference because of increased temperature).

Gravity settling alone can be used to treat only loose, unstable emulsions. When other treating methods destabilize the emulsion and create coalescence, which increases water droplet size, however, gravity settling provides separation of water from oil.

Retention Time

In a gravity settler, such as an oil-treating tank or the coalescing section of an oil-treating vessel, coalescence will occur. Because of the small forces at work, however, the rate of contact between water droplets is small and coalescence seldom occurs immediately when two droplets collide. Thus the process of coalescence, although it will occur with time, follows a steep exponential curve where successive doubling of retention time results in small incremental increases in droplet size.

The addition of retention time alone, after some small amount necessary for initial coalescence, may not significantly affect the size of the water droplet that must be separated by gravity to meet the desired oil quality. A taller tank will increase the retention time but will not decrease the upward velocity of the oil or may not significantly increase the size of the water drop that must be separated from the oil. Thus the additional retention time gained by the taller tank may not materially affect the water content of the outlet oil.

A larger-diameter tank will increase the retention time. More important, it will slow the upward velocity of the oil and thus allow smaller droplets of water to settle out by gravity. In this case, it may not have been the increase in retention time that improved the oil quality but rather the reduction in flow velocity, which decreased the size of the water droplets that can be separated from the oil by gravity.

Centrifugation

Because of the difference in density between oil and water, centrifugal force can be used to break an emulsion and separate it into oil and water. Small centrifuges are used to determine the BS&W content of crude oil emulsion samples. A few centrifuges have been installed in the oil field to process emulsions. They have not been widely used for treating emulsions, however, because of high initial cost, high operating cost, low capacity, and a tendency to foul.

Distillation

Distillation can be used to remove water from crude oil emulsions. The water, along with lighter oil fractions, can be distilled by heating and then separated by appropriate means. The lighter oil fractions are usually returned to the crude oil.

The only current use of distillation is in the "flash system" used in 15°API and lower oil. These systems use the excess heat in the oil received from the treater or treating system and convert this sensible heat to latent heat at or near atmospheric pressure. The flashed steam is condensed in a surface condenser in the incoming cooler

stream of raw crude, thus scavenging the excess heat that would ordinarily be wasted. Fig. 19.20 shows a typical flash distillation system for dehydrating emulsions of heavy viscous crude oils.

The disadvantage of distillation is that it is expensive and that all the dissolved and suspended solids contained in the water are left in the oil when the water is removed by evaporation.

Emulsion-Treating Equipment and Systems

The design of equipment or a system for treating crude oil emulsions and the sizing of each piece of equipment for a specific application requires experience and engineering judgment. It would be ideal if a procedure existed that would permit the engineer to infer from measured properties of the emulsion the most economical treating process, taking into account treating temperature, chemical usage, and physical size of treating equipment. Unfortunately, such a procedure is not available and the engineer must rely on experience and empirical data from other wells or fields in the area and on laboratory experiments.

For example, the economic balance between the amount of chemical and heat to use to destabilize the emulsion and aid in coalescence is difficult to predict. Almost all emulsion-treating systems use demulsifying chemicals. In most instances, the lower the treating temperature, the greater the amount of chemical required to treat the emulsion. In many areas of west Texas and the Gulf of Mexico, some operators do not add heat to treat the relatively light crudes that are produced. Other operators under the same conditions add heat when treating similar crudes to minimize chemical cost and the size of the emulsion-treating equipment.

Another example is the economic balance that must be considered between those factors that promote coalescence (chemicals, water wash, heat, coalescing plates, etc.) and the size of the treating vessels. The larger the size of the treating vessel, the smaller the size of water droplets that can be separated from the emulsion. Thus the use of coalescing aids may reduce the size of the equipment by increasing the size of the water droplet that must be separated from the oil to meet the required quality. The savings in vessel costs must be balanced against the increased capital and operating cost (e.g., fuel and increased maintenance because of plugging) of the coalescing aids.

Bottle tests in the laboratory provide a means for estimating ranges of treating temperature and retention time for design purposes. Unfortunately, these tests are static in nature and do not model closely the dynamic effects of water droplet dispersion and coalescence that occur in the actual equipment because of flow through control valves, pipes, inlet diverters, baffles, and water-wash sections. Bottle tests, however, can be useful in estimating treating parameters such as temperature, demulsifier volume, settling time, etc.

When evaluating empirical data from similar wells or fields, the designer should recognize that the temperature at which an emulsion is treated may not be as critical as the viscosity of the crude at that temperature. The design of an oil-treating system can be assisted by observing an existing system, knowing the viscosity of the crude at treating temperature, and calculating from the flow geometry and Stokes' law the minimum size water droplet

Fig. 19.20—Typical flash distillation system for dehydrating emulsions of heavy viscous crude oils.

that can be settled from the crude. A treating system can then be designed that will heat the emulsion to the temperature required to obtain the same viscosity that exists in the sample field, and then any one of the pieces of equipment or combinations thereof described in the next section can be selected and sized so that all water droplets larger than the calculated minimum diameter can be separated from the oil.

Because of the uncertainties in attempting to scale up from laboratory data or to infer designs from empirical data from similar wells or fields, a new treating system should be designed with either larger equipment or more heat input capacity than the engineer calculates to be necessary. The amount of "overdesign" to be built into the treating system depends on an assessment of the cost of the extra capacity balanced against the risk of not being able to treat the design throughput.

Description of Equipment Used in Treating Crude Oil Emulsions

The characteristics of the emulsion to be treated should be understood before a treating system is selected. Several different types of equipment or systems may satisfactorily resolve an emulsion, but one particular type of equipment or system may be superior to others because of basic considerations in design, operation, initial cost, maintenance

cost, operating cost, and performance. Effort should be made to select the minimum number of pieces of equipment or the simplest design for each treating system to optimize initial and operating costs.

The combination of the various emulsion-treating methods that will provide the lowest use of chemical, lowest treating temperature, lowest loss of light hydrocarbons, lowest overall treating cost, and the best performance should be used. Experience and empirical data may guide the buyer to the optimum combination of treating methods, but field testing will be required to confirm the selection.

The following discussion describes various emulsion-treating equipment and systems. Each piece of treating equipment and each treating system affords a wide selection of the type, configuration, size, component selection, component design, and usage. Additional treating equipment can usually be added to each unit or system until the desired treating results are obtained. The design and selection of all the components of the treating system should be made at the time of initial purchase and installation. Because of the modular design of most systems, however, if the selected equipment does not perform as desired or if operating conditions change, additional features can usually be added or operating procedures altered to obtain the desired results.

Fig. 19.21—Typical vertical FWKO.

Free Water Knockouts

Where large quantities of water are produced, it usually is desirable to separate the free water before attempting to treat the emulsion. When oil and water are agitated with moderate intensity and then allowed to settle for a period of time, three distinct phases normally will form: a layer of essentially clean oil at the top with a small amount of water dispersed in the oil in very small droplets, relatively clean water (free water) at the bottom with a small amount of dispersed oil in very small droplets, and an emulsion phase in between. With time, the amount of emulsion will approach zero as coalescence occurs.

The free water is the water that separates in 3 to 10 minutes. It may contain small droplets of dispersed oil that may require treatment before disposal. Equipment to do this is discussed in Chap. 15.

Free-water knockouts (FWKO's) are designed as either horizontal or vertical pressure vessels. Fig. 19.21 is a schematic of a vertical FWKO, and Fig. 19.22 shows a horizontal FWKO. The fluid enters the vessel and flows against an inlet diverter. This sudden change in momentum causes an initial separation of liquid and gas, which will prevent the gas from disturbing the settling section of the vessel. In some designs, the separating section contains a downcomer that directs the liquid flow below the oil/water interface to aid in water-washing the emulsion.

The liquid-collecting section of the vessel provides sufficient time for the oil and emulsion to form a layer of oil at the top, while the free water settles to the bottom. When there is appreciable gas in the inlet stream, a three-phase separator can be used as an FWKO. See Chap. 12 for a description of both vertical and horizontal three-phase separators.

Sometimes a cone-bottom vertical three phase separator is used. This design is used if sand production is anticipated to be a major problem. The cone is normally at an angle to the horizontal of between 45 and 60°. If a cone is used, it can be the bottom head of the vessel, or for structural reasons, it can be installed internally in the vessel. In such a case, a gas-equalizing line must be installed to ensure that the vapor behind the cone is always in pressure equilibrium with the interior of the vessel. Water jets can be used to dislodge and flush the sand from the vessel.

Oil and water are usually separated more quickly and completely in an FWKO when the liquid travels through the vessel in a horizontal rather than a vertical direction. Horizontal flow permits a less restricted downward movement of the water droplets. If the emulsion flows vertically upward, the water must move downward through an upward-moving stream; therefore, the downward movement of water is retarded by upward movement of the oil and emulsion.

Fig. 19.22—Typical horizontal FWKO.

It is possible to add a heating tube to an FWKO, as shown in Fig. 19.23, or to add heat upstream of the FWKO. In such cases, even though the vessel may be called an FWKO, it is performing the function of an emulsion treater.

Many configurations are possible for providing baffles and maintaining levels in an FWKO. A good design will provide the functions described previously, i.e., degassing, water-washing, and providing sufficient retention time and correct flow pattern so that free water will be removed from the emulsion.

When the free water is removed, it may or may not be necessary to treat the oil further. In many fields producing light oil, a well-designed FWKO with ample settling time and with a reasonable chemical-treating program can provide pipeline-quality oil. Most often, however, further emulsion treating is required downstream of the FWKO.

Storage Tanks

Oil generally should be water-free before it is flowed into lease storage tanks. If there is only a small percentage of water in the oil and/or if the water and oil are loosely emulsified, however, it may be practical to allow the water to settle to the bottom of the oil storage tank and to draw off the water before oil shipment. This practice is not generally recommended or followed, but for small volumes of free or loosely emulsified water on small leases or for low-volume marginal wells, it may be a practical and economical procedure.

When a storage tank is used for dehydration, the oil is flowed into the tank and allowed to settle. When the tank is full of liquid, flow into the tank is stopped or

switched to another tank and the tank is allowed to remain idle while water settles out of the oil. After the water has been separated from the oil by settling, water is drained from the bottom of the tank and the oil is gauged, sampled, and pumped or drained to a truck or pipeline. No water-wash is used in conjunction with the standard storage tank. If there is a water-wash, its shallowness and the absence of a proper spreader causes it to be of little or no benefit.

Settling Tanks

Various names are given to settling tanks used to treat oil. Some of the most common are gunbarrels, wash tanks, and dehydration tanks. The design of these tanks differs in detail from field to field and company to company. All contain all or most of the basic elements shown in Fig. 19.24.

The emulsion enters a gas separation chamber or gas boot where a momentum change causes separation of gas. Gas boots can be as simple as the piece of pipe shown in Fig. 19.24, or they can contain more elaborate nozzles, packing, or baffles to help separate the gas. If there is much gas in the well stream, it is usually preferable to use a two- or three-phase separator upstream of the settling tank. In this case, the gas boot must separate only the gas that is liberated as the pressure decreases during flow from the separator to the settling tank.

A downcomer directs the emulsion below the oil/water interface to the water-wash section. On most large tanks, a spreader is used to distribute the flow over the entire cross section of the tank. This minimizes short-circuiting. The more the upward-flowing emulsion spreads out and

Fig. 19.23—Schematic view of FWKO with heating element in each end.

approaches plug (or uniform) flow, the slower its average upward velocity and the smaller the water droplets that will settle out of the emulsion.

There are many types of spreader designs. Spreaders can be made by cutting slots in plate, use of angle iron, or holes in pipe. By causing the emulsion stream to separate into many small streams, the spreader causes a more intimate contact with the water to help promote coalescence in the water-wash section. This is shown in Figs. 19.25 and 19.26. Most spreaders contain small holes or slots to divide the oil and emulsion into small streams. Large holes (3 to 4 in. in diameter) will not be nearly as effective in dividing the stream as small holes ($\frac{3}{8}$ to 1 in. in diameter). In designing a spreader, however, it is important that the fluid is not agitated to the point where shearing of the water droplets in the emulsion takes place, causing the emulsion to become harder to separate. In addition, small holes can be more easily plugged with solids and are difficult to clean. Free-flow coalescing devices, such as S.P. PacksTM (Fig. 19.18), can be installed on the downcomer/spreader to promote coalescence and to minimize shearing of the water droplets by the spreader.

As the emulsion rises above the oil/water interface, water droplets settle from the oil countercurrent to the flow of the oil by gravity. Because there may be very little coalescence above the oil/water interface, increasing the height of the oil-settling section above some minimum to aid in spreading out the flow may not materially affect the oil outlet quality.

Fig. 19.24—Typical settling tank with internal downcomer and emulsion spreader.

Fig. 19.25—Proper design of well fluid inlet distributor for wash or gunbarrel tank showing use of small holes in distributor.

Sometimes oil collectors similar in design to oil spreaders are used to aid in establishing plug flow. The oil collector must not allow vortexing and should collect oil from the top of the tank in such a way that horizontal movement of the oil will be minimized.

Some tanks discharge the water through a water collector designed to cause the flow of water to approach plug flow conditions more nearly. The water outlet collector must prevent vortexing of the water and must minimize horizontal movement of the water. The water outlet collector should be located near the tank bottom. There must be enough vertical distance between it and the inlet spreader to allow sufficient clarification of the water, and it should be at least 6 to 12 in. above the tank bottom to allow for accumulation of sand.

Some tanks have elaborate sand-jetting and drain systems that may or may not be part of the water-collector system. It may be difficult to make these drains operate satisfactorily because the water flow to each drain must be on the order of 3 ft/sec to suspend the sand. Sand drains may lengthen the amount of time between tank cleanings, but the additional cost of sand drains in tanks may not be warranted.

In Fig. 19.24, the oil/water interface is established by an external adjustable weir sometimes called a water leg. The height of the interface is determined by the difference in height of oil outlet and weir and the fluid properties. It may be calculated from

$$h_{wd} = (h_{oo} - h_{ww}) \frac{\gamma_o}{\gamma_w} + h_{ww} \quad (4)$$

Fig. 19.26—Improper design of well fluid inlet for wash or gunbarrel tank.

where

h_{wd} = height of water-draw-off overflow nipple in weir box above tank bottom, ft,

h_{oo} = height of clean oil outlet above tank bottom, ft,

h_{ww} = desired height of water-wash in tank above tank bottom, ft,

γ_o = specific gravity of oil, and

γ_w = specific gravity of water.

Water legs are used successfully for emulsions where the gravity is above 20°API and there is sufficient difference in gravity between the oil and water. Marginal performance is obtained on oil between 15 and 20°API. Below 15°API, water legs normally are not used.

It is also common to control the oil/water interface with internal weirs or with an interface liquid-level controller and a water-dump valve. In heavy oils, electronic probes are most often used to sense the interface and operate a water-dump valve. In lighter oils, floats that sink in the oil and float in the water are more common.

Not all settling tanks contain all the sections and design details described previously. The choice depends on the overall process selected for the facility, emulsion properties, flow rates, and desired effluent qualities. While Fig. 19.24 is representative of the majority of settling tanks currently in use, other tanks have a different flow pattern. A series of parallel vertical baffles from the bottom of the vertical tank to above the oil level, as shown in Fig. 19.27, cause the flow of the emulsion to be

horizontal rather than vertical. With this type of flow path, the water droplets fall at right angles to the oil flow, rather than countercurrent to the oil flow. Some settling tank designs employ a vortex or swirling motion at the inlet of the tank to aid in coalescence and settling and to minimize short-circuiting. Many settling tanks employ heat to aid in the treatment process. Heat can be added to the liquid by an indirect heater, a direct heater, or any type of heat exchanger.

A direct fired heater, sometimes referred to as a "jug" heater, is one in which the fluid to be heated comes in direct contact with the immersion-type heating tube or element of the heater. Direct fired heaters are generally used to heat low-pressure noncorrosive liquids. These units normally are constructed so that the heating tube can be removed for cleaning, repair, or replacement.

An indirect fired heater is one in which the fluid passes through pipe coils or tubes immersed in a bath of water, oil, salt, or other heat-transfer medium that, in turn, is heated by an immersion-type heating tube similar to the one used in the direct fired heater. The contents of the bath of an indirect fired heater are caused to circulate by thermosiphonic currents. The immersion-type heating tube heats the bath, which heats the fluid flowing through coils immersed in the bath. When water is used as the bath, water free of impurities will prolong the life of the heater and prevent fouling of the surface of the heating tube and coils.

Indirect fired heaters are less likely to catch on fire than direct fired heaters and generally are used to heat corrosive or high-pressure fluids. They usually are constructed so that the heating tube and pipe coil are individually removable for cleaning and replacement. They tend to be more expensive than direct fired heaters.

Heat exchangers normally are used where waste heat is recovered from an engine, turbine, or other process stream or where fired heaters are prohibited. In complex facilities, especially offshore, a central heat-transfer system recovering waste heat and supplying it through heat exchangers to all process heat demands is sometimes more economical and may be the only way to meet established safety regulations.

Advantages of heating the entire stream of emulsion before it enters the settling tank are as follows.

1. After the fluid is heated, it flows through piping and into the flume pipe or gas boot of the gunbarrel tank. This moderate agitation of the heated fluid can assist in coalescence of water droplets.

2. The emulsion is heated before it reaches the gunbarrel, which aids in removing gas from the oil in the gas boot. This helps maintain quiescence in the settling portion of the gunbarrel.

3. The heater and gunbarrel can be sized independently, which allows flexibility in sizing the system.

4. Water-wash volume in the gunbarrel can be adjusted over a wide range, providing additional flexibility.

5. Continuous flow of fresh fluids through the heater tends to prevent coking and scaling and helps keep the heating surface clean, which will prolong the heater life.

Heat can also be supplied to the system by circulating the water in the water-wash section to a heater and back to the tank. The hot-water-wash section warms the incoming emulsion. A thermosiphon caused by density differences of the hot and the cold water can be used as the

Fig. 19.27—Plan view of vertical tank with horizontal flow settling pattern.

driving force for the circulation if the heat source is not far from the tank. The water also may be pumped to the heater and circulated back through the flume, as shown in Fig. 19.28. In this system, the settling space in the gunbarrel may be disturbed by gas released from the oil when it comes in contact with the hot water. It has two advantages. First, oil will not be overheated because it never comes in contact with the heating element in the heater but is heated by the water bath in the gunbarrel. This minimizes vapor losses from the oil and tends to maintain maximum oil gravity. It also minimizes coking and scaling. Second, this system is as safe from fire hazards as a system involving a fired vessel can be because only water flows through the heater. There is no oil or gas in the fired vessel.

Settling or gunbarrel tanks can also be heated directly with a fire tube, as shown in Fig. 19.29, or with internal heat exchangers, using steam or other heat media. Heat exchangers can be either pipe coils or plate-type heating elements.

Plate-type heating elements are usually 18 to 32 in. by about 5 to 8 ft. These usually are preferred over pipe coils because the heat-transfer coefficient is 10 to 20% higher for the plate-type heating elements when immersed in oil than for a corresponding area of pipe. Further, the gentle agitation brought about by the convection flow of the oil up the surface of the plate-type element assists in coalescence. Plate-type heating elements are available with a wide range of pressure ratings. They can be purchased for steam service or hot-water service, but the same unit should not be used for both because the construction of the cells is different for the two types of heating media.

Pipe coils are popular because of the local availability of materials. The cost is normally slightly higher than for plate-type exchangers, however, especially in larger installations.

When settling tanks are heated directly, they operate in much the same manner as vertical or horizontal emulsion treaters.

Fig. 19.28—Heater and gunbarrel in forced circulation method of heating.

Fig. 19.29—Heated gunbarrel emulsion treater.

Vertical Emulsion Treaters

The most commonly used one-well lease emulsion treater is the vertical unit. A typical design is shown in Fig. 19.30. Flow enters near the top of the treater into a gas separation section. This section must have adequate dimensions to separate the gas from the liquid. If the treater is located downstream of a separator, this section can be very small. The gas separation section should have an inlet diverter and a mist extractor.

The liquid flows through a downcomer to the bottom portion of the treater, which serves as an FWKO and water-wash section. If the treater is located downstream of an FWKO, the bottom section can be very small. If the total wellstream is to be treated, this section should be sized for sufficient retention time to allow the free water to settle out. This will minimize the amount of fuel gas needed to heat the liquid rising through the heating section.

The oil and emulsion flows upward around the fire tubes to a coalescing section, where sufficient retention time is provided to allow the small water droplets to coalesce and to settle to the water section. Treated oil flows out the oil outlet. Any gas flashed from the oil because of heating flows through the equalizing line to the gas space above. The oil level is maintained by pneumatic or lever-operated dump valves. The oil/water interface level is controlled by an interface controller or an adjustable external water leg.

It is necessary to prevent steam from being formed on the fire tubes. This can be done by employing the "40° rule"—i.e., the operating pressure is kept equal to the

pressure of saturated steam at a temperature equal to the operating temperature plus 40°F. This is desirable because the normal full-load temperature difference between the fire tube wall and the surrounding oil is approximately 30°F in most treaters. Allowing 10°F for safety, the 40° rule will prevent flashing of steam on the wall of the heating tube.

Baffles and spreader plates may be placed in the coalescing section of the treater above the fire tubes. Many treaters were originally equipped with excelsior or "hay" packs. In most applications these may not be needed, but a manway may be provided in case one may need to be added in the field.

Although Fig. 19.30 shows a treater with a fire tube, it is also possible to use an internal heat exchanger to provide the required heat or to heat the emulsion before it enters the treater. For safety reasons, some offshore operators prefer a heat-transfer fluid and a pipe or plate heat exchanger inside the treater rather than a fire tube.

Horizontal Emulsion Treaters

For most multiwell leases, horizontal treaters normally are preferred. Fig. 19.31 shows a typical design of a horizontal treater. Flow enters the front section of the treater where gas is flashed. The liquid flows downward to near the oil/water interface where the liquid is water-washed and the free water is separated. Oil and emulsion rises past the fire tubes and flows into an oil surge chamber. The oil/water interface in the inlet section of the vessel is controlled by an interface-level controller, which operates a dump valve for the free water.

The oil and emulsion flows through a spreader into the back or coalescing section of the vessel, which is fluid-packed. The spreader distributes the flow evenly throughout the length of this section. Treated oil is collected at the top through a collection device used to maintain uniform vertical flow of the oil. Coalescing water droplets fall countercurrent to the rising oil. The oil/water interface level is maintained by a level controller and dump valve for this section of the vessel.

A level control in the oil surge chamber operates a dump valve on the oil outlet line regulating the flow of oil out the top of the vessel and maintaining a liquid-packed condition in the coalescing section. Gas pressure on the oil in the surge section allows the coalescing section to be liquid-packed.

The inlet section must be sized to handle separation of the free water and heating of the oil. The coalescing section must be sized to provide adequate retention time for coalescence to take place and to allow the coalescing water droplets to settle downward countercurrent to the upward flow of the oil.

Fig. 19.32 shows another design of a horizontal emulsion treater with a different flow pattern that minimizes vertical flow of the emulsion. Oil, water, and gas enter the top of the treater at the left side (facing the burners) and travel toward the front and downward. Gas remains at the top, and oil and water are heated as required. Some heat is applied to the water in this section, but because this section has its own temperature controller, it can be regulated up or down for optimum performance.

The cross section in Fig. 19.32 shows that the emulsion flows under a longitudinal baffle and through a large slot in the partition plate near the front of the treater at

Fig. 19.30—Schematic view of typical vertical emulsion treater.

the bottom of the fire tube where it is water-washed. In the right compartment of Section AA, the oil and emulsion flow longitudinally up across the fire tube at about a 10 to 15° incline from horizontal.

The heating and settling section separation baffle blocks the passage of foam at the top and blocks emulsion at the bottom. Heated oil travels through a slot in a partition that is about at the centerline of the top fire tube. Free water is allowed to travel under the baffle. As emulsion accumulates at the interface, it rises to touch the fire tube, which is only 6 in. above the interface. The fire tube then tends to heat and eliminate the emulsion pad to maintain a uniform emulsion-pad thickness.

Channeling, skimming, and stratifying are all reduced by the application of louvered baffles, which are made of a stainless steel sheet punched with a louvered pattern that ranges from 15 to 60% open area. The baffles are solid at the top to prevent foaming or skimming and extend down near but do not touch the water. All the emulsion goes through the louvered openings, which provide a slight impedance to flow to develop even flow distribution and aid in coalescence.

Oil level in the treater is maintained by a weir and an oil box. Water level in the treater is critical; thus a weir is placed approximately 5 ft from the rear head seam, and the oil/water interface level upstream of this weir is maintained by the weir. Adjustment of the water-level controller, which is located downstream of this weir, has no effect on the water level in the main treater body upstream of the weir.

Because the emulsion flow path in this design is essentially horizontal, the water particles are not opposed by the velocity of upflowing oil as in a treater with a vertical flow pattern. This is especially important in heavy crudes where the differential specific gravity between oil and water is small and the settling velocity is low.

Fig. 19.31—Typical horizontal emulsion treater with vertical flow.

Fig. 19.32—Horizontal emulsion treater with horizontal flow.

Fig. 19.33—Typical horizontal electrostatic emulsion treater with vertical flow.

Other flow patterns are available if different baffle designs are used in horizontal treaters. The two described previously are examples to show the concepts that are most generally applied. Other methods of heating the emulsion can be used if it is desirable to eliminate the fire tubes.

Electrostatic Coalescing Treaters

Electrostatic treating can be used in either vertical or horizontal emulsion treaters by including electrical grids in the settling or coalescing sections. Figs. 19.33 and 19.34 show how grids can be installed in the horizontal treaters shown in Figs. 19.31 and 19.32.

Two grids of electrodes typically are installed in electrostatic emulsion treaters. One is wired to a source of electric current and the other is grounded. The emulsion flows between these electrodes, which are charged with a very high voltage. The electrodes are installed in the vessel to provide a final stage of coalescence to the emulsion after it has already been treated to near pipeline quality. In the design of Fig. 19.33, the upflowing oil passes the "hot" electric grid, which is usually steel or stainless steel rods or bars spaced 4 to 6 in. apart. This grid is stationary and hangs from multiple electric insulators. AC current is wired to this grid from an external single-phase transformer. The "cold" electric grid is mounted directly above the hot grid and is adjustable from 2.5 to 12 in. from the hot grid. The normal operating spacing between the two grids is usually 4 to 6 in.

Coalescing takes place between the oil/water interface and the hot grid, as well as between and above the grids. The oil continues vertically to the outlet collector pipe with

small calibrated holes in the top of the pipe to ensure uniform distribution. The electric section has no oil/gas interface. All gas must be removed in the heating section.

The electric coalescing function in the treater shown in Fig. 19.34 is similar to the horizontal grid unit of Fig. 19.33 except that the vertical grids provide the advantage of the horizontal flow pattern for the emulsion and improve the performance of this unit.

In addition to the safety controls normally found on emulsion treaters with fireboxes, there are also low-liquid-level safety switches on the electric treater to avoid the possibility of the electric power being applied when the high-voltage grid is surrounded with gas instead of liquid.

The greater the voltage gradient, the greater the forces causing coalescence. Experimental data show, however, that at some voltage gradient the water droplets can be pulled apart and a tighter emulsion can result. For this reason, electrostatic treaters are normally equipped with a mechanism for adjusting the voltage gradient in the field so that the optimum can be obtained.

The voltage gradient can be changed (1) by selecting optional transformer voltage taps. (2) by adjusting the voltage gradient by raising or lowering the oil/water interface in units using horizontal grids—the water level is, in effect, a grounded electrode against which most of the coalescing takes place; or (3) by adjusting the hot or cold grid location to change the voltage gradient.

The transformer is normally an 18,000- to 20,000-V secondary, single-phase, oil-filled, 100%-reactance-type transformer. It is mounted on the top, side, or end of the treater with a short, high-voltage conduit connected to an

Fig. 19.34—Typical horizontal electrostatic emulsion treater with vertical electric grids for horizontal flow of fluids.

appropriate entrance probe assembly. The high-voltage line is entirely submerged in transformer oil, which is normally a highly refined hydrocarbon that has been vacuum dried and contains no moisture.

The application of electrostatic treaters should be limited to "polishing" of oil to avoid chaining and short-circuiting of the grids. They are particularly effective in reducing the water content of oil to very low levels (less than 0.5 to 1.0%). Electrostatic coalescence may also aid in reducing heat and/or chemicals required to treat crude oil to a specific quality.

Desalting Crude Oil

Most produced water contains salts, which may cause problems in production and refining processes when the solids precipitate to form scale on heaters, plug exchangers, etc. This can cause accelerated corrosion in piping and equipment.

In almost all cases, the salt content of crude oil consists of salt dissolved in small droplets of water that are dispersed in the crude. In some instances, the produced oil can contain crystalline salt, which forms because of changes in pressure and temperature as the fluid flows up the wellbore and through the production equipment. Crystalline salt will flow out with the water and is not of importance in desalting operations.

The salinity of produced brine varies widely, but most produced water falls in the range of 15,000 to 130,000 ppm of equivalent NaCl. Crude oil containing only 1.0% water with a 15,000 ppm salt content will have 55 lbm salt/1,000 bbl of water-free crude. The chemical composition of these salts varies, but the major portion is nearly always NaCl with lesser amounts of calcium and

magnesium chloride. Because of the operational problems associated with salts, most refineries buy crude at a salt content of 10 to 20 lbm/1,000 bbl, then desalt the oil to 1 to 5 lbm/1,000 bbl before charging to crude stills.

The purpose of a desalting system is to reduce the salt content of the treated oil to acceptable levels. In cases where the salinity of the produced brine is not too great, salt content can be reduced by merely ensuring a low fraction of water in the oil. In this case, the terms desalting and emulsion treating are identical, and the concepts and equipment described previously can be used.

The required maximum concentration of water in oil to meet a known salt specification can be derived from

$$C_{so} = 0.35 C_{sw} \gamma_w f_w, \quad (5)$$

where

C_{so} = salt content of the oil, lbm/1,000 bbl,

C_{sw} = concentration of salt in produced water, ppm,

γ_w = specific gravity of produced water, and

f_w = volume fraction of water in crude oil.

If the produced brine has a high salt concentration, it may not be possible to treat the oil to a low enough water content (less than 0.2 to 0.25% is difficult to guarantee). In such a case, desalting implies the mixing of low-salt-content water with the emulsion before treating, as shown in Fig. 19.35. This lowers the effective value of C_{sw} in Eq. 5. If a single-stage desalting system will require too much dilution water, then a two-stage system, such as that shown in Fig. 19.36, is used.

Fig. 19.35—Single-stage desalting with dilution water injection.

Although it is possible to desalt with most of the emulsion-treating equipment discussed previously, most desalting systems use electrostatic treaters to obtain the lowest possible water content in the oil and thus minimize the amount of dilution water needed.

One of the most important parts of desalting systems is the method and efficiency of the method of mixing the wash water with the crude. The smaller the diameter of the wash-water drops dispersed in the oil, the greater the possibility of their coming in contact and coalescing with entrained saltwater droplets.

Excessive agitation when mixing the wash water with the crude oil can result in emulsions that are too tight (stable) to resolve easily. Therefore, the amount of mixing provided should be adjustable to zero. This requirement tends to make pumps and level-control valves poor choices for mixing. The most commonly used mixing system consists of some type of special mixing tee or static mixer followed by a globe-type mixing valve.

Mixing efficiency in a desalting system refers to the fraction of wash water that actually mixes with the produced water. The remainder of the water, in effect, bypasses the desalting stage and is disposed of as free water. A mixing efficiency of 70 to 85% can be considered a reasonable range of attainment. Part of the energy for mixing is obtained from the pressure of the wash water, which should enter the mixer at approximately 25 psi above the pressure in the vessel.

Reverse Emulsions

Most emulsions are the water-in-oil type; they occur much more frequently than the oil-in-water type. Oil-in-water (reverse) emulsions are most likely to be produced where the WOR is high, the dissolved solids content of the water is low, the water is slightly alkaline, and the oil has a naphthenic base. The oil content of these emulsions may vary from as low as a few ppm to 40%. They may vary in consistency from watery thin to a moderately heavy cream.

The produced water from some leases and ballast water from some oil tankers contain sufficient oil to be or have the characteristics of an oil-in-water emulsion. Such water is usually treated with chemicals formulated for water treating and with equipment described in Chap. 15.

Reverse emulsions may not require much, if any, heat. Because the external phase is water, the viscosity is quite low at ambient temperature. The chemicals used to treat reverse emulsions are usually some type of surface-active compounds that will neutralize the charges on the oil particles and allow them to coalesce during the gentle agitation that should follow introduction and mixing of the chemical with the emulsion. Overtreatment of this type of emulsion with chemical can result in stabilization rather than breaking of the emulsion.

Empirical data and experience are required to design equipment and/or systems for resolving reverse emulsions.

Fig. 19.36—Two-stage desalting using second-stage recycle.

Treating Emulsions Produced From EOR Projects

Standard emulsion-treating procedures, equipment, and systems used during primary and secondary oil production may not be adequate to treat the emulsions encountered in EOR projects. EOR methods of oil production—such as in-situ combustion and steam, CO_2 , caustic, polymer, and micellar (surfactant/polymer) floods—may result in the production of emulsions that may not respond to treatment normally used in primary and secondary oil production operations.

The treatment of the emulsions from EOR projects is usually handled independent of the primary and secondary emulsions from the same fields. Emulsion-treating procedures, equipment, and systems have been and are continuing to be developed for use in these EOR projects.

Clarification of Water Produced with Emulsions

Even though a normal (water-in-oil) emulsion exists in the oil production system, when produced water is separated from crude oil, the water usually contains small quantities of oil. The oil has been divided into small particles and dispersed in the water by agitation and turbulence caused by flow in the formation; into the wellbore; through the bottomhole pump, standing valve, traveling valve, and tubing; reciprocation of sucker rods; flow through the wellhead choke, flowline, manifold, oil and gas separator, and treating system; and by surface transfer pumps.

These small particles of oil will be suspended in the water and held there by mechanical, chemical, and electrical forces. The amount of oil contained in the untreated produced water in most systems will vary from an average low of about 5.0 ppm to an average high of about 2,000 ppm. In some water systems, oil contents as high as 20,000 ppm (2.0%) have been observed.

The oil particles in the untreated produced water will usually vary in size from 1 to about 1,000 μm , with most of the oil particles ranging between 5 and 50 μm in diameter.

Nine methods can be used to remove oil from the produced water: chemical, heat, gravity settling (skim tanks, API separators, etc.), coalescence (plate, pipe/free flow), tilted plate (corrugated) interceptors, flotation, flocculation, filtering, and combinations of the above. Refer to Chap. 15 for a discussion of the details of deoiling the produced water.

Operational Considerations for Emulsion-Treating Equipment

Burners and Fire Tubes

The design of burners and fire tubes is of importance because of the high cost of fuel and the operating problems that can occur when they malfunction. The burner should be designed to provide a flame that does not impinge on the walls of the fire tube, but that is almost as long as and concentric with the fire tube. If the flame touches the fire-tube wall, hot spots can develop, which can lead to premature failure.

Burners should not be allowed to cycle off and on frequently because thermal stresses caused by temperature reversals can damage the firebox. The combustion con-

trols should be accessible and designed so that the operator can easily adjust the air and gas to achieve optimum flame pattern and peak combustion efficiency.

A reliable pilot burner is required. Many operators and some regulatory agencies require burner safety shutdown valves that will shut off fuel to the burner in case of pilot failure. Unless specifically requested by the purchaser, most small emulsion treaters normally will not include this feature.

API RP 14C, "Analysis, Design, Installation and Testing of Basic Surface Safety Systems for Offshore Production Platforms," contains a basic description of recommended safety devices needed for fired- and exhaust-heated units. Consideration should be given to installing these devices on onshore, as well as offshore, fired treaters. They include process high-temperature shutdown, burner exhaust high-temperature shutdown, low-flow devices and check valves for heat exchangers, high- and low-pressure shutdown sensors, pressure-relief valves, flame arresters, fan motor starter interlocks on forced draft burners, etc.

Every gas-fired crude oil heating unit should be provided with fuel gas from which liquids have been "scrubbed." In large facilities, this can be accomplished with a central fuel-gas scrubber or filter providing fuel gas to all fired units. Many small facilities are equipped with individual fuel-gas scrubber vessels for each fired unit. These fuel-gas scrubbers are typically 8 to 12 in. in diameter and 2 to 4 ft tall, and contain a float-operated shutoff valve. If liquid enters the fuel-gas scrubber, the float will close a valve and stop gas flow to the burners of the heating unit. This will prevent oil from entering the combustion chamber and possibly prevent a fire.

Most fire tubes that transfer heat to crude oil or emulsion are sized to transfer 7,500 Btu/hr-sq ft, although some manufacturers use heat-transfer rates as high as 10,000 Btu/hr-sq ft. Fire tubes that transfer heat to the water-wash section of a treater, as in a vertical treater, are sized for 10,000 Btu/hr-sq ft, although some manufacturers use heat-transfer rates as high as 15,000 Btu/hr-sq ft. These higher rates are not recommended because they can be overly optimistic and thus may undersize the required fire tube area.

The temperature controller, fuel control valve, pilot burner, main burner, combustion safety controls, and fuel-gas scrubber for controlling and cleaning the fuel gas for fired treating vessels should be inspected and cleaned periodically as required. A schedule of preventive maintenance is recommended for this equipment.

Deposits of soot, carbon, sulfur, and other solids, if any, should be removed from the combustion space periodically to prevent reduction in heating capacity and loss of combustion efficiency. On oil-fired units, the following items should be inspected and maintained periodically: combustion controls, burner nozzles, combustion refractory, air/fuel control linkages, oil pump, oil preheater, pressure and temperature gauges, and O_2 and/or CO_2 analyzers.

Cleaning Vessels

Crude oil emulsions may contain mud, silt, sand, salts, asphalt, paraffin, and other impurities produced in conjunction with crude oil and accompanying water. In most

instances, these impurities are present in small quantities and add little to the treating problem. However, the treating problem may be made difficult and expensive because of the presence of one or more of these impurities in appreciable quantity. Special equipment and techniques may be required to handle these materials.

It is good practice to equip all treating vessels with cleanout openings and/or washout connections so that the vessels can be drained and cleaned periodically. Larger vessels should be equipped with manways to facilitate cleaning them. Steam cleaning may be required periodically. Acidizing may be required to remove calcium carbonate or similar deposits that cannot be removed by hot water or by steam cleaning.

One of the most likely causes of difficulty in operating fired emulsion-treating vessels is the deposition of solids on heating tubes and nearby surfaces. It is desirable to prevent such deposits, but if they cannot be prevented, these surfaces should be cleaned periodically. The deposits insulate the heating tube, reducing heating capacity and efficiency. Also, these materials may cause accelerated corrosion.

Of the salts commonly found in oilfield waters, the chlorides, sulfates, and bicarbonates of sodium, calcium, and magnesium are predominant. The most prevalent of the chlorides is NaCl. Calcium and magnesium chloride are next in quantity. These salts can be found in practically all water associated with crude oil. Salts are seldom found in the crude oil, but if they are present, they are mechanically suspended and not dissolved in it.

Emulsion-heating equipment is particularly susceptible to scaling and coking. These processes of deposition are not distinctly separate but may occur simultaneously. Also, one may hasten the other.

Calcium and magnesium carbonates and calcium and strontium sulfates are readily precipitated on heating surfaces in emulsion-treating equipment by decomposition of their bicarbonates and the resultant reduced solubility in the water carrying them. These materials will be deposited in pipes, tubes, fittings, and the inside surface of treating vessels. Maximum deposition will occur at the hottest surfaces, such as on heating coils and fire tubes.

Scale deposition also may occur when pressure on the fluid is reduced. This is the result of release of CO₂ from the bicarbonates in salt water to form insoluble salts that tend to adhere to surfaces of equipment containing the fluid.

Coke is not generally a primary fouling material. When deposits of salt, scale or any other fouling material build up, however, coking begins as soon as the insulating effect of the fouling material causes the skin temperature of the heating surface (heating tube or element) to reach 600 to 650°F. At this temperature, coke begins to form, which further aggravates fouling and reduces heat transfer. Once coking starts, a burnout of the firebox may follow quickly.

In areas where fluids cause considerable scaling or coking, the amount of such deposits can be reduced to a minimum by decreasing the treating temperature or by use of chemical inhibitors, properly designed spreader plates, and favorable fluid velocities through the equipment. Arranging the internals of the equipment so that all surfaces are as smooth and continuous as possible will also reduce such deposits. The operator should periodically inspect the equipment internally and clean the surfaces as required

if trouble-free operation is to be obtained over a long period of time. It is impossible to eliminate the deposition of solids entirely in emulsion-treating equipment, but it can be minimized.

Removing Sand and Other Settled Solids

Sand and silt may be produced with many crude oils. They may settle out in the vessel and be difficult to remove. It is common to shut down and drain the vessel periodically for cleaning. Sand can be removed from the unit with rakes and shovels or with a vacuum truck. The use of "sand pans," automated water jets, and drain systems can eliminate or minimize the problem of sand and silt in emulsion-treating vessels, but it is very difficult to eliminate sand buildup in large-diameter tanks.

Sand pan is the name given to a special perforated or slotted box or enclosure located in the bottom portion of a vessel or tank. Sand pans are designed to cover the area of the vessel that the flow of discharging water will clean. Often they are designed to work in conjunction with a set of water jets. The sand pans for horizontal vessels usually consist of elongated, inverted V-shaped troughs that are located parallel with and on the bottom of the vessels and that straddle the vertical centerline of the vessel. In the design in Fig. 19.37, the sand pans have sides that make an angle of 60° with the horizontal. The bottom edges of the sloping sides are serrated with 2-in. V-shaped slots and are welded to the interior of the shell of the treater. Most sand pans used in horizontal vessels are 5 ft long; a 60-ft-long horizontal vessel will typically have 11 sand pans and 11 sand-dump valves.

Sand pans, without a water jet system, have satisfactorily removed sand from most horizontal vessels up to 6 or 8 ft in diameter. Horizontal vessels larger than 4 ft in diameter should be equipped with a water jet system in addition to sand pans to keep sand cleaned from the vessel. Typical sand pans with a water jet system are illustrated in Fig. 19.37.

In vertical vessels, the sand pan may be a flanged and dished head approximately one-third the diameter of the vessel in which it is concentrically located. The sand pan is usually serrated around the periphery where it is welded to the bottom head of the vertical vessel concentric with the water outlet.

Water jets usually are designed to flow approximately 3.0 gal/min of water through each jet with a differential pressure of 30 psi. Standard jets are available for this service that have a 60° flat fan jet pattern. The jets are usually spaced on 12- or 16-in. centers. The water jet header is U-shaped so that the vessel is cleaned on both sides of the sand pan simultaneously. The water jets can be programmed for all the jets to flow at the same time, or they can be controlled by operation of the water jets and the sand dump valves in sequential cycles.

One problem in removing sand from vessels is that very few, if any, water-discharge control valves can withstand the abuse of sand-cutting during the water-discharge period for the long term. The partial answer to this problem is to arrange the instrumentation to open and close the water-discharge control valve on clean sand-free water and to use special slurry-type valves.

The most sophisticated sand-removal systems use programmable logic controllers. This solves the problem of selection of the proper time intervals between dumps

Fig. 19.37—Sand pans and water jet system in a horizontal vessel.

and automatically controls the length of the water/sand discharge. The timing must be coordinated with the water jet system and the normal water-dump controller. A properly designed sand-removal system with proper water-jetting and water/sand dumping can operate for many years without the need for a shutdown to clean out the sand or to repair or replace the dump valve.

Most emulsion-treating systems that handle large volumes of sand should not rely on hand or non-programmed operation for removal of the sand. If the operator fails to activate the dump valve often enough, the sand will cover the sand pans and plug or partially plug the water outlet, and the drains will become inoperative. With sand pans in the treater but without a programmer, large volumes of sand will usually cause trouble by plugging or partially plugging the water outlets and/or by cutting or wearing the drain valve.

Because both the amount and type of sand vary greatly, the length and frequency of the water-jetting and dumping cycles must vary to suit local conditions. Most of the coarser sand will settle out in the inlet end of the treater; the fine sand will settle out near the outlet end of the treater. It may be necessary to cycle the water jets and drain valves near the inlet end of the treater three to four times more frequently than those near the outlet end of the unit. Many timers are set for 30 minutes between jetting and dumping cycles and for 20- to 60-second jetting and dumping periods.

Interfacial Buildup

Interfacial buildup, sometimes referred to as sludge, is material that may collect at or near the oil/water interface of emulsion-treating tanks and vessels. Interfacial

buildup may contain paraffin, asphaltenes, bitumen, water, sand, silt, salt, carbonates, oxides, sulfides, and other impurities mixed with the emulsion. It can be removed from the vessel through a drain installed at the interface. The most common procedure, however, is to close the water dump valve and float it out to a bad-oil tank for further processing or disposal. Interfacial buildup can also be discharged with the water by opening the water-drain valve.

Corrosion

Emulsion-treating equipment that handles corrosive fluids should periodically be inspected internally to determine whether remedial work is required. Extreme cases of corrosion may require a reduction in the working pressure of the vessel or repair or replacement of vessel and piping. Periodic ultrasonic tests can measure the wall thickness of vessels and piping to detect the existence and extent of corrosion.

Corrosion of emulsion-treating equipment is usually mitigated or controlled by a combination of the following.

Exclusion of Oxygen. Corrosion rates in most oilfield applications can be kept low if O_2 is excluded from the system. Care must be taken in the process design to install and maintain gas blankets on all tanks in the process and to exclude rainwater from the system. Recycled water from sump systems and storage tanks is a prime source for O_2 entry into the process.

Corrosion Inhibitors. An inhibitor is a material that, when added in small amounts to an environment potentially corrosive to a metal or alloy, effectively reduces

the corrosion rate by diminishing the tendency of the metal or alloy to react with the solution. Inhibitors, in the form of liquid solutions or compounds, can be injected into the flow stream in the flowline, manifold, or production system to inhibit corrosion that would occur otherwise.

Cathodic Protection. Sacrificial galvanic anodes are commonly used for cathodic protection. They are made of a metal that will provide sacrificial protection to the steel vessel because of its relative position in the galvanic series. Most galvanic anodes used in emulsion treaters are about 3 to 6 in. in diameter and about 3 to 4 ft long. Multiple anodes usually are installed in each vessel. The anodes usually are sized to last from 10 to 20 years. They are considered expendable and are always installed in the vessel through a flange or quick coupling so that they can be easily replaced when expended.

The galvanic anodes must be installed so that they are immersed in the water, which serves as an electrolyte. They will not protect the treater if they are immersed in the oil. The anodes must "see" all metal surfaces that are to be protected—i.e., there must be no obstructions between the anodes and the surface they are to protect. Each anode should be located as near the center of the compartment or area they are to protect as practical.

An impressed electric-current cathodic protection system can also be used to inhibit corrosion. It is a direct electric current supplied by a device using a power source external to the electrode system. The DC current can be obtained by rectifying AC current. When resistivity of the electrolyte ranges from 25 to 300 $\Omega \cdot \text{cm}$ and above, consideration should be given to the use of an impressed current system. Impressed current systems are difficult and costly to maintain, however, and usually require skilled technicians.

Electrical current density requirements for cathodic protection of emulsion-treating vessels usually range from 5 to 40 mA/sq ft of bare water-immersed steel.

Internal Coating. Emulsion-treating vessels can be coated internally for protection from corrosion. It is important that the internal surfaces and the welds of the vessels be properly prepared to receive the coating. A coating system must be selected that will withstand the physical and chemical environment to which it will be exposed. Coating specifications, application techniques, and final inspection are very important considerations. Most coating systems will contain some holidays (breaks in the coating) or may be damaged in shipping or installation. Therefore, coating alone should not be relied on to prevent corrosion.

Steel tanks can be galvanized or lined in the field with fiberglass or other coatings. Some operators use fiberglass tanks in their emulsion-treating process, while others feel that this represents an unnecessary fire hazard.

Special Metallurgy. In particularly severe environments, such as where large quantities of CO_2 are expected and where O_2 cannot be practically eliminated from the system, it is possible to minimize corrosion by using stainless steel vessels or an internal stainless cladding in carbon steel vessels. In most low-pressure applications, stainless vessels are less expensive than clad vessels. It may also be cheaper to use a stainless vessel than one that is internally coated because of the labor required to prepare and to coat the internal surfaces of the vessel.

Level Controllers and Gauges

A wide selection of liquid-level controllers is available for liquid/gas control and for oil/water interface control in light crude oil (above 20°API) systems. For interfacial controllers in light crude oils, floats that sink in the oil but float in the water normally are used.

For heavy crude oils, electronic interface controllers have been very successful. These operate on the principle of the differences between oil and water electrical conductivity, electrical capacitance, or radio frequency. The most common type is called "capacitance probes"; they use the dielectric strength of the fluid in which they are immersed.

Standard gauge glasses (reflex or transparent) are used on 20°API crude oil and higher. Reflex gauges normally are used on liquid/gas levels and transparent gauges for oil/water levels. Armored gauge glasses normally are used on pressure vessels and tubular gauge glasses on tanks. Some operators use the tubular gauge glasses on low-pressure treating equipment. Tubular gauge glasses normally are furnished on standard low-pressure vessels unless armored gauges are specified.

For API gravities below 20°API, gauge glasses are not recommended, particularly for interfacial service, because they are difficult or impossible to read. In lieu of gauge glasses, a system of sample valves is used with the sample lines all piped to a single point just above a sample box. Generally, the lines are insulated to keep them warm. A nameplate is clamped on each sample valve to designate the elevation it represents in the treater. The sample box is fitted with a drain line piped to the sump.

Water-in-Oil Detectors (BS&W Monitors)

Several companies manufacture devices for detecting and measuring the water content of crude oil. They are commonly called BS&W monitors. BS&W monitors are typically analog instruments that measure dielectric strength and are specifically designed for determination of the water content of crude oil containing a low percent of water. They do not operate satisfactorily on streams containing free water. The unit provides a water reading corresponding to the water content of the oil. It can be made to alarm, record, and control if the detected percentage exceeds the field-selectable preset limit of BS&W content.

Special Safety Features for Electrostatic Treaters

Because of the high voltage and the associated potential hazard to personnel that can result from entering a drained vessel with the grids activated, electrostatic treaters require a positive shutdown switch for the high-voltage transformer. This disconnects the transformer if the fluid level falls below a predetermined level in the treating vessel. Some manufacturers install an internal grounding device inside the treater that grounds the hot grid if fluid is not present.

Changing Excelsior Packs

Excelsior used in treating emulsions may have a serviceable life ranging from just a few days to several years. The best grade excelsior should be used because cost of the excelsior is small compared to the expense of removing and replacing it. In some fields, the excelsior must be chopped into blocks with an ax and removed in chunks.

Serviceable life of the excelsior may be extended by periodically washing it with hot water. The water level can be allowed to build up above the top of the excelsior pack and the water heated to about 210°F. The temperature should be kept this high for about 1 hour. The water should be drained quickly from the vessel while it is hot. The hot water may carry most of the foreign material with it. If the application of heat only partially cleans the excelsior, a second heating may clean it further. Care should be taken to use water that will not deposit solids in the treater while it is being heated.

Economics of Treating Crude Oil Emulsions

The object of operating oil-producing properties is to deliver consistently the maximum volume of highest-API-gravity oil to the pipeline at the lowest possible cost. Emulsions should be prevented wherever feasible and treated at the lowest cost where they cannot be prevented.

Implementation of the following directives can minimize the occurrence of emulsions and the costs of treating.

1. Eliminate production of water with oil where possible and practical.

2. Minimize the investment in emulsion-treating equipment by studying the treating problem and the selection and use of appropriate treating methods, equipment, and procedures. The emulsion treating system should be as small as possible, yet capable of adequately handling treating requirements on the lease. Treating systems may be initially oversized to allow for future development, lease expansion, or increased water production. Such anticipation of future needs should be considered when treating equipment is purchased; however, needlessly oversized systems involve unnecessary expense and accomplish nothing that properly sized systems will not accomplish.

3. Minimize the loss of oil with water and salvage oil from interfacial sludge and tank bottoms where feasible. Oil may be discharged with the water as it flows from FWKO's, emulsion treaters, gunbarrels, or other treating vessels. The fraction of oil is low and the oil is usually dispersed in small droplets. Sometimes this oil is pumped along with the water to disposal wells or delivered to operators of water disposal companies without recovery or without credit being received by the lease. This oil loss can be minimized by maintaining proper operating variables with adequately sized and maintained vessels and controls and by properly designed water treating systems.

4. Minimize chemical treating costs by use of the most appropriate chemical demulsifier compound(s), the optimum quantity of chemical, the proper location and method of injection of chemical, the proper means of intimately mixing chemical with emulsion, and the proper use of heat. Treating chemicals are not recoverable and constitute a continuing expense. Some crude oil can be adequately treated by chemical injection used in conjunction with coalescing and/or settling without heat. However, some emulsions require an increased temperature during the coalescing and settling period. A proper balance of chemical and heat aids in providing the most economical and efficient treating system. The chemicals must be intimately mixed with emulsion so that a minimum amount of chemical will provide maximum benefit. Chemicals may be wasted by being injected into the oil in large slugs and not intimately mixed with the emulsions.

5. Ensure that chemicals added to the produced fluids are compatible. Some corrosion inhibitors can cause emulsions or affect the action of oil-treating chemicals. Chemicals used in produced-water-treating systems may be recycled to the oil-treating system with the skimmed oil and cause emulsion-treating problems.

6. Conserve gravity and volume of oil by using optimum treating temperature, cooling oil before discharging to storage, discharging vent gases from treating vessels through cooler oil in stock tanks, maintaining slight gas pressure on treating system and storage tanks, and using vapor recovery equipment on vessels and tanks. Crude oil emulsions should be resolved at the lowest effective temperature. Excessive heat drives condensable vapors from the oil, and they are discharged with the gas. Loss of these light ends lowers the API gravity of the oil and simultaneously reduces the oil volume. A further disadvantage of overheating is the increased maintenance required on treating systems caused by hot spots, salt deposition, scaling, and increased rate of corrosion, especially of the fireboxes.

7. Use all treating equipment to the best advantage. By careful observations, supervision, and record keeping, emulsion-treating equipment can be used to maximum efficiency. Transfer of equipment and alterations or additions to the treating system may be made to use existing equipment better. Constant testing and vigilance are required to obtain maximum results.

8. Practice preventive maintenance to minimize irretrievable loss of oil production because of downtime for equipment repairs. The more complex the treating system, the greater will be the possibility of mechanical failure. Oversized and overly complex systems have a greater failure frequency than more appropriately designed, simpler, and more compact systems.

9. Exchange information on treating methods and results among company personnel, with other operators, engineering firms, vendors, and chemical-treating companies. Experience can be gained and shared by personnel responsible for handling treating problems, which will result in lower treating costs.

Cost records are important in oil emulsion-treating operations. To achieve optimum operation of emulsion-treating equipment at minimum cost, proper records must be kept of operating temperatures, pressures, fuel and/or power consumption, chemical usage, performance, etc. Such records should be kept on a daily, weekly, or monthly basis, reviewed regularly, and kept available for supervisory personnel.

Cost records make it possible to predict whether an existing system should be modified or replaced. Justification for modifying or replacing an existing system will depend on the efficiency of the system, and this can be determined best from accurate and reliable cost and performance records. Cost records on existing methods or systems will assist in determining the type, kind, and size of treating systems for new leases. Treating cost records should make it possible to determine current operating costs, probable installation costs for new systems, and probable future operating costs of similar systems.

Each operator should determine what is to be charged to emulsion-treating costs. Listed in Table 19.2 is an outline of items that may be considered part of the data base for a cost-accounting system. Some of these items will

not be applicable to all treating systems, and some operators may elect to group some of the categories. A comprehensive general listing is presented for those who wish to consider all items of cost. Special systems and conditions may require additional cost items.

It is necessary to consider all factors listed in Table 19.2 if complete and accurate treating cost records are to be compiled. This information should be obtained and recorded on a continuous daily, weekly, or monthly basis, and it must be accurate and concise if cost records are to be of maximum value.

Investment costs must include the initial cost of all equipment used, including the cost of transporting it to the location, of erecting and installing the equipment, and of readying the system for operation. Such items as pipe and pipe fittings, valves, grade work, foundations, and fencing should be included.

The labor cost should include supervisory personnel, cost of company gang and contract gang, and other labor required to obtain, install, and put the treating system into operation. Operating cost should be kept separate from maintenance cost and should include such items as supervisory labor, operating labor, chemicals, fuel, and miscellaneous supplies. Maintenance cost should include cost of maintaining and repairing all treating equipment. This should include such items as cleaning, repairing, painting, and other similar items.

The Overall System Performance section should include an accurate record of the volume of oil treated and the volume of water separated, treated, and handled. This part of the record should also include reference to troubles experienced with the system and a commentary on day-to-day performance of the unit or system.

Key Equations in Metric Units

$$Q = 53.09 \Delta T (0.5 q_o \gamma_o + q_w \gamma_w), \quad (2)$$

where

Q is in watts,
 ΔT is in Kelvin,
 q_o is in m^3/d ,
 γ_o is dimensionless,
 q_w is in m^3/d , and
 γ_w is dimensionless.

$$v = \frac{5.43 \times 10^{-10} (\Delta \gamma_{ow}) d^2}{\mu_o}, \quad (3)$$

where

v is in m/s ,
 $\Delta \gamma_{ow}$ is dimensionless,
 d is in μm , and
 μ_o is in $\text{Pa}\cdot\text{s}$.

Chapter 20

Gas Properties and Correlations

Robert S. Metcalfe, Amoco Production Co.*

Molecular Weight

Molecules of a particular chemical species are composed of groups of atoms that always combine according to a specific formula. The chemical formula and the international atomic weight table provide us with a scale for determining the weight ratios of all atoms combined in any molecule. The molecular weight, M , of a molecule is simply the sum of all the atomic weights of its constituent atoms. It follows, then, that the number of molecules in a given mass of material is inversely proportional to its molecular weight. Therefore, when masses of different materials have the same ratio as their molecular weights, the number of molecules present is equal. For instance, 2 lbm hydrogen contains the same number of molecules as 16 lbm methane. For this reason, it is convenient to define the term "lbm mol" as a weight of the material in pounds equal to its molecular weight. (Similarly, a "g mol" is its weight in grams.) One lbm mol of any compound, therefore, represents a fixed number of molecules.

Ideal Gas

The kinetic theory of gases postulates that a gas is composed of a large number of very small discrete particles. These particles can be shown to be identified with molecules. For an ideal gas, the volume of these particles is assumed to be so small that it is negligible compared with the total volume occupied by the gas. It is assumed also that these particles or molecules have neither attractive nor repulsive forces between them. The average energy of the particles or molecules can be shown to be a function of temperature only. Thus, the kinetic energy, E_k , is independent of molecule type or size. Since kinetic energy is related to mass and velocity by

$$E_k = \frac{1}{2}mv^2,$$

it follows that small molecules (less mass) must travel faster than large molecules (more mass) when both are

at the same temperature. Molecules are considered to be moving about in all directions in a random manner as a result of frequent collisions with one another and with the walls of the containing vessel. The collisions with the walls create the pressure exerted by the gas. Thus, as the volume occupied by the gas is decreased, the collisions of the particles with the walls are more frequent, and an increase in pressure results. It is a statement of Boyle's law that this increase in pressure is inversely proportional to the change in volume at constant temperature.

$$\frac{V_1}{V_2} = \frac{p_2}{p_1},$$

where p is the absolute pressure and V is the volume.

Further, if the temperature is increased, the velocity of the molecules and, therefore, the energy with which they strike the walls of the containing vessel will be increased, resulting in a rise in pressure. To maintain the pressure constant while heating a gas, the volume must be increased in proportion to the change in absolute temperature. This is a statement of Charles's law,

$$\frac{V_1}{V_2} = \frac{T_1}{T_2},$$

where T is the absolute temperature and p is constant.

From a historical viewpoint, it is interesting to note that the observations of Boyle and Charles in no small degree led to the establishment of the kinetic theory of gases, rather than vice versa.

It follows from this discussion that, at zero degrees absolute, the kinetic energy of an ideal gas, as well as its volume and pressure, would be zero. This agrees with the definition of absolute zero, which is the temperature at which all the molecules present have zero kinetic energy.

*Author of the original chapter on this topic in the 1962 edition was Charles F. Weinaug.

Because the kinetic energy of a molecule is dependent only on temperature, and not on size or type of molecule, equal molecular quantities of different gases at the same pressure and temperature would occupy equal volumes. The volume occupied by an ideal gas, therefore, depends on three things: temperature, pressure, and number of molecules (moles) present. It does not depend on the type of molecule present. The ideal-gas law, which is actually a combination of Boyle's and Charles's laws, is a statement of this fact:

$$pV = nRT, \dots\dots\dots (1)$$

where

p = pressure,

V = volume,

n = number of moles,

R = gas-law constant, and

T = absolute temperature.

The gas-law constant, R , is a proportionality constant dependent only on the units of p , V , n , and T . Table 20.1 presents different values of R for the various units of these parameters.

Critical Temperature and Pressure

Typical PVT relationships for a pure fluid are illustrated in Fig. 20.1. The curve segment B-C-D defines the limits of vapor/liquid coexistence, B-C being the bubblepoint curve of the liquid and C-D, the dewpoint curve of the vapor. Any combination of temperature, pressure, and volume above that line segment indicates that the fluid exists in a single phase. At low temperatures and pressures, the properties of equilibrium vapors and liquids are extremely different—e.g., the density of a gas is low while that of a liquid is relatively high. As the pressure and temperature are increased along the coexistence curves, liquid density, viscosity, etc. generally decrease while vapor density, viscosity, etc. generally increase. Thus, the difference in physical properties of the coexisting phases decreases. These changes continue as the temperature and pressure are raised until a point is reached where the properties of the equilibrium vapor and liquid become equal. The temperature, pressure, and volume at this point are called the "critical" values for that species. Location C on Fig. 20.1 is the critical point. The critical temperature and pressure are unique values for each species and are useful in correlating physical properties. Critical constants for some of the commonly occurring hydrocarbons and other components of natural gas can be found in Table 20.2.

Fig. 20.1—Typical pressure volume diagram for pure component.

TABLE 20.2—SOME PHYSICAL CONSTANTS OF HYDROCARBONS

Number	Compound	Formula	Molecular Weight	Vapor Pressure (100°F, psia)	Critical Constants			Gas Density (60°F, 14.696 psia) Calculated as Ideal Gas*

Specific Gravity (Relative Density)

The specific gravity of a gas, γ , is the ratio of the density of the gas at a given pressure and temperature to the density of air at the same pressure and temperature. The ideal-gas laws can be used to show that the specific gravity (ratio of densities)* is also equal to the ratio of the molecular weights. When the ideal-gas assumptions are not valid (high pressures or most real gases), this will not always be true. By convention, specific gravities of all gases at all pressures are defined as the ratio of the molecular weight of the gas to that of air (28.966).

Mole Fraction and Apparent Molecular Weight of Gas Mixtures

The analysis of a gas mixture can be expressed in terms of a mole fraction, y_i , of each component, which is the ratio of the number of moles of a given component to the total number of moles present. Analyses also can be expressed in terms of the volume, weight, or pressure fraction of each component present. Under limited sets of conditions, where gaseous mixtures conform reasonably well with the ideal-gas laws, the mole fraction can be shown to be equal to the volume fraction but not to the weight fraction. The apparent molecular weight of a gas mixture is equal to the sum of the mole fraction times the molecular weight of each component.

Specific Gravity of Gas Mixtures

The specific gravity (γ_g) of a gas mixture is the ratio of the density of the gas mixture to that of air. It is measured easily at the wellhead in the field and, therefore, is used as an indication of the composition of the gas. As mentioned earlier, the specific gravity of gas is proportional to its molecular weight (M_g) if it is measured at low pressures where gas behavior approaches ideality. Once again, by convention, the specific gravity is defined as the mole weight of the gas mixture divided by 28.966. Specific gravity also has been used to correlate other physical properties of natural gases. To do this, it is necessary to assume that the analyses of gases vary regularly with their gravities. Since this assumption is only an approximation and is known to do poorly for gases with an appreciable nonhydrocarbon content, it should be used only in the absence of a complete analysis or of correlations based on a complete analysis of the gas.

Dalton's Law

The partial pressure of a gas in a mixture of gases is defined as the pressure that the gas would exert if it alone were present at the same temperature and volume as the mixture. Dalton's law states that the sum of the partial pressures of the gases in a mixture is equal to the total pressure of the mixture. This law can be shown to be true if the ideal-gas laws apply.

Amagat's Law

The partial volume of a gas in a mixture of gases is defined as that volume which the gas would occupy if it alone were present at the same temperature and pressure as the

mixture of the gases. If the ideal-gas laws hold, then Amagat's law, that the sum of the partial volumes is equal to the total volume, also must be true.

Real Gases

At low pressures and relatively high temperatures, the volume of most gases is so large that the volume of the molecules themselves may be neglected. Also, the distance between molecules is so great that the presence of even fairly strong attractive or repulsive forces is not sufficient to affect the behavior in the gas state. However, as the pressure is increased, the total volume occupied by the gas becomes small enough that the volume of the molecules themselves is appreciable and must be considered. Also, under these conditions, the distance between the molecules is decreased to the point where the attractive or repulsive forces between the molecules become important. This behavior negates the assumptions required for ideal-gas behavior, and serious errors are observed when comparing experimental volumes to those calculated using the ideal-gas law. Consequently, a real-gas law was formulated (in terms of a correction to the ideal-gas law) by use of a proportionality term called the compressibility factor, z . The real-gas law is thus

$$pV = znRT. \quad \dots \dots \dots (2)$$

Tables of compressibility factors are available for most pure gases as functions of temperature and pressure. Compressibility factors for mixtures (or unknown pure compounds) are measured easily in a Burnett¹ apparatus or a variable-volume PVT equilibrium cell. Excellent correlations are also available for the calculation of compressibility factors as discussed in the section on equations of state (EOS's). For this reason, compressibility factors are no longer routinely measured on dry gas mixtures or most of the leaner wet gases. Rich gas condensate systems require other equilibrium studies, and compressibility factors can be obtained routinely from these data. A knowledge of the compressibility factor means that the density, ρ , is also known from the relationship

$$\rho = \frac{pM}{zRT},$$

because $V = (nM)/\rho$, where M is the molecular weight.

Many times it is more convenient to report compressibilities than densities because the range in z is usually small—e.g., between 0.3 and 2.0.

Principle of Corresponding States

The principle of corresponding states has been useful in correlating the properties of gases. This principle was developed because observers noticed that the behavior of pure gases was qualitatively similar when compared (on p - V plots, for instance) even though the quantitative values of p and V were very dissimilar. The idea was advanced that the properties of substances could be correlated if they were all compared at "corresponding" values of T and p , which could be referenced easily. In the application

*Although specific gravity is used throughout this chapter, this traditional term will not be used under the SI system. It will be replaced by "relative density." Also, API gravity eventually will disappear as a measure of relative density.

Fig. 20.2A—Compressibility factor for natural gases at pressures of 10,000 to 20,000 psia (from Ref. 2).

Fig. 20.2B—Compressibility factors for natural gases near atmospheric pressures.

and

$$p'_{pc} = \frac{p_{pc} T'_{pc}}{T_{pc} + y_{H_2S}(1 - y_{H_2S})\epsilon},$$

where

$$\epsilon = 120[(y_{CO_2} + y_{H_2S})^{0.9} - (y_{CO_2} + y_{H_2S})^{1.6}]$$

$$+ 15(y_{H_2S}^{0.5} - y_{H_2S}^{4.0}), \dots \dots \dots (4)$$

T'_{pc} = corrected pseudocritical temperature,
 p'_{pc} = corrected pseudocritical pressure,
 y_{CO_2} = mole fraction of CO_2 in mixture, and
 y_{H_2S} = mole fraction of H_2S in mixture.

The correction factor, ϵ , has been plotted against hydrogen sulfide and carbon dioxide concentrations in Fig. 20.4 for convenience. This correction is reported to reproduce compressibility factors with less than 1% error.

Equations of State

An EOS seeks to describe specific PVT relationships of fluids mathematically. There are hundreds of these equations ranging from those for a specific pure compound to generalized forms that claim to relate the properties of multicomponent mixtures. Naturally, there is a large range of complexity from the simple ideal-gas law to

Fig. 20.2C—Compressibility factors for natural gases at low reduced pressures.

modern equations with 15 or more universal constants plus adjustable parameters. Historically, use of these equations has been limited to applications by researchers having large computing facilities. Recently, however, operating engineers have been provided with the same computing tools previously reserved only for researchers and special projects. The use of EOS's, therefore, has become relatively common. Some applications, such as calculation of compressibility factors, are possible on hand-held programmable calculators. The modern engineer should not forget the use of EOS's when the need arises for calculation or estimation of fluid properties.

Van der Waals' Equation

Van der Waals⁶ added terms to the ideal-gas law in an attempt to take into account forces between molecules as well as volume of the molecules themselves. His equation becomes

$$\left(p + \frac{a}{V_M^2}\right)(V_M - b) = RT, \quad \dots\dots\dots (5)$$

where V_M is the molar volume and a and b are constants characteristic of the gas.

The term b is a constant to correct for the volume occupied by the molecules themselves. The term a/V_M^2 is a correction factor to account for the attraction between molecules as a function of the average distance between them (which is related to the molar volume). When an EOS such as the van der Waals equation is applied to mixtures, either special constants for a and b must be developed for each mixture or constants for each gas in the mixture must be included in the equation along with adjustments for the interaction between unlike gases. The latter is the more common approach.

Van der Waals' law extends the range of pressures and temperatures for describing gas behavior beyond that of the ideal-gas law. However, it has two disadvantages in actual application. The correction factors are inadequate at very high pressures and it is not always easy to obtain the mixture coefficients and interaction constants. In addition, this two-parameter formulation does not really treat the attractive and repulsive forces correctly. Despite these criticisms, modifications of the van der Waals equation have been used successfully in industry for many years.

Redlich and Kwong⁷ developed the first major extension of the two-parameter EOS when they proposed their own form and showed how they related the a and b terms to R , p_c , and T_c . Other researchers since have modified the original Redlich and Kwong equation to improve its accuracy and generality further. Most notable of the modifications are those of Soave,⁸ Zudkevitch and Joffe,⁹ and Peng and Robinson.¹⁰ Some companies have their own versions, such as the one published by Yarbrough.¹¹

The most common equations of state in use today and the computer programs available are the following.

1. The Starling-Hon¹² extension of the Benedict-Webb-Rubin¹³ EOS:

$$\begin{aligned} p = RT\rho_M + & \left(B_o RT - A_o - \frac{C}{T^2} + \frac{D_o}{T^3} - \frac{E_o}{T^4}\right)\rho_M^2 \\ & + \left(bRT - a - \frac{d}{T}\right)\rho_M^3 + \alpha(a+d)\rho_M^6 \\ & + \left(\frac{c\rho_M^2}{T^2}\right)(1 + \gamma\rho_M^2) \exp(-\gamma\rho_M^2), \quad \dots\dots\dots (6) \end{aligned}$$

Fig. 20.3—Pseudocritical properties of natural gases.

Fig. 20.4—Pseudocritical temperature adjustment factor, ϵ , °F.

Fig. 20.5—Viscosity of pure compounds at 14.7 psia.

where A_o , B_o , C , D_o , E_o , a , b , c , d , α , and γ are empirical constants, and ρ_M equals n/V_M (subscript M refers to molar values). This equation usually is called the "BWRS" and is available from Exxon Corp.

2. The Peng-Robinson¹⁰ EOS (EquiphaseTM):

$$p = \frac{RT}{V_M - b} - \frac{a(T)}{V_M(V_M + b) + b(V_M - b)}, \quad (7)$$

where a and b are constants characteristic of the fluid, $a(T)$ is a functional relationship, and V_M is the molar volume. It is available from the Gas Processors Suppliers Assn. (GPSA).

3. The Soave⁸ modification of the Redlich-Kwong⁷ EOS:

$$p = \frac{RT}{V_M - b} - \frac{a(T)}{V_M(V_M + b)}, \quad (8)$$

where $a(T)$ is a functional relationship. It, too, is available from the GPA.

The first equation, BWRS, is an empirical form using 11 constants. The values of these constants have been determined from properties measured on many different fluids. It is extremely accurate in the prediction of most thermodynamic properties. Eqs. 7 and 8 are variations of the original equation proposed by van der Waals and as such are not as accurate as the BWRS for calculation of pure component properties or properties of mixtures of light hydrocarbons. Both the Peng-Robinson and the

Soave RK EOS's are more reliable for phase equilibrium calculations or for calculation of properties of gas condensate systems. One cannot assess their accuracy directly because it is dependent on how well the constants represent the specific components.

The Redlich-Kwong EOS and its extension are cubic in compressibility factor. J.J. Martin¹⁴ proposed a generalized cubic equation that, through suitable adjustment of parameters, can be used to obtain any other cubic including those that have been proposed after his work was published. All cubic equations have limitations in their ability to represent behavior at near-critical conditions. They are incorrect in the prediction of the critical compressibility factor and/or the shape of the critical isotherm. They can be manipulated by additional terms to circumvent this problem but errors then appear in some other region of pressure-temperature-composition space. In general, however, EOS's can be used routinely to calculate gas properties for both hydrocarbon and nonhydrocarbon systems and their mixtures.

One particularly useful application of EOS's in gas property estimations is the direct calculation of the compressibility factor, z . As noted previously, the principle of corresponding states can be used to obtain compressibilities with reasonable accuracy. However, one can solve an EOS directly for z quite readily. The most reliable methods for typical natural gases are those of Robinson and Jacoby¹⁵ and Hall and Yarborough.¹⁶ Robinson and Jacoby proposed the following equations.

$$p = \frac{RT}{V_M - b} - \frac{a}{\sqrt{T}V_M(V_M + b)}, \quad (9)$$

$$a_i = \alpha_i + \beta_i T, \quad (10)$$

and

$$b_i = \gamma_i + \delta_i T, \quad (11)$$

where α , β , γ , and δ are constants for Substance i , and for mixtures

$$a_{ij} = \frac{1}{2}[K_{ij}a_i + (1 - K_{ij})a_j],$$

$$a_m = \sum_i \sum_j y_i y_j a_{ij},$$

and

$$b_m = \sum_i y_i b_i,$$

where K_{ij} is a constant for each binary pair when used for mixtures.

Their equations are another modification of the Redlich-Kwong equation designed specifically for the region of temperatures from 70 to 250°F and pressures below 1,500 psia. It is untested for gas mixtures containing large amounts of C₄₊ material. Within these stated limits, it should be expected to calculate compressibility factors with less than 2% error.

The Hall-Yarborough equation is

$$z = \frac{(1 + x + x^2 - x^3) - Ax + Bx^C}{(1 - x)^3}, \quad (12)$$

Fig. 20.6—Viscosity of gases at 14.7 psia.

where

$$\begin{aligned} z &= \text{compressibility factor,} \\ A &= (14.76t - 9.76t^2 + 4.58t^3), \\ B &= (90.7t - 242.2t^2 + 42.4t^3), \\ C &= 1.18 + 2.82t, \\ x_i &= b\rho_M/4, \\ b &= 0.245(RT_c/p_c) \exp[-1.2(1-t)^2], \text{ and} \\ t &= T_c/T. \end{aligned}$$

It is designed specifically to fit the Standing-Katz charts and provides excellent results for multicomponent systems. Hall and Yarborough also include the correction factors proposed by Wichert and Aziz for systems with high concentrations of nonhydrocarbons. The method has been programmed for hand calculators by Ajitsaria.¹⁷ Note that the equations contain both z and ρ_M , making the solution trial and error and not well suited for use without a computer or calculator algorithm.

Viscosity

Viscosity is an important property in determining resistance to flow during production and marketing of gas. Generally, the viscosity of a gas increases with increasing pressure, except at very low pressures where it becomes more or less independent of the pressure. At low pressures, the viscosity of a gas, unlike that for liquids, increases as the temperature is raised. This is caused by the increasing activity of the molecules as temperature increases. Viscosity of a fluid is obtained by determining the force per unit area necessary to shear two parallel planes with a standard spacing and velocity difference. The standard unit of viscosity is the poise, which is defined as 1 dyne·s/cm² [6.9 lbf·sec/sq in.]. However, the common unit is the centipoise (0.01 poise). Carr *et al.*¹⁸ used the data of many researchers to produce Fig. 20.5, which presents viscosities as a function of temperature at atmospheric pressure for a number of pure compounds.

Viscosity Correlations

Viscosities can be estimated both by the principle of corresponding states and by a residual viscosity function based on reduced density. Carr *et al.*,¹⁸ using the the-

Fig. 20.7—Viscosity ratio vs. pseudoreduced temperature.

ories of transport processes, correlated viscosities of pure gases and gas mixtures against molecular weight and temperature. Fig. 20.6 presents their correlation for viscosities at atmospheric pressure. Fig. 20.7 permits estimation of a pressure correction for gas viscosities by corresponding-states techniques. The ratio of the viscosity at some elevated pressure to the viscosity from Fig. 20.6 is plotted against pseudoreduced temperature and pressure. Viscosities calculated from this correlation should be expected to have less than 2% error.

The residual viscosity function ($\mu - \mu^*$) also has been used to correlate gas viscosities with even better success than the corresponding-states technique described previously. (μ^* is a correlating parameter obtained from Fig. 20.8.) Thodos *et al.*^{19,20} have shown that the residual viscosity function can be well correlated against density, thereby making it a useful tool for both gas and liquid viscosities. The Thodos method requires two steps, as does the technique of Carr *et al.* First μ^* must be estimated, then the effect of pressure can be calculated from another correlation. The correlation for μ^* is shown in Fig. 20.8, and the effects of pressure can be estimated

Fig. 20.8—Thodos viscosity correlation.

Fig. 20.9—Thodos viscosity correlation—pressure correction.

from Fig. 20.9. Viscosities calculated using the correlations of Thodos *et al.* can be expected to have an accuracy on the order of 3%.

To use Figs. 20.8 and 20.9, one must first calculate the average mole weight of the mixture, $\bar{M}_g = \sum y_i M_i$, and the pseudocritical temperature, pressure, and volume by Kay's rules (T_c in units of Kelvin and V_c in $\text{cm}^3/\text{g mol}$) or Fig. 20.3 if the C_{7+} concentration is small. Alternatively, the correlation of Matthews *et al.*²¹ (Fig. 20.10) may be used to get T_c and p_c for C_{7+} fractions. The following may be used for V_c of the C_{7+} fraction.

$$(V_c)_{C_{7+}} = 1.561(M_{C_{7+}}/\rho_R)^{1.15},$$

where $M_{C_{7+}}$ is the molecular weight of the C_{7+} fraction, and ρ_R is the relative density of the C_{7+} fraction.

Calculation of the pseudocritical density, ρ_{pc} , and the viscosity parameter, ξ , are as follows.

$$\rho_{pc} = \bar{M}_g/V_{pc} \quad \dots \dots \dots (13)$$

and

$$\xi = \frac{(T_{pc})^{1/2}}{(\bar{M}_g)^{1/2}(p_{pc})^{1/2}}, \quad \dots \dots \dots (14)$$

where T_{pc} is the pseudocritical temperature, K, and p_{pc} is the pseudocritical pressure, atm. Caution: This is a correlation and the terms should not be converted to a consistent set of units.

Fig. 20.10—Pseudocritical properties of C_{7+} fractions.

For very quick estimations, Katz² provides graphs of viscosity vs. temperature ($^{\circ}\text{F}$) and pressure (psia) for gas gravities ranging from 0.6 to 1.0. Errors can be expected to be on the order of 4 to 5%.

If gas density is not known it can be obtained from the compressibility factor through $\rho_g = M_g p / (z_g RT)$. Compressibility factors can be obtained by using the methods discussed above. Reduced conditions then can be calculated making sure ρ and ρ_{pc} are in the same units. It is possible to use Fig. 20.8 to obtain μ^* and then obtain ξ from $\mu^* = (\mu^* \xi) / \xi$. The final step is to obtain $(\mu - \mu^*)\xi$ from Fig. 20.9 and solve for μ with $\mu = \mu^* + [(\mu - \mu^*)\xi] / \xi$.

Within the limitations of each correlation, that of Carr *et al.* may have a slight advantage. That of Thodos *et al.* is a more general relationship and can be used for both gases and liquids, making it the preferred method for phase equilibrium calculations or for the near-critical region.

Natural Gasoline Content of Gas

In the handling and evaluating of gas, determination of natural gasoline or liquefiable content is important. This can be accomplished because the liquid volumes of the heavier components in natural gasoline are essentially additive. The required number of cubic feet of gas to form, by condensation, 1 gal of various materials is shown in Table 20.2 under the heading "cu ft gas/gal liquid." Mole fraction, or cubic feet of any component per cubic foot of mixture, divided by the cubic feet of gas per gallon of liquid gives the total gallons of liquid that each component could contribute to the natural gasoline per cubic

foot of gas mixture. If only a part of the component under consideration is to be recovered as liquid, a suitable correction must be made. Using the principle of additive volumes, the sum of contributions of each component can be assumed to give the recoverable gasoline content per cubic foot. Use of this procedure can lead to errors of about 10% if relatively large amounts of aromatic and/or naphthenic compounds are present.

Formation Volume Factor

The gas FVF, B_g , is defined as barrels of reservoir gas contained in 1 scf. It is sometimes erroneously reported as the reciprocal of this definition. In either case, it is a way of relating reservoir PV to produced surface volumes. The definition of B_g assumes that no liquids will condense as the reservoir gas is brought to standard conditions (60°F and 1 atm [288 K and 100 kPa]). This may be an invalid assumption for gas condensates but is probably acceptable for most wet gases.

The real-gas law, $pV = znRT$, can be used to convert measurements at standard conditions to reservoir conditions. If the above assumption holds, then

$$\frac{p_{rc} V_{rc}}{z_{rc} T_{rc}} = \frac{p_{sc} V_{sc}}{z_{sc} T_{sc}}, \quad \dots \dots \dots (15)$$

where the subscript rc refers to reservoir conditions and sc to standard conditions. Since, by definition,

$$B_g = \frac{V_{rc}}{V_{sc}},$$

it follows that

$$B_g = 0.005035 \frac{T_{rc} z_{rc}}{p_{rc} z_{sc}} \quad \dots \dots \dots (16)$$

when T is in °R and p in psia, or

$$B_g = 0.34722 \frac{T_{rc} z_{rc}}{p_{rc} z_{sc}}$$

when T is in K and p in kPa.

Many times it is assumed that $z_{sc} = 1.0$, but this is not necessarily true. If greater precision is desired, Fig. 20.2B or 20.2C can be used to determine z for the gas at standard conditions. For rough engineering calculations, this extra precision may not be required.

Coefficient of Isothermal Compressibility

Reservoir engineering equations that deal with system compressibility require a gas compressibility term. This is not the gas compressibility factor, z , but the coefficient of isothermal compressibility, c_g . It is defined as the rate of change of volume with respect to pressure at constant

temperature divided by the actual volume. It can be written in differential form as

$$c_g = -\frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T.$$

If a gas is ideal it can easily be shown that $c_g = 1/p$. As we have already discussed, however, reservoir gases and most surface gases do not follow the ideal-gas law. Consequently, this result should only be considered as an order-of-magnitude approximation.

When the real-gas law, $pV = znRT$, is differentiated to calculate c_g , the result is

$$c_g = \frac{1}{p} - \frac{1}{z} \left(\frac{\partial z}{\partial p} \right)_T. \quad \dots \dots \dots (17)$$

If z 's are known as function of pressure, it can be evaluated over a small range as

$$c_g = \frac{1}{p} - \frac{1}{z} \left(\frac{\Delta z}{\Delta p} \right).$$

However, Trube²² has correlated a term called pseudoreduced compressibility against pseudoreduced pressure to eliminate the need for these evaluations. His definition of pseudoreduced compressibility is

$$c_{pr} = c_g \times p_{pc}, \quad \dots \dots \dots (18)$$

and is nondimensional. The correlating work of Trube is presented in Figs. 20.11 and 20.12. A knowledge of pseudoreduced temperature and pseudoreduced pressure is required to obtain the pseudoreduced compressibility. The coefficient of isothermal compressibility then can be calculated directly from this relationship. Trube does not give any estimates of the accuracy of his correlation, but a method based on pseudoreduced properties should be at least as accurate as the z -factor correlations on which it is based because the coefficient of compressibility is a slope rather than an absolute number.

Vapor Pressure

At a given temperature, the vapor pressure of a pure compound is the pressure at which vapor and liquid coexist at equilibrium. The term "vapor pressure" should be used only in conjunction with pure compounds and is usually considered as a liquid (rather than gas) property. For a pure compound, there is only one vapor pressure at any temperature. A plot of these pressures for various temperatures is shown in Fig. 20.13 for n-butane. The temperature at which the vapor pressure is equal to 1 atm (14.696 psia or 101.32 kPa) is known as the normal boiling point.

The Clapeyron equation gives a rigorous quantitative relationship between vapor pressure and temperature:

$$\frac{dp_v}{dT} = \frac{L_v}{T \Delta V}, \quad \dots \dots \dots (19)$$

Fig. 20.11—Reduced compressibility coefficients for low pseudoreduced pressures and fixed pseudoreduced temperatures.

Fig. 20.12—Reduced compressibility coefficients for moderate pseudoreduced pressures and fixed pseudoreduced temperatures.

Fig. 20.13—Vapor pressure of n-butane.

where

p_v = vapor pressure,

T = absolute temperature,

ΔV = increase in volume while vaporizing 1 mole, and

L_v = molal latent heat of vaporization.

Assuming ideal-gas behavior of the vapor and neglecting the liquid volume, the Clapeyron equation can be simplified over a small temperature range to give the approximation

$$\frac{d \ln p_v}{dT} = \frac{L_v}{RT^2},$$

which is known as the Clausius-Clapeyron equation.

This equation suggests that a plot of logarithm of vapor pressure against the reciprocal of the absolute temperature would approximate a straight line. Such a plot is useful in interpolating and extrapolating data over short ranges. However, the shape of this relationship for real substances is not a straight line but rather S-shaped. Therefore, the use of the Clausius-Clapeyron equation is not recommended when other methods are available.

Cox Chart

Cox²³ further improved the method of estimating vapor pressure by plotting the logarithm of vapor pressure against an arbitrary temperature scale. The vapor-pressure/temperature plot forms a straight line, at least for the reference compound, and usually for most of the materials related to the reference compound. This is especially true for petroleum hydrocarbons. A Cox chart using water as a reference material is shown in Fig. 20.14. In addition to forming nearly straight lines, compounds of the same family appear to converge on a single point.

Fig. 20.14—Cox chart for normal paraffin hydrocarbons.

Thus, it is necessary to know only vapor pressure at one temperature to estimate the position of the vapor-pressure line. This approach is very handy and can be much better than the previous method. Its accuracy is dependent to a large degree on the readability of the chart.

Calingeart and Davis Equation

The Cox chart was fit with a three-parameter function by Calingeart and Davis.²⁴ Their equation is

$$\ln p_v = A - \frac{B}{T - C}, \quad (20)$$

where A and B are empirical constants, and, for compounds boiling between 32 and 212°F, C is a constant with a value of 43 when T is in K, and C is a constant with a value of 77.4 when T is in °R.

This equation generally is known as the Antoine²⁵ equation because he proposed one of very similar nature that used 13 K for the constant C . Knowledge of the vapor pressure at two temperatures will fix A and B and permit approximations of vapor pressures at other temperatures. Generally, the Antoine approach can be expected to have less than 2% error and is the preferred approach if the vapor pressure is expected to be less than 1,500 mm Hg [200 kPa] and if the constants are available.

Lee-Kesler

Vapor pressures also can be calculated by corresponding-states principles. The most common expansions of the Clapeyron equation lead to a two-parameter expression. Pitzer extended the expansion to contain three parameters:

$$\ln p_{vr} = f^0(T_r) + \omega f^1(T_r), \quad (21)$$

where p_{vr} is the reduced vapor pressure (vapor pressure/critical pressure), f^0 and f^1 are functions of reduced temperature, and ω is the acentric factor.

Lee and Kesler²⁶ have expressed f^0 and f^1 in analytical forms:

$$f^0 = 5.92714 - (6.09648/T_r) - 1.28862 \ln T_r + 0.169347(T_r)^6 \quad (22)$$

and

$$f^1 = 15.2518 - (15.6875/T_r) - 13.4721 \ln T_r + 0.43577(T_r)^6, \quad (23)$$

which can be solved easily by high-speed computer or a hand-held calculator. Lee-Kesler is the preferred method of calculation but should be used only for nonpolar liquids.

The advent of computers and calculators makes use of approximations and charts much less advantageous than they were in the 1960's. Values of acentric factors can be found in Ref. 27, which also presents many other available vapor-pressure correlations and calculation techniques with comments about their advantages and limitations.

Example Problems

TABLE 20.4—DATA FOR EXAMPLE PROBLEM 2

	Mole Fraction	T_c (°R*)	p_c (psia*)	M_i^*
Methane	0.8319	343	668	16.04
Ethane	0.0848	550	708	30.07
Propane	0.0437	666	616	44.09
i-butane	0.0076	735	529	58.12
n-butane	0.0168	766	551	58.12
i-pentane	0.0057	829	490	72.15
n-pentane	0.0032	846	489	72.15
Hexanes	0.0063	914	437	86.17
	1.0000			

*From Table 20.2.

Solution. First calculate the apparent mole weight from information in Table 20.3.

$$\bar{M}_g = \sum y_i M_i = 20.424.$$

Then

$$\begin{aligned}\gamma_g &= \bar{M}_g / M_a = \sum y_i M_i / 28.966 \\ &= 20.424 / 28.966 \\ &= 0.705,\end{aligned}$$

where M_a is the molecular weight of air = 28.966.

Example Problem 2. Calculate actual density of the same mixture at 1,525 psia and 75°F.

Solution.

$$\rho_g = \frac{p \bar{M}_g}{z_g R T},$$

$$p = 1,525 \text{ psia},$$

$$\bar{M}_g = 20.424,$$

$$R = 10.73 \frac{\text{psia} \times \text{cu ft}}{^\circ\text{R} \times \text{lbm mol}} \quad (\text{from Table 20.1}),$$

$$T = 75^\circ\text{F} + 460 = 535^\circ\text{R}, \text{ and}$$

$$z_g \text{ must be obtained from Fig. 20.2.}$$

Calculate z_g from known composition or gas gravity in Table 20.4. From the known gas composition we obtain

$$T_{pc} = \sum y_i T_{ci} = 393.8^\circ\text{R},$$

$$T_{pr} = \frac{535}{393.8} = 1.36,$$

$$p_{pc} = \sum y_i p_{ci} = 662.6 \text{ psia},$$

$$p_{pr} = \frac{1,525}{662.6} = 2.30, \text{ and}$$

$$z_g = 0.712.$$

From gas gravity we obtain

$$\bar{M}_g = \sum y_i M_i = 20.424$$

and

$$\gamma_g = \frac{\bar{M}_g}{M_a} = \frac{20.424}{28.966} = 0.705.$$

From Fig. 20.3 we obtain

$$T_{pc} = 392^\circ\text{R},$$

$$T_{pr} = \frac{535}{392} = 1.36,$$

$$p_{pc} = 663 \text{ psia},$$

$$p_{pr} = \frac{1,525}{663} = 2.30,$$

and

$$z_g = 0.712.$$

Conclusion. Composition and gas gravity methods yield identical results for this hydrocarbon gas at surface processing conditions. Then,

$$\rho_g = \frac{1,525 \times 20.424}{0.712 \times 10.73 \times 535}$$

$$= 7.62 \text{ lbm/cu ft} = 0.122 \text{ g/cm}^3.$$

Example Problem 3. Calculate the z factor for the reservoir fluid in Table 20.5 at 307°F and 6,098 psia. For the C₇₊ fraction:

$$\gamma = 0.825 (40^\circ\text{API}),$$

$$\bar{M}_g = 119, \text{ and}$$

the experimental $z_g = 0.998$.

Solution. From the known gas composition we obtain (Fig. 20.2)

$$T_{pc} = \sum y_i T_{ci} = 487^\circ\text{R},$$

$$T_{pr} = \frac{767}{487} = 1.58,$$

$$p_{pc} = \sum y_i p_{ci} = 822 \text{ psia},$$

$$p_{pr} = \frac{6,098}{824} = 7.42, \text{ and}$$

$$z_g = 0.962 \text{ } (-4\% \text{ error}).$$

TABLE 20.5—DATA FOR EXAMPLE PROBLEM 3

	Mole Fraction	T_c (°R)	p_c (psia)	M_g
Nitrogen	0.1186	228	493	28.02
Methane	0.3836	343	668	16.04

i-pentane	0.0051	829	490	72.15
n-pentane	0.0052	846	489	72.15
Hexanes	0.0067	914	437	86.17
Heptanes plus	0.0373	1,116*	453*	119.00
Total	1.0000			

* Obtained from Fig. 20.10.

From gas gravity we obtain

$$\bar{M}_g = \sum y_i M_i = 31.87, \text{ and}$$

$$\gamma_g = \bar{M}_g / M_a = \frac{31.87}{28.966} = 1.100.$$

$$T_{pc} = 524^\circ \text{R},$$

$$T_{pr} = \frac{767}{524} = 1.464,$$

$$p_{pc} = 652 \text{ psia},$$

$$p_{pr} = \frac{6,098}{652} = 9.35, \text{ and}$$

$$z_g = 1.087 \text{ (9\% error)}.$$

By including corrections to calculated criticals with Wichert and Aziz's chart we obtain

$$\epsilon = 31.2 \text{ (Fig. 20.4),}$$

$$T'_{pc} = 487 - 31 = 456^\circ \text{R},$$

$$p'_{pc} = (822)(456) / [487 + (0.2419)(1 - 0.2419)(31.2)],$$

$$= 762 \text{ psia}.$$

$$T_{pr} = \frac{767}{456} = 1.68,$$

$$p_{pr} = \frac{6,098}{762} = 8.00, \text{ and}$$

$$z_g = 1.010 \text{ (1\% error)}.$$

Example Problem 4. Calculate the viscosity at 150°F and 2,012 psia for the gas of the composition shown in Table 20.6.

TABLE 20.6—DATA FOR EXAMPLE PROBLEM 4

	Mole Fraction	M_i Molecular Weight	T_c (°R)	p_c (psia)
Nitrogen	0.158	28.02	228	492
Methane	0.739	16.04	343	668
Ethane	0.061	30.07	550	708
Propane	0.034	44.09	666	616
i-butane	0.002	58.12	735	529
n-butane	0.006	58.12	765	551
Total	1.000			

Solution by the Carr-Kobayashi-Burrows Method.

$$T_{pc} = \sum y_i T_{ci} = 350^\circ \text{R},$$

$$T_{pr} = \frac{460 + 150}{350} = 1.74,$$

$$p_{pc} = \sum y_i p_{ci} = 639 \text{ psia},$$

$$p_{pr} = \frac{2,012}{639} = 3.15,$$

$$\bar{M}_g = \sum y_i M_i = 19.98, \text{ and}$$

$$\gamma_g = \frac{19.98}{28.966} = 0.690.$$

$$\text{Viscosity at } 150^\circ \text{F, } 1 \text{ atm (Fig. 20.6)} = 0.0116 \text{ cp}$$

$$\text{Correction for N}_2 \text{ (Fig. 20.6)} = +0.0013 \text{ cp}$$

$$\text{Viscosity, } \mu_1 = 0.0129 \text{ cp}$$

$$\text{Viscosity ratio, } \mu/\mu_1 \text{ (Fig. 20.7)} = 1.32$$

$$\text{Viscosity, } \mu = (1.32)(0.0129) = 0.0170 \text{ cp}$$

Solution by the Thodos Method.

$$v_{pc} = \sum y_i v_{ci} = 104.5 \text{ cm}^3/\text{g mol}.$$

Viscosity parameter,

$$\xi = \frac{(T_{pc})^{1/6}}{(\bar{M}_g)^{1/2} (p_{pc})^{1/3}}$$

$$= \frac{(350/1.8)^{1/6}}{(19.98)^{1/2} (639/14.7)^{1/3}} = 0.0435.$$

Pseudocritical density,

$$\rho_{pc} = \frac{\bar{M}_g}{v_{pc}} = \frac{19.98}{104.5} = 0.1912 \text{ g/cm}^3.$$

$$\text{Viscosity factor, } \mu^* \xi \text{ (Fig. 20.8)} = 55 \times 10^{-5},$$

$$\mu^* = 55 \times 10^{-5} / 0.0435 = 0.0126 \text{ cp}.$$

Density,

$$z_g = 0.876 \text{ (Fig. 20.2),}$$

$$\rho_g = \frac{\bar{M}_g p}{z_g R T} = \frac{(19.98)(2,012)}{(0.876)(10.73)(610)} = 7.017 \text{ lbm/cu ft}$$

$$= 0.112 \text{ g/cm}^3, \text{ and}$$

$$\rho_{pr} = 0.112/0.1912 = 0.58.$$

Viscosity factor, $(\mu - \mu^*)\xi = 18.9 \times 10^{-5}$ (from Fig. 20.9).

Viscosity, $\mu = \mu^* + (\mu - \mu^*)\xi/\xi$

$$= 0.0126 + 18.9 \times 10^{-5}/0.0435$$

$$= 0.0169 \text{ cp.}$$

Results. Carr *et al.* = 0.0170 cp, Thodos *et al.* = 0.0169 cp, and experimental = 0.0172 cp.

Conclusion. Excellent results are obtained from either correlation for viscosity of a natural gas.

Example Problem 5. A new discovery in the Lower Tuscaloosa formation produces a gas consisting of 96% C₁ and 4% C₂. There is no liquid production at the surface. Reservoir conditions are 6,000 psia and 245°F. Calculate the gas formation volume factor and the coefficient of isothermal compressibility.

Solution. The pseudocritical pressure and temperature of the mixture are

$$\begin{aligned} T_{pc} &= 0.96 \times 343 = 329.3 \\ &+ 0.04 \times 550 = \underline{22.0} \\ &= 351.3^\circ\text{R.} \end{aligned}$$

and

$$\begin{aligned} p_{pc} &= 0.96 \times 668 = 641.3 \\ &+ 0.04 \times 708 = \underline{28.3} \\ &= 669.6 \text{ psia.} \end{aligned}$$

The reduced quantities at reservoir (subscript *rc*) and surface (subscript *sc*) conditions are

$$(T_{pr})_{rc} = \frac{245 + 459.6}{351.3} = \frac{704.6}{352.24} = 2.00,$$

$$(T_{pr})_{sc} = \frac{60 + 459.6}{351.3} = 1.48,$$

$$(p_{pr})_{rc} = \frac{6,000}{669.6} = 8.96,$$

and

$$(p_{pr})_{sc} = \frac{14.7}{669.6} = 0.022.$$

From Fig. 20.2, $z_{rc} = 1.095$, $z_{sc} = 0.998$ (probably could have assumed 1.0), and

$$B_g = 0.005035 \frac{T_{rc} z_{rc}}{p_{rc} z_{sc}} = \frac{0.005035 \times 704.6 \times 1.095}{6,000 \times 0.998}$$

$$= 0.00065 \text{ RB/scf.}$$

From Fig. 20.11, by using $T_{pr} = 2.00$ and $p_{pr} = 8.96$, we obtain:

$$c_{pr} = 0.074,$$

$$c_{pr} = c_g \times p_{pc},$$

and

$$c_g = \frac{c_{pr}}{p_{pc}} = \frac{0.074}{669.6} = 0.0001105$$

$$= 110.5 \times 10^{-6} \text{ psi}^{-1}.$$

By using a computer to calculate the numerical derivative of z with respect to pressure, we get $c_g = 107.4 \times 10^{-6} \text{ psi}^{-1}$, which indicates Trube's correlation to be in error by about 3%.

Example Problem 6. The vapor pressure of pure hexane as a function of temperature is 54.04 kPa at 50°C and 188.76 kPa at 90°C. Estimate the vapor pressure of hexane at 100°C, using all the methods outlined in the text.

Solution. Clausius-Clapeyron. The Clausius-Clapeyron equation can be solved graphically by plotting log of vapor pressure vs. reciprocal absolute temperature and extrapolating. It also can be solved by slopes.

$$T_1 = 50^\circ\text{C} [581.67^\circ\text{R}],$$

$$1/T_1 = 0.001719,$$

$$T_2 = 90^\circ\text{C} [617.67^\circ\text{R}],$$

$$1/T_2 = 0.001619,$$

$$p_v \text{ at } T_1 = 54.04 \text{ kPa} = 7.8374 \text{ psia,}$$

$$\log p_v = 0.89417,$$

$$p_v \text{ at } T_2 = 105.37 \text{ kPa} = 15.2826 \text{ psia,}$$

$$\log p_v = 1.18420,$$

$$\Delta \log p_v = -0.29003,$$

$$1/T_1 - 1/T_2 = 0.0001, \text{ and}$$

$$\text{slope} = \Delta \log p_v / \left(\frac{1}{T_1} - \frac{1}{T_2} \right) = \frac{-0.29003}{0.0001}$$

$$= -2900.3.$$

Solving $\log p_v = -2900.3(1/T) + b$ for b yields

$$b = 5.87977,$$

$$T_3 = 100^\circ\text{C} = 671.67^\circ\text{R, and}$$

$$1/T_3 = 0.001489.$$

Solving for p_v at 100°C:

$$\log p_v = -2900.3(0.001489) + 5.87977$$

$$= 1.56122, \text{ and}$$

$$p_v = 36.4102 \text{ psia [251.04 kPa]}.$$

However, if you know that the vapor pressure at 70°C is 105.37 kPa, you can use the 70 to 90°C temperature differential to calculate the slopes and ultimately will calculate $p_v = 35.81 \text{ psia} = 246.7 \text{ kPa}$.

Cox Chart.²⁸ From Fig. 20.14, the vapor pressure at 100°C can be approximated between 35 and 36 psia. A larger chart is required for more precise readings.

The Calingart and Davis or Antoine Equation. This can be used by obtaining the Antoine constants from Reid *et al.*²⁷ For n-hexane, with temperature in K, these constants are $A = 15.8366$, $B = 2697.55$, and $C = -48.78$. Then,

$$\ln p_v = A - \frac{B}{T + C}$$

$$= 15.8366 - \frac{2697.55}{373 - 48.78} = 3.60223, \text{ and}$$

$$p_v = 36.68 \text{ psia [252.73 kPa]}.$$

Lee-Kesler. The use of the Lee-Kesler equation requires p_c , T_c , and ω for n-hexane. These can be obtained from Table 20.2.

$$p_c = 436.9 \text{ psia [29.7 atm]}$$

$$T_c = 453.7^\circ\text{F or } 913.3^\circ\text{R or } 507.4 \text{ K, and}$$

$$\omega = 0.3007.$$

For 100°C,

$$T_r = 0.7351,$$

$$(T_r)^6 = 0.15782,$$

$$\ln T_r = -0.30775,$$

$$f^0 = 5.92714 - (6.09648/0.7351) + 1.28862(0.30775)$$

$$+ 0.169347(0.15782),$$

and

$$f^1 = 15.2518 - (15.6875/0.7351) + 13.4721(0.30775)$$

$$+ 0.43577(0.15782).$$

Therefore,

$$f^0 = 5.92714 - 8.29340 + 0.39657 + 0.02673$$

$$= -1.94296,$$

$$f^1 = 15.2518 - 21.34063 + 4.14604 + 0.06877$$

$$= -1.87402,$$

$$\ln p_{vr} = -1.94296 + 0.3007(-1.87402)$$

$$= -2.50648,$$

$$p_{vr} = \frac{p_v}{p_c} = 0.0816,$$

and

$$p_v = 0.0816 \times 29.7 = 2.4235 \text{ atm} = 35.62 \text{ psia}$$

$$= 245.59 \text{ kPa}.$$

Experimental Value. 35.69 psia = 245.90 kPa.

Conclusions. Lee-Kesler gives the best answer, but the Clausius-Clapeyron method can be even more accurate if the extrapolation is short.

Nomenclature

- a = constant characteristic of the fluid
- a_i = constant for Substance i
- a_{ij} = mixture parameter
- a_m = Parameter a characteristic
- $a(T)$ = functional relationship
- A = empirical constant
- A_o = empirical constant
- b = constant characteristic of the fluid
- b_i = constant characteristic for Substance i
- b_m = Parameter b for mixture
- B = empirical constant
- B_g = gas FVF
- B_o = empirical constant
- c = empirical constant
- c_g = coefficient of isothermal compressibility
- C = constant with value of 43 when temperature is in K, and a value of 77.4 when temperature is in °R
- d = empirical constant
- D_o = empirical constant
- E_k = kinetic energy
- E_o = empirical constant
- f^0, f^1 = functions of reduced temperature
- K_{ij} = constant for each binary pair when used for mixtures
- L_v = molar latent heat of vaporization
- m = mass
- M = molecular weight
- M_a = molecular weight of air
- $M_{C_{7+}}$ = molecular weight of C_{7+} fraction
- M_g = average mole weight of gas mixture
- p = absolute pressure
- p_c = critical pressure

p_{ci} = critical pressure of Component i in gas mixture
 p_{pc} = pseudocritical pressure of gas mixture
 p'_{pc} = corrected pseudocritical pressure
 p_r = reduced pressure
 p_{rc} = pressure at reservoir conditions
 p_{sc} = pressure at standard conditions
 p_v = vapor pressure
 p_{vr} = reduced vapor pressure (vapor pressure/critical pressure)
 R = absolute temperature
 t = ratio of critical to absolute temperature
 T_c = critical temperature
 T_{ci} = critical temperature of Component i in gas mixture
 T_{pc} = corrected pseudocritical temperature
 T_r = reduced temperature
 T_{rc} = temperature at reservoir conditions
 T_{sc} = temperature at standard conditions
 v = velocity
 V = volume
 V_c = critical volume
 $(V_c)_{C_7+}$ = critical volume of C_7+ fraction
 V_M = molar volume
 V_r = reduced volume
 V_{rc} = volume at reservoir conditions
 V_{sc} = volume at standard conditions
 ΔV = increase in volume while vaporizing 1 mole
 x_i = mole fraction of Component i in liquid
 y_{CO_2} = mole fraction of CO_2 in mixture
 y_{H_2S} = mole fraction of H_2S in mixture
 y_i = mole fraction of Component i in gas mixture
 z = compressibility factor
 z_{rc} = compressibility factor at reservoir conditions
 z_{sc} = compressibility factor at standard conditions

Chapter 21

Crude Oil Properties and Condensate Properties and Correlations

Paul Buthod, U. of Tulsa*

Introduction

All crude oils are composed primarily of hydrocarbons, which are made by the combination of the elements carbon and hydrogen. In addition, most crudes contain sulfur compounds and trace quantities of oxygen, nitrogen, and heavy metals. The difference in crude oils is caused by the amount of sulfur compounds and by the types and molecular weights of the hydrocarbons making up the oil.

The hydrocarbons found in crude oil range in size from the smallest molecule, methane, which contains 1 atom of carbon, to the largest ones, which contain nearly 100 atoms of carbon. The types of hydrocarbon compounds are paraffin, naphthene, and aromatic, found in raw crude, and olefin and diolefin, which are sometimes found in refined products after thermal treatment. Since any crude oil will have several thousand different compounds in it, it has been impossible so far to develop exact analyses of the actual compounds present. Three methods of reporting analyses are available—ultimate analysis, chemical analysis, and evaluation analysis.

Ultimate analysis lists the composition in percentages of the elements carbon, hydrogen, nitrogen, oxygen, and sulfur. This tells very little about the type of compounds present or the physical characteristics of the oil. It is useful, however, in determining the amount of sulfur that must be removed. Table 21.1 shows the ultimate analysis of several crude oils.

Chemical analysis gives composition in percentage of paraffin, naphthene, and aromatic-type compounds present in the crude. This type of analysis can be determined with fair accuracy by means of chemical reaction and solvency tests. An analysis of this sort gives an idea of the usefulness of refined products but does not give any

means of predicting the amount of various refined products. Table 21.2 gives the chemical analysis of several fractions of four crude oils.

The crude-oil evaluation consists primarily of a fractional distillation of the oil followed by physical-property tests (for parameters such as gravity, viscosity, and pour point) on the distillation products. Since the primary means of separating products in the refinery is fractionation, this analysis makes it possible to predict yields of refined products and physical properties studied in the evaluation. The evaluation curves shown in Fig. 21.1 make it possible to predict the physical properties of the refined products. As an example of the use of evaluation curves, Table 21.3 shows product yields and properties when a refinery is operated for maximum gasoline yield, and Table 21.4 shows product yields and properties when the objective is to produce lubricating oils and diesel fuel.

Since the early 1970's, much research has been performed on the use of the gas chromatograph to generate simulated distillations. This has the advantage of producing crude-oil evaluation curves with very small samples of crude and in a period of about an hour, compared with about a gallon of crude for a fractional distillation column and about 2 days for the analysis. The simulated distillation is called ASTM Test Method D2887.¹

Base of Crude Oil

Since the beginning of the oil industry in the U.S., it has been convenient to separate crude oils into three broad classifications or bases. These three, paraffin, intermediate, and naphthene, are useful as general classifications but lead to ambiguity in many instances. Because a crude may exhibit one set of characteristics for

*This author also wrote the original chapter on this topic in the 1962 edition.

**Universal Oil Products Co., Chicago.

its light materials and another set for the heavy-lube fractions, the USBM has developed a more useful method of classifying oils.

Two fractions (called "key fractions") are obtained in the standard Hempel distillation procedure. Key Fraction 1 is the material that boils between 482 and 527°F at atmospheric pressure. Key Fraction 2 is the material that boils between 527 and 572°F at 40 mm absolute pressure. Both fractions are tested for API gravity, and Key Fraction 2 is tested for cloud point. In naming the type of oil, the base of light material (Key Fraction 1) is named first, and the base of the heavy material (Key Fraction 2) is named second. If the cloud point of Key Fraction 2 is above 5°F, the term "wax-bearing" is added. If the pour point is below 5°F, it is termed "wax-free."

Thus, "paraffin-intermediate-wax-free" would mean a crude that has paraffinic characteristics in the gasoline portion and intermediate characteristics in the lube portion and has very little wax. Table 21.5 shows the criteria used in establishing bases of oil by the USBM method.

Several attempts have been made to establish an index to give a numerical correlation for the base of a crude oil. The most useful of these is the characterization factor K developed in Ref. 2,

$$K = \frac{\sqrt[3]{\bar{T}_B}}{\gamma}$$

in which \bar{T}_B is the molal average boiling point (degrees Rankine) and γ is the specific gravity at 60°F. This has been used successfully in correlating not only crude oils, but refinery products both cracked and straight-run. Typical numerical values for characterization factors are listed in Table 21.6.

In addition to the relationship between the characterization factor and the specific gravity and boiling point defined above, a number of other physical properties have been shown to be related to the characterization factor. Among these properties are viscosity, molecular weight, critical temperature and pressure, specific heats, and percent hydrogen.

Table 21.7 shows characterization factors for a

TABLE 21.6—TYPICAL CHARACTERIZATION FACTOR VALUES

Product	Characterization Factor
Pennsylvania stocks (paraffin base)	12.1 to 12.5
Mid-Continent stocks (intermediate)	11.8 to 12.0
Gulf Coast stocks (naphthene base)	11.0 to 11.8
Cracked gasoline	11.5 to 11.8
Cracking-plant combined feeds	10.5 to 11.5
Recycle stocks	10.0 to 11.0
Cracked residuum	9.8 to 11.0

number of worldwide crudes and products and typical hydrocarbon compounds that have the same characterization factor as the oil in question.

Physical Properties

Fig. 21.2 shows the relationship of carbon-to-hydrogen ratio, average molecular weight, and mean average boiling point as a function of API gravity and characterization factor. The *API Technical Data Book*³ has published a number of correlations for physical properties of petroleum. For the most accurate data, this reference should be consulted.

When oil is heated or cooled in a processing operation, the amount of heat required is best obtained by the use of the specific heat. Fig. 21.3 shows the specific heat of liquid petroleum oils as a function of API gravity and temperature. This chart is based on a characterization factor of 11.8, and if the oil being studied is other than that, there is a correction shown at the lower right side of the chart. The number obtained for the specific heat should be multiplied by this correction factor. Certain paraffin hydrocarbons are also shown on the chart. No correction need be applied to these.

If vaporization or condensation occurs in a processing operation, the heat requirements are most easily handled by the use of total heats. Fig. 21.4 gives total heats of petroleum liquid and vapor, with liquid at 0°F as a reference or zero point. This eliminates the necessity of selecting a latent heat, specific heats of both vapor and liquid, and deciding at what temperature to apply the latent heat. Certain corrections must be applied for characterization factor and for pressure.

TABLE 21.7—CHARACTERIZATION FACTORS OF A FEW HYDROCARBONS, PETROLEUMS, AND TYPICAL STOCKS

Characterization Factor	Hydrocarbons	Typical Crude Oils	Miscellaneous Products
14.7	propane		
14.2	propylene		
13.85	isobutane		
13.5 to 13.6	butane		94.5 API adsorption gasoline
13.0 to 13.2	butane-1 and isopentane		Four Venezuelan paraffin waxes

Fig. 21.5—Approximate relation between viscosity, temperature, and characterization factor.

An important physical property of petroleum necessary in studying flow characteristics is viscosity. Viscosity of petroleum is often reported in Saybolt Universal Seconds (SUS), derived from one of the common routine tests for oils. For engineering calculation, however, the viscosity should be obtained in centipoise. The relation between these two systems, according to the U.S. Bureau of Standards, is

$$\frac{\mu_o}{\gamma_o} = 0.219 t_{SU} - \frac{149.7}{t_{SU}},$$

where

μ_o = viscosity, cp

γ_o = specific gravity of oil at measured temperature, and

t_{SU} = Universal Saybolt viscosity, seconds.

An accurate correlation for viscosity is difficult, especially for viscous oils, but an estimate of viscosity may be obtained from Fig. 21.5. Four characterization factors are given, and interpolation must be made for other factors.

True-Boiling-Point Crude-Oil Analyses

A number of true-boiling-point crude-oil analyses are included in Table 21.8. In addition to the gravity, viscosity, sulfur content, and characterization factor, there is a breakdown of typical products made from each crude. This table may be used either to estimate the value of the products listed or to plot and evaluate any set of products obtained (see Fig. 21.1). The table is separated first according to state, and within each group according to gravity.

When the quality of a product is indicated as good or excellent, it means not only that the quality is good but that it is present in normal amounts and that a salable product can be made without excessive treatment.

Table 21.9 shows the analysis of the gas and liquid phases after a stage separation of several condensates.

Nelson⁴ gives a compilation of 164 crudes and lists the gravity, characterization factor, sulfur content, and viscosity of each. Those tables include yields of typical refined products, along with their physical properties and an indication of their quality. A true-boiling-point curve can be generated by plotting the end points of these products against the cumulative volume percent yield. If the characterization factor is plotted on the same graph, the characterization factor at any instantaneous boiling point can be calculated. When instantaneous temperatures and characterization factors at different percents are known, specific gravity, API gravity, and viscosity curves may be estimated. Thus, evaluation curves such as those in Fig. 21.1 may be produced for any of the 164 crudes listed. A typical page of these data is shown in Table 21.8.

More recently, a series on evaluations of non-U.S. crude oils was published.⁵ The format is similar to those in Nelson's compilation,⁴ but the physical properties are usually more complete. An example of an analysis from this series is shown in Table 21.10.

The USBM in Bartlesville, OK, began making distillation analyses before 1920. This laboratory [U.S. DOE Bartlesville Energy Technology Center (BETC)] has continued to evaluate crude oil up to the present time and has two publications^{6,7} that show the distillation data along with gravity and viscosity of the distilled fractions. They also show the percentage composition of the fractions in terms of paraffins, naphthenes, and aromatics. This set of tables uses the correlation index rather than characterization factor as a correlating number. In general, low correlation index (I_c) numbers indicate highly paraffinic (pure paraffin hydrocarbons, $I_c=0$). High numbers indicate a high degree of aromaticity (benzene, $I_c=100$). The correlation index is defined as follows.

$$I_c = 473.7 \gamma - 456.8 + 87552/\bar{T}_B,$$

where γ is the specific gravity of the fraction at 60°F and \bar{T}_B is the average normal boiling point in degrees Rankine.

All U.S. DOE analysis data have been built into the BETC Crude Oil Analysis Data Bank.⁸ The data retrieval system, Crude Oil Analysis System (COASYS), is available by telephone hookup, and customers may search, sort, and retrieve analyses from the file. More than 30 keywords are available for searching; for example, YEAR, APIG, LOC, GEOL and SULF, allow a search on year analyzed, API gravity, location by state and country, geological formation, and percent sulfur in the oil, respectively. Table 21.11 shows the type of information obtained in a typical analysis retrieved from a computer search by COASYS.

Bubblepoint Pressure Correlations*

In the study of reservoir flow properties, it is important to know whether the fluid in the reservoir is in the liquid,

vapor, or two-phase state. With crude oils, the fluid may be subcooled liquid, but with some dissolved gas. Upon reduction in reservoir pressure, a point where the gas starts to come out of solution, called "bubblepoint pressure," is reached. At this point the flow characteristics change. Some of the earliest work in this field was done by Lacey, Sage, and Kircher.⁹

Several empirical correlations have been developed to predict the bubblepoint pressure, and some of these are presented later.

Dewpoint-Pressure Correlations

The dewpoint, like the bubblepoint, is characterized by a substantial amount of one phase in equilibrium with an infinitesimal amount of the other phase. At the dew-

point, the liquid phase is at its minimum. In general, petroleum-reservoir systems that involve dewpoint behavior at reservoir conditions are characterized by (1) surface gas/oil ratios (GOR's) greater than 6,000 cu ft/bbl in most instances; (2) lightly colored tank oils, usually straw-colored to light orange for reservoir systems at 3,000 to 5,000 psi but grading to brown for systems at 7,000 psi and greater; (3) tank oil gravity usually greater than 45°API; and (4) methane content usually greater than 65 mol%.

Few dewpoint-pressure correlations of reservoir systems have been published. Sage and Olds¹⁰ published a very general correlation of the behavior of several San Joaquin Valley, CA, systems. A correlation developed by Organick and Golding¹¹ is discussed in

detail. Calculation of the dewpoint pressure by means of the composition and equilibrium ratios is discussed in Chap. 23.

Sage and Olds' Correlation

Laboratory studies on five San Joaquin Valley systems resulted in the correlation shown in Table 21.12. The basis for the 160°F data presented in this table is shown in Fig. 21.6. Although the five systems correlate within themselves, it is not known how representative the correlation is of systems from other fields. The data are reproduced here more as a guide to dewpoint-pressure behavior than as a means of estimating precise values of dewpoints.

Organick and Golding's Correlation

This correlation relates saturation pressure of a system directly to its chemical composition by means of two generalized composition characteristics \bar{T}_B , the molal average boiling point, and \bar{W}_m , a modified weight average equivalent molecular weight. The saturation pressure may be either bubble-point pressure, dewpoint pressure, or the very special case of critical pressure. The 15 working charts (Figs. 21.7 through 21.21) cover

primarily conditions that pertain to dewpoints, and it is in this capacity that they will be discussed. The reader should be aware, however, that the charts also may be used to estimate critical pressure and temperature of the more volatile systems. The correlation has limited usefulness as a bubblepoint-pressure correlation because it covers primarily high-volatility systems. system. The short-cut method suffices for most calculations.

Calculation of \bar{T}_B . The molal average boiling point of the system is defined as

$$\bar{T}_B = \sum y \times \bar{T}_a, \dots \dots \dots (1)$$

where y is the mole fraction and \bar{T}_a the atmospheric boiling point.

Boiling points of the pure compounds (methane, ethane, nitrogen, carbon dioxide, etc.) are listed in Chap. 20. The boiling point of the C_7^+ fraction is taken as the Smith and Watson¹² mean average boiling point (MABP). The MABP can be calculated from the ASTM distillation curve, the procedure being first to calculate the ASTM volumetric average boiling point (VABP, °F) and then to apply a correction factor to obtain the

MABP. The VABP is the average of the temperatures at which the distillate plus loss equals 10, 30, 50, 70, and 90% by volume of the ASTM charge, that is,

$$\bar{T}_V = \frac{T_{10\%} + T_{30\%} + T_{50\%} + T_{70\%} + T_{90\%}}{5}, \dots\dots(2)$$

where \bar{T}_V is the ASTM volumetric average boiling point.

The correction to add to \bar{T}_V to obtain the mean average boiling point is given in Table 21.13 as a function of \bar{T}_V and the slope of the ASTM curve between the 10 and 90% distilled points. In the correlation, \bar{T}_V is in degrees Rankine (i.e., °F+460).

Calculation of \bar{W}_m . The modified weight average equivalent molecular weight, \bar{W}_m , is a more complex function to evaluate. It is defined as the equivalent molecular weight multiplied by the summation of the weight fractions. The equivalent molecular weight of a paraffin hydrocarbon compound is its true molecular

weight. For other than straight-chain paraffin compounds (isoparaffins and olefins), the equivalent molecular weight is defined as the molecular weight that an n-paraffin would have if it boiled at the same temperature as the isoparaffin or olefin in question. Values of the equivalent molecular weights for natural-gas constituents are given in Table 21.14.

The equivalent molecular weight of the C₇+ fraction is determined by calculating the Watson characterization factor, K_W , and using Fig. 21.7. Use of the characterization factor permits some account to be taken of the paraffinicity of the heavy-end material.

$$K_W = \frac{\sqrt[3]{\bar{T}_C}}{\gamma_g}, \dots\dots\dots(3)$$

where \bar{T}_C is the cubic average boiling point, °R. The cubic average boiling point (\bar{T}_C) is obtained by adding the corrections in Table 21.15 to the ASTM \bar{T}_V , °F.

Example Problem 1. The dewpoint pressure at 200°F for a well effluent having the composition shown in Table 21.16 is predicted as follows.

1. Calculating first the properties of the separator liquid C_7^+ , we have

$$\bar{T}_V = \frac{232 + 260 + 313 + 383 + 497}{5} = 337^\circ\text{F}$$

and

$$10-90\% \text{ slope} = \frac{497 - 232}{80} = 3.31.$$

From Table 21.13, MABP is $337 - 22.5 = 315^\circ\text{F}$ or 775°R . From Table 21.15, CABP is $337 - 8.3 = 329^\circ\text{F}$ or 789°R , giving

$$K_w = \frac{\sqrt[3]{789}}{0.7535} = 12.3.$$

From Fig. 21.7 the \bar{W}_m for the C_7^+ material from the separator liquid is estimated to be 142.

Properties of the C_7^+ material from the separator gas are assumed to be equal to those of n-octane (i.e., $T_B = 718^\circ\text{R}$, $W_m = 114$).

2. Calculating values of \bar{T}_B and \bar{W}_m for the well effluent, we obtain the results shown in Table 21.17.

3. Having calculated \bar{T}_B and \bar{W}_m for the well effluent, we can now determine the desired dewpoint pressure at 200°F by interpolation between Figs. 21.14 and 21.15. At $\bar{T}_B = 240^\circ\text{F}$, the dewpoint pressure is

$$\frac{\bar{W}_m = 50}{4,850} = \frac{\bar{W}_m = 45}{4,000},$$

and the calculated dew point (at $\bar{W}_m = 49$) is 4,680 psia.

It will be noticed that at 4,680 psia and 200°F the material is about 200°F and 900 psi above the critical temperature and pressure of the system. (From Figs. 21.14 and 21.15, the locus of critical states line gives $T_c = 0^\circ\text{F}$ and $p_c = 3,800$ psia.)

Fig. 21.21—Saturation pressure vs. temperature at $W_m = 25$. Parameter T_B .

Accuracy of Organick-Golding Correlation. About 50% of the 214 points that form the basis for the correlation were in error less than 5% and 82% were in error less than 10%. Standard deviation of all points is about 7.0%.

Total Formation Volume Correlations

The total formation volume factor (FVF) defines the total volume of a system regardless of the number of phases present. Vink *et al.*¹³ have shown that it is possible to have more than two hydrocarbon phases in equilibrium when the system contains an excessively large amount of one component. Naturally occurring systems usually exist in either one or two phases. For this reason, the term “two-phase formation volume” has become synonymous with total formation volume.

The relationship of specific volume and density to the total formation volume is the same as indicated in the preceding section for the oil-formation volume.

Total Formation Volume Factors of Gas-Condensate Systems

Total formation volume factors, specific volumes, and densities of gas-condensate systems may be calculated by use of the ideal gas-law equation with the proper compressibility factor applied provided that the liquid phase present does not amount to an appreciable fraction of the

system volume. Usually, at reservoir pressures and temperatures and for systems whose composition can be expressed as having a surface GOR greater than 10,000 cu ft/bbl, the presence of 10 vol% liquid phase will not cause errors greater than 2 or 3% when the two-phase mixture density is calculated as though the mixture existed in only a single phase. This comes about because the partial volumes of components in the liquid phase are substantially the same as the partial volumes of the same components in the vapor phase.

Calculations from Composition of the Condensate System. As outlined previously, the formation volume (total or single phase) can be calculated from the relation

$$B = \frac{M_{ro} v_{ro}}{L M_{st} v_{st}}, \quad \dots \dots \dots (4)$$

where

- M_{ro} = molecular weight of reservoir system,
- v_{ro} = specific volume of reservoir system,
- M_{st} = molecular weight of stock-tank oil,
- v_{st} = specific volume of stock-tank oil, and
- L = moles of stock-tank oil per 1 mole of reservoir system.

L can be calculated by use of equilibrium ratios and the methods outlined in Chap. 23.

To use the pseudoreduced-temperature/pseudoreduced-pressure/compressibility chart in the calculation of v_{ro} , it is necessary to determine suitable pseudocritical temperature and pressure values for the heptanes and

heavier components. These values can be obtained by the chart shown in Fig. 21.22. The following example illustrates the calculation of M_{ro} and v_{ro} .

Example Problem 2. The specific volume of a gas-condensate system at reservoir conditions given the system molal analysis shown in Table 21.18 is calculated as follows, assuming 1 pound mole of system.

$$T_{pr} = \frac{460 + 199}{370.7} = 1.78,$$

$$p_{pr} = \frac{2,500}{666.0} = 3.75,$$

$$z = 0.885 \text{ (from Fig. 20.2)}$$

and at 2,500 psia and 199°F

$$v_{ro} = \frac{zRT}{Mp} = \frac{0.885 \times 10.73 \times 659}{19.39 \times 2,500} = 0.129,$$

where T_{pr} is the pseudoreduced temperature, p_{pr} the pseudoreduced pressure, z the compressibility factor, and v_{ro} the specific volume (cu ft/lbm) at reservoir conditions.

In the above solution, two phases are present at 2,500 psia, as the dewpoint pressure calculated by the method of Organick and Golding is 2,690 psia at 199°F. Probably no correlation will indicate directly the amount of liquid present at pressures less than the dewpoint pressure, although it can be calculated by use of suitable equilibrium-ratio and density data.

Calculations from GOR and Produced Fluid Properties. A second method of calculating specific volume or formation volume on the basis of the gas-law equation was developed by Standing.¹⁴ This method uses a correlation (Fig. 21.23) to obtain the gravity of the well effluent (or reservoir system) from the condensate liquid/gas ratio, gas gravity, and the stock-tank-oil gravity of the surface products. The effluent gravity is then used to obtain values of pseudocritical temperatures and pressures and, by means of these, to evaluate compressibility factors for the entire effluent. The condensate curve of Fig. 21.24 should be used when employing this method.

Example Problem 3. The total formation volume of a gas-condensate system at reservoir conditions given the parameters in Table 21.19 is calculated as follows, assuming 1 bbl of stock-tank condensate.

$$\gamma_g = \frac{3,700 \times 0.65 + 170 \times 1.20}{3,700 + 170} = 0.675$$

and 1 bbl condensate per million cubic feet is

$$\frac{325}{3.70 + 0.17} = 84,$$

where γ_g is the gravity of total surface gas.

Pressure, psia	400 to 5,000
GOR, cu ft/bbl	75 to 37,000
Temperature, °F	100 to 258
Gas gravity	0.59 to 0.95
Tank-oil gravity, °API	16.5 to 63.8

From Fig. 21.23, at 45°API

$$\gamma_{lw}/\gamma_{gt} = 1.367$$

and

$$\gamma_{lwr} = 1.367 \times 0.675 = 0.923,$$

where

γ_{lw} = well fluid gravity,

γ_{gt} = trap gas gravity,

and

γ_{lwr} = well fluid reservoir gravity.

From Fig. 21.24,

$$T_{pc} = 432$$

and

$$p_{pc} = 647.$$

At reservoir conditions of 3,000 psia and 250°F,

$$T_{pr} = \frac{460 + 250}{432} = 1.64,$$

$$p_{pr} = \frac{3,000}{647} = 4.64,$$

and from Fig. 20.2

$$z = 0.845.$$

By using 350 lbm/bbl for water, the weight of stock-tank condensate per barrel is

$$\frac{350 \times 141.5}{131.5 + ^\circ\text{API}} = 281.$$

TABLE 21.21—DATA FOR CALCULATING TOTAL FORMATION VOLUME OF THE GAS-CONDENSATE SYSTEM DESCRIBED IN EXAMPLE PROBLEM 4

Reservoir pressure, psia	3,000
Reservoir temperature, °F	250
GOR (condensate total), cu ft/bbl	11,900
Gas gravity (total)	0.675

Reservoir pressure, psia	1,329
Reservoir temperature, °F	145
GOR, cu ft/bbl	
Separator	566
Tank	37
Total	603
Gas gravity	0.674
Tank-oil gravity, °API	36.4

From Fig. 21.23 the molecular weight of stock-tank condensate, M_c , is 140, moles of stock-tank condensate per barrel is $281/140 = 2.00$, moles of surface gas per barrel of stock-tank condensate is $1/325 \times (3,870 \times 10^3) \times 1/379 = 31.4$, and total moles per barrel of stock-tank condensate is $2.00 + 31.4 = 33.4$.

From gas law,

$$V = \frac{nzRT}{p} = \frac{33.4 \times 0.845 \times 10.73 \times 710}{3,000} = 71.7$$

and

$$V = \frac{71.7}{5.615} = 12.8,$$

where the first value of V is in cubic feet and the second in barrels, giving a formation volume B_i of 12.8 bbl/bbl of stock-tank condensate.

Total Formation Volume Factors of Dissolved Gas Systems

A suitable correlation for obtaining total formation volume factors of both dissolved gas and gas-condensate systems was developed by Standing.¹⁵ This correlation is shown in Fig. 21.25, and the graphical chart for simplified use of the correlation is given by Fig. 21.26. The correlation contains 387 experimental points, 92% of which are within 5% of the correlation. Range of the data comprising the correlation is given in Table 21.20.

Example Problem 4. The total formation volume of the gas-condensate system described in Example Problem 3 is calculated as follows, given the data in Table 21.21.

Fig. 21.24—Pseudocritical properties of gases and condensate well fluids.

Fig. 21.25—Formation volume of gas plus liquid phases from GOR, total gas gravity, tank-oil gravity, temperature, and pressure.

Fig. 21.26—Chart for calculating total formation volume by Standing's correlation.

$$\gamma_o = \frac{141.5}{131.5 + 45} = 0.802$$

and

$$\begin{aligned} & \frac{R(T)^{0.5}}{(\gamma_g)^{0.3}} \times (\gamma_o)^{2.9 \times 10^{-0.00027R}} \\ &= 11,900 \frac{(250)^{0.5}}{(0.675)^{0.3}} \times (0.802)^{2.9 \times 10^{-0.00027 \times 11,900}} \\ &= 11,900 \frac{15.8}{0.877} \times (0.802)^{1.0} \\ &= 1.72 \times 10^5 \end{aligned}$$

where γ_o is the tank-oil specific gravity.

From Fig. 21.25, $B_t = 13 + \text{bbl/bbl of tank oil}$.

From Fig. 21.26, $B_t = 13.7 \text{ bbl/bbl of tank oil}$.

Example Problem 5. The total formation volume of well production at reservoir conditions given the data in Table 21.22 is calculated as follows.

From Fig. 21.26, $B_t = 1.72 \text{ bbl/bbl of tank oil}$. Experimental value calculated from PVT test results is 1.745 bbl/bbl of tank oil.

Nomenclature

B = formation volume, m^3 (bbl)
 I_c = correlation index
 K = characterization factor
 L_c = moles of stock-tank condensate per barrel
 L_o = moles of stock-tank oil per 1 mole of reservoir system, kmol/m^3 (lbm mol/gal)
 M = molecular weight
 M_{ro} = molecular weight of reservoir system
 M_{st} = molecular weight of stock-tank oil
 n = total moles
 p_c = critical pressure, psia (lbf/sq in.)
 p_{pr} = pseudoreduced pressure
 R = universal gas constant
 t_{SU} = Universal Saybolt viscosity, seconds
 T = temperature, $^{\circ}\text{F}$
 T_c = critical temperature, $^{\circ}\text{C}$ ($^{\circ}\text{F}$)

Chapter 22

Oil System Correlations

H. Dale Beggs, Petroleum Consultant*

Introduction

Knowledge of petroleum fluids' physical properties is required by petroleum engineers for both reservoir and production system calculations. These properties must be evaluated at reservoir temperature and various pressures for reservoir performance studies, and at conditions of both changing pressure and temperature for wellbore hydraulics calculations.

If reservoir fluid samples are available, the fluid properties of interest can be measured with a pressure-volume-temperature (PVT) analysis. However, these analyses usually are conducted at reservoir temperature only and the variation of the properties with temperature is not available for production system calculations. Also, in many cases a PVT analysis may not be available early in the life of the reservoir or may never be available because of economic reasons. To overcome these obstacles, empirical correlations have been developed for predicting various fluid physical properties from limited data. The development and application of several of these empirical correlations are presented in this chapter. Methods for estimating physical properties for both saturated and undersaturated oils as functions of pressure, temperature, stock-tank oil gravity, and separator gas gravity are given.

Fluid properties are calculated here only for oil systems with and without fluid composition known. Methods for calculating physical properties of gas-condensate systems are presented in Chaps. 21, 23, and 30. Therefore, no correlations for dewpoint pressure are presented, as the dewpoint pressure can be calculated with the procedures outlined in Chap. 21 if the composition of the fluid is known.

Many of the older correlations were presented in graphical form only and are therefore not suitable for use in computers or programmable calculators. These graphs are converted to equation form where possible.

The generally accepted definitions of the fluid properties correlated in this chapter are as follows.*

Oil density, ρ_o , is the ratio of the mass of the oil plus its dissolved or solution gas per unit volume, which varies with temperature and pressure.

Bubblepoint pressure, p_b , is the pressure at which the first bubble of gas evolves as the pressure on the oil is decreased. It also is frequently called "saturation pressure," as the oil will absorb no more gas below that pressure. The bubblepoint pressure varies with temperature for a particular oil system.

Solution gas/oil ratio (GOR), R_s , is the amount of gas that will evolve from the oil as the pressure is reduced to atmospheric from some higher pressure. It is usually expressed in units of scf/STB. The gas is frequently referred to as "dissolved gas."

Oil formation volume factor (FVF), B_o , is the volume occupied by 1 STB oil plus its solution gas at some elevated pressure and temperature. It is usually expressed as bbl/STB. It is a measure of the shrinkage of the oil as it is brought to stock-tank conditions.

Total FVF, B_t , means the volume occupied at some elevated pressure and temperature by 1 STB oil, its remaining solution gas, and the free gas ($R_{sf} - R_s$) that has evolved from the oil. It is also expressed as bbl/STB.

Oil viscosity, μ_o , measures the oil's resistance to flow, defined as the ratio of the shearing stress to the rate of shear induced in the oil by the stress. It is usually measured in centipoise and is required for both reservoir and piping system calculations.

Interfacial tension (IFT), σ_o , is the force per unit length existing at the interface between two immiscible fluids. This property is not required in most reservoir calculations but is a parameter in some correlations for piping system calculations. It is usually expressed in units of dyne/cm.

*The original chapter on this topic in the 1962 edition was written by Marshall B. Standing.

*General terms are defined in the Glossary at the end of this chapter.

Fig. 22.1—Pseudoliquid density of systems containing methane and ethane.

Oil Density Determination

Oil density is required at various pressures and at reservoir temperature for reservoir engineering calculations. The variation with temperature must be calculated for production system design calculations. An equation for oil density is

$$\rho_o = \frac{350\gamma_o + 0.0764\gamma_g R_s}{5.615B_o}, \quad (1)$$

where

- ρ_o = oil density, lbm/cu ft,
- γ_o = oil specific gravity,
- γ_g = gas specific gravity,
- R_s = solution or dissolved gas, scf/STB,
- B_o = oil FVF, bbl/STB,
- 350 = density of water at standard conditions, lbm/STB,
- 0.0764 = density of air at standard conditions, lbm/scf, and
- 5.615 = conversion factor, cu ft/bbl.

If the pressure and temperature conditions are such that all of the available gas is in solution—i.e., the pressure is above the bubblepoint at the temperature of interest—

increased pressure will merely compress the liquid and increase its density. For the case of $p > p_b$, the oil density is calculated from

$$\rho_o = \rho_{ob} \exp[c_o(p - p_b)], \quad (2)$$

where

- ρ_o = oil density at p , T ,
- ρ_{ob} = oil density at p_b , T ,
- p = pressure, psia,
- p_b = bubblepoint pressure at T , psia, and
- c_o = oil isothermal compressibility at T , psi^{-1} .

Correlations for calculating R_s , B_o , c_o and p_b at various conditions are presented later.

In the petroleum industry, it is common to express gravity in terms of the API gravity of the oil, or:

$$\gamma_o = \frac{141.5}{131.5 + \gamma_{\text{API}}}, \quad (3)$$

where γ_o is oil specific gravity, and γ_{API} is oil gravity, °API.

Density From Ideal Solution Principles—Composition Known

The principle of ideal solutions states that the volume of the total solution is the sum of the individual component volumes. The principle applies at atmospheric pressure for fluids in which the components are closely related chemically, such as petroleum. If the composition of the fluid is known, the density at standard conditions (14.7 psia and 60°F) may be calculated from

$$\rho_{sc} = \frac{\sum_{i=1}^C m_i}{\sum_{i=1}^C V_i} = \frac{\sum m_i}{\sum m_i / \rho_i}, \quad (4)$$

where

- m_i = mass of the i th component,
- V_i = volume of the i th component,
- ρ_i = density of the i th component at standard conditions, and
- C = number of components.

Once the density at standard conditions is calculated, it must be corrected for compressibility and thermal expansion if the density at other conditions is required. This can be accomplished by use of charts presented by Standing.¹

When the ideal solution principle is applied to reservoir oils that contain large amounts of dissolved gas, it is obvious that the fluid cannot be brought to standard or stock-tank conditions and still remain in the liquid phase. This limitation is overcome by calculating a pseudoliquid density, the value of which depends on the mass or weight fractions of methane and ethane in the fluid. The pseudoliquid density correlation was presented by Standing¹ and is illustrated in Fig. 22.1.

Fig. 22.2—Density correction for compressibility of hydrocarbon liquids.

Fig. 22.3—Density correction for thermal expansion of hydrocarbon liquids.

The procedure for calculating oil density at any pressure and temperature when the composition is known is as follows.

1. Calculate the mass or weight of the ethane and heavier components in the mixture.
2. Calculate the density of the propane and heavier components with Eq. 4.
3. Calculate the weight or mass percent of ethane in the ethane and heavier mixture.
4. Calculate the weight percent methane in the total mixture.
5. Determine the pseudoliquid density from Fig. 22.1.
6. Correct for compressibility with Fig. 22.2
7. Correct for thermal expansion with Fig. 22.3.

Example Problem 1. Using the known composition of a reservoir fluid as given in Table 22.1, calculate the den-

sity at the bubblepoint pressure of 3,280 psi and temperature of 218°F.

Solution.

1. Weight of ethane plus = $130.69 - 7.046 = 123.46$ lbm.

2. Density of propane plus equals (weight of propane plus) divided by (volume of propane plus):

$$\frac{130.69 - 7.046 - 1.296}{2.227} = 54.94 \text{ lbm/cu ft.}$$

3. Weight percent ethane in ethane plus:

$$\frac{1.296(100)}{123.46} = 1.05.$$

TABLE 22.1— EXAMPLE PROBLEM 1 SOLUTION

Component	Mole Fraction, y_i	Mole Weight of Components, M_i	Weight of Components $m_i = y_i M_i$ (lbm)	Liquid Density of Components,* ρ_i	Liquid Volume of Components,* $V_i = m_i / \rho_i$ (cu ft)
C ₁	0.4404	16.0	7.046		
C ₂	0.0432	30.1	1.296		
C ₃	0.0405	44.1	1.786	31.66	0.0564
C ₄	0.0284	58.1	1.650	35.77**	0.0461
C ₅	0.0174	72.2	1.256	39.16**	0.0321

* at 60°F and 14.7 psia.

** Arithmetic average of iso and normal values.

Fig. 22.4—Apparent liquid density of natural gases.

4. Weight percent methane in methane plus:

$$\frac{7.046(100)}{130.69} = 5.39.$$

5. From Fig. 22.1, $\rho_{sc} = 50.8$ lbm/cu ft at 60°F and 14.7 psia.

6. From Fig. 22.2, the correction for pressure is 0.89 lbm/cu ft.

Therefore, the density at 3,280 psia and 60°F is $50.8 + 0.89 = 51.7$ lbm/cu ft.

7. From Fig. 22.3, the correction for temperature is -3.57 lbm/cu ft. Therefore, the density at 3,280 psia and 218°F is

$$51.7 - 3.57 = 48.1 \text{ lbm/cu ft.}$$

Density From Ideal Solution Principles—Composition Unknown

The procedure for estimating oil density outlined in the preceding section used charts for determining the apparent gas density, which required knowledge of the total fluid composition. Katz² extended the apparent density concept to apply to natural gases in general. This results in a method that can be used when solution GOR stock-tank-oil gravity, and gas gravity are known. The fluid composition is not required. The correlation for the apparent density of the dissolved gas as a function of oil and gas gravity is shown in Fig. 22.4. The gravity of the produced gas is calculated as a volume-weighted average of the gas evolved at the separator and the stock tank.

Application of Fig. 22.4 in estimating the oil density from limited data is illustrated in Example Problem 2. In this example, the fluid passed through two separators between the wellhead and the stock tank.

Example Problem 2. Calculate the density and specific volume of the oil system at the bubblepoint conditions of $p_b = 3,280$ psia at $T = 218^\circ\text{F}$. The stock-tank oil gravity

is 27.4°API and the quantities and gravities of the produced gas are given in Table 22.2.

Solution.

1. Average gas gravity, $\bar{\gamma}_g = \Sigma R_i \gamma_{gi} / \Sigma R_i$,

$$\bar{\gamma}_g = \frac{(414)(0.640) + 90(0.897) + 25(1.540)}{414 + 90 + 25} = 0.726,$$

and

$$\gamma_o = \frac{141.5}{131.5 + 27.4} = 0.89.$$

2. Molecular weight of produced gas, $M_g = \gamma_g (M_{\text{air}})$;

$$M_g = 0.726(28.97) = 21.03 \text{ lbm/mol.}$$

3. Mass of dissolved gas, m_g , is given by

$$\frac{529 \text{ scf/STB}}{379.5 \text{ scf/mol}} (21.03 \text{ lbm/mol}) = 29.32 \text{ lbm/STB.}$$

4. Mass of stock-tank oil, m_o , is given by

$$350 \text{ lbm/STB}(0.89) = 311.50 \text{ lbm/STB.}$$

Fig. 22.4 shows that the apparent liquid density of the dissolved gas is about 24.9 lbm/cu ft at 60°F and 14.7 psia. This is used to calculate the volume of the dissolved gas.

5. Volume of dissolved gas, V_g , is given by

$$\frac{m_g}{\rho_g} = \frac{29.32 \text{ lbm/STB}}{24.9 \text{ lbm/cu ft}} = 1.178 \text{ cu ft/STB.}$$

6. Volume of stock-tank oil, V_o , is given by

$$5.615 \text{ cu ft/STB.}$$

7. Pseudoliquid density, ρ_{sL}

$$\begin{aligned} &= \frac{m_o + m_g}{V_o + V_g} \\ &= \frac{311.50 \text{ lbm/STB} + 29.32 \text{ lbm/STB}}{5.615 \text{ cu ft/STB} + 1.178 \text{ cu ft/STB}} \\ &= 50.17 \text{ lbm/cu ft.} \end{aligned}$$

TABLE 22.2—PRODUCED GAS CHARACTERISTICS

	R (scf/STB)	γ_g
First-stage separator	414	0.640
Second-stage separator	90	0.897
Stock tank	25	1.540
Total	529	

Correction of the density for compression and thermal expansion is accomplished with Figs. 22.2 and 22.3.

Fig. 22.2 shows that the pressure correction to 3,280 psia is 0.90 lbm/cu ft. Therefore,

$$\rho_{3280, 60} = 50.17 + 0.90 = 51.07 \text{ lbm/cu ft.}$$

Fig. 22.3 shows that the temperature correction to 218°F is -3.63 lbm/cu ft. Therefore,

$$\rho_{3280, 218} = 51.07 - 3.63 = 47.44 \text{ lbm/cu ft.}$$

The specific volume of the oil is defined as the reciprocal of the density. Therefore,

$$V_o = \frac{1}{\rho_o} = \frac{1}{47.44} = 0.021 \text{ cu ft/lbm.}$$

Bubblepoint-Pressure Correlations

Reservoir performance calculations require that the reservoir bubblepoint pressure be known. This is determined from a PVT analysis of a reservoir fluid sample or calculated by flash calculation procedures if the composition of the reservoir fluid is known. However, since this information is frequently unavailable, empirical correlations for estimating p_b from limited data were developed. These correlations may be used to estimate bubblepoint or saturation pressure as a function of reservoir temperature, stock-tank oil gravity, dissolved-gas gravity, and solution GOR at initial reservoir pressure. That is,

$$p_b = f(T_R, \gamma_{API}, \gamma_g, R_{sb}).$$

A value for $R_{sb} = R_{si}$ can be obtained from the initial solution GOR (produced) if the reservoir pressure is above p_b , where R_{sb} is the solution GOR at bubblepoint pressure and R_{si} is the solution GOR at initial reservoir pressure.

Three methods for estimating bubblepoint pressure are presented. The correlations were developed by use of experimentally measured bubblepoint pressures obtained from PVT analyses on reservoir fluid samples. Other correlations were developed for application in specific reservoirs, but the methods presented here gave good results over a wide range of oil systems.

Standing Correlations

Standing³ presented an equation and nomograph to estimate bubblepoint pressures greater than 1,000 psia. The correlation was based on 105 experimentally determined bubblepoint pressures of California oil systems. The average error of the correlation when applied to the data used to develop the method was 4.8% and 106 psi. The ranges of data used to develop the method are given in Table 22.3.

The gases evolved from the systems used to develop the correlation contained essentially no nitrogen or hydrogen sulfide. Some of the gases contained CO₂, but in quantities less than 1 mol%. No attempt was made to

characterize the tank oils other than by the API gravity. The value for gas gravity to be used is apparently the volume-weighted average of the gas from all stages of separation. The correlation should apply to other oil systems as long as the compositional makeup of the gases and crudes is similar to those used in developing the method.

The equation for estimating bubblepoint pressure is

$$p_b = 18 \left(\frac{R_{sb}}{\gamma_g} \right)^{0.83} \times 10^{\gamma_g}, \dots \dots \dots (5)$$

where

- y_g = mole fraction gas,
- = $0.00091(T_R) - 0.0125\gamma_{API}$,
- p_b = bubblepoint pressure, psia,
- R_{sb} = solution GOR at $p \geq p_b$, scf/STB,
- γ_g = gas gravity (air=1.0),
- T_R = reservoir temperature, °F, and
- γ_{API} = stock-tank oil gravity, °API.

A nomograph developed from Eq. 5 is shown in Fig. 22.5. The example bubblepoint determination shown in the nomograph is calculated with Eq. 5 in the following example.

Example Problem 3. Estimate p_b where $R_{sb} = 350$ scf/STB, $T_R = 200^\circ\text{F}$, $\gamma_g = 0.75$, and $\gamma_{API} = 30^\circ\text{API}$.

Solution.

$$y_g = 0.00091(200) - 0.0125(30) = -0.193.$$

$$p_b = 18 \left(\frac{350}{0.75} \right)^{0.83} \times 10^{-0.193}.$$

$$p_b = 1,895 \text{ psia.}$$

Lasater Correlation

A correlation by Lasater⁴ was developed in 1958 from 158 experimental data points, which included the ranges of variables shown in Table 22.4.

The correlation was presented graphically in the form of two charts. Equations were fitted to these graphical correlations to enhance the use of this method with computers or calculators. The graphical correlations are shown in Figs. 22.6 and 22.7.

The following procedure is used to estimate p_b using Figs. 22.6 and 22.7.

TABLE 22.3—DATA PARAMETERS AND RANGES

p_b , psia	130 to 7,000
T_R , °F	100 to 258
R_{sb} , scf/STB	20 to 1,425
γ_{API} , °API	16.5 to 63.8
γ_g (air = 1.0)	0.59 to 0.95

Fig. 22.5—Chart for calculating bubblepoint pressure by Standing's correlation.

1. Find the effective molecular weight of the stock-tank oil from the API gravity using Fig. 22.6.

2. Calculate the mol fraction of gas in the system from

$$y_g = \frac{R_{sb}/379.3}{R_{sb}/379.3 + 350\gamma_o/M_o} \quad (6)$$

3. Find the bubblepoint pressure factor, $p_b\gamma_g/T_R$, from Fig. 22.7

4. Calculate the bubblepoint pressure $p_b = [(p_b\gamma_g)/T] \cdot T_R/\gamma_g$ where T_R is in °R.

The following equations can be used to replace Figs. 22.6 and 22.7.

Equations for Fig. 22.6

For $\text{API} \leq 40$:

$$M_o = 630 - 10\gamma_{\text{API}} \quad (7)$$

For $\text{API} > 40$:

$$M_o = 73,110 (\gamma_{\text{API}})^{-1.562} \quad (8)$$

Equations for Fig. 22.7

For $y_g \leq 0.60$:

$$\frac{p_b\gamma_g}{T_R} = 0.679 \exp(2.786y_g) - 0.323 \quad (9)$$

TABLE 22.4—VARIABLE RANGES

p_b , psia	48 to 5,780
T_R , °F	82 to 272
γ_{API} , °API	17.9 to 51.1
γ_g	0.574 to 1.223
R_{sb} , scf/STB	3 to 2,905

For $y_g > 0.60$:

$$\frac{p_b\gamma_g}{T_R} = 8.26y_g^{3.56} + 1.95 \quad (10)$$

A nomograph that combines Figs. 22.6 and 22.7 is presented in Fig. 22.8. The example given in Fig. 22.8 is worked with the equations in the following example.

Example Problem 4. Given the following data, use the Lasater method to estimate p_b .

$R_{sb} = 500$ scf/STB, $T_R = 200^\circ\text{F} = 660^\circ\text{R}$, $\gamma_g = 0.80$, $\gamma_{\text{API}} = 30$, and $\gamma_o = 0.876$.

Solution.

$$M_o = 630 - 10(30) = 330.$$

Fig. 22.6—Effective molecular weight related to tank-oil gravity.

$$y_g = \frac{500/379.3}{500/379.3 + 350(0.876)/330} = 0.587.$$

$$\frac{p_b \gamma_g}{T_R} = 0.679 \exp[2.786(0.587)] - 0.323;$$

$$\frac{p_b \gamma_g}{T_R} = 3.161.$$

$$p_b = \frac{3.161(660)}{0.80} = 2,608 \text{ psia.}$$

Vasquez and Beggs Correlation

Vasquez and Beggs⁵ used results from more than 600 oil systems to develop empirical correlations for several oil properties including bubblepoint pressure. The data encompassed very wide ranges of pressure, temperature, oil gravity, and gas gravity and included approximately 6,000 measured data points for R_s , B_o and μ_o at various pressures and temperatures. The ranges of the pertinent parameters are given in Table 22.5.

It was found that the gas gravity was a strong correlating parameter and, unfortunately, usually is one of the variables of most questionable accuracy. The gravity of the evolved gas depends on the pressure and temperature of the separators, which may not be known in many cases. The gas gravity used to develop all the correlations reported by Vasquez and Beggs was that which would result from a two-stage separation. The first-stage pressure was chosen as 100 psig and the second stage was the stock tank. If the known gas gravity resulted from a first-stage separation at a pressure other than 100 psig, the corrected gas gravity to be used in the correlations can be obtained from Eq. 11. If separator conditions are unknown,

Fig. 22.7—Lasater's correlation of bubblepoint-pressure factor with gas-mole fraction.

the uncorrected gas gravity may be used in the correlations for p_b , R_s , B_o , and c_o .

$$\gamma_{gc} = \gamma_g [1.0 + 5.912 \times 10^{-5} \gamma_{API} T_s \log(p_s/114.7)], \quad (11)$$

where

γ_{gc} = corrected gas gravity,

γ_g = gas gravity resulting from a separation at p_s , T_s

T_s = separator temperature, °F,

p_s = separator pressure, psia, and

γ_{API} = oil gravity, °API.

Fig. 22.8—Chart for calculating bubblepoint pressure by Lasater's correlation.

The correlations are presented in equation form only. The bubblepoint pressure is calculated from

$$p_b = \left\{ \frac{R_{sb}}{C_1 \gamma_g \exp[C_3 \gamma_{API}/(T_R + 460)]} \right\}^{1/C_2}, \quad (12)$$

where

- p_b = bubblepoint pressure, psia,
- R_{sb} = solution GOR at p_b , scf/STB,
- γ_g = gas gravity,
- γ_{API} = oil gravity, °API, and
- T_R = temperature, °F.

The accuracy of the correlation was greater if the samples were divided into ranges of oil API gravity. A dividing point of 30°API was chosen. The values of the constants in Eq. 12 depend on API gravity of the stock-tank oil and are given in Table 22.6.

TABLE 22.5—VARIABLE RANGES

p_b , psia	50 to 5,250
T_R , °F	70 to 295
R_{sb} , scf/STB	20 to 2,070
γ_{API} , °API	16 to 58
γ_g	0.56 to 1.18

Example Problem 5. Calculate the bubblepoint pressure for the oil system given in Example Problem 4 using the Vasquez and Beggs correlation and the following data. Use the uncorrected gas gravity. R_{sb} = 500 scf/STB, T_R = 220°F, γ_g = 0.80, and γ_{API} = 30°API.

Solution.

Eq. 12 and the correct C values from Table 22.1 give:

$$p_b = \left[\frac{500}{0.0362(0.80) \exp[25.724(30)/680]} \right]^{1/1.0937};$$

$$p_b = 2,562 \text{ psia.}$$

This compares well with the value of 2,608 obtained in Example Problem 4 with Lasater's correlation. With Standing's Eq. 5, a value of 2,415 psia is obtained.

Accuracy of Bubblepoint Correlations

Comparison of the accuracy with which the measured bubblepoint pressures used in each correlation agreed with

TABLE 22.6—CONSTANTS FOR BUBBLEPOINT EQUATION

	°API ≤ 30	°API > 30
C_1	0.0362	0.0178
C_2	1.0937	1.1870
C_3	25.7240	23.9310

TABLE 22.7—COMPARISON OF ACCURACY OF BUBBLEPOINT-PRESSURE CORRELATIONS

	Standing	Lasater	Vasquez-Beggs
Number of points in correlations	105	158	5,008
Data points within 10% of correlation, %	87	87	85
Data points more than 200 psi in error, %	27		
Mean error, %	4.8	3.8	-0.7

values determined from the final correlation shows that the Vasquez and Beggs correlation is the most accurate, followed by Lasater's and then by Standing's. This is shown in Table 22.7.

Solution GOR for Saturated Oils

Both reservoir engineering and production engineering calculations require estimates of the amount of dissolved gas remaining in solution at oil system pressures below bubblepoint pressure. The amount of free gas—that is, the gas that has evolved from 1 STB oil as the pressure is reduced below p_b —is $R_{sb} - R_s$, where R_s is the gas remaining in solution at the pressure of interest. In effect, any pressure below the original bubblepoint pressure is also a bubblepoint pressure, since the oil is saturated with gas at this pressure. Therefore, the correlations presented in the previous section can be solved for solution GOR and a value of R_s can be obtained at any pressure less than the reservoir p_b . That is, $R_s = f(p, T, \gamma_{API}, \gamma_g)$.

The nomographs presented in Figs. 22.5 and 22.8 can be used to determine R_s by entering the bubblepoint axis at the pressure of interest and proceeding "backward" through the graph to determine R_s .

Standing Correlation

$$R_s = \gamma_g \left(\frac{p}{18 \times 10^{\gamma_g}} \right)^{1.204}, \quad (13)$$

where

$$\begin{aligned} \gamma_g &= 0.00091(T) - 0.0125(\gamma_{API}), \\ R_s &= \text{solution GOR, scf/STB,} \\ p &= \text{pressure, psia,} \\ \gamma_g &= \text{gas gravity,} \\ \gamma_{API} &= \text{oil gravity, } ^\circ\text{API, and} \\ T &= \text{temperature of interest, } ^\circ\text{F.} \end{aligned}$$

Lasater Correlation

$$R_s = \frac{132755 \gamma_o \gamma_g}{M_o (1 - \gamma_g)}, \quad (14)$$

where M_o is obtained from Eq. 7 or 8 and γ_g is calculated by either Eq. 9 or 10, depending on whether the value of the pressure factor is less than or greater than 3.29.

$$\text{For } \frac{p\gamma_g}{T} < 3.29:$$

$$\gamma_g = 0.359 \ln \left(\frac{1.473 p \gamma_g}{T} + 0.476 \right), \quad (15)$$

$$\text{For } \frac{p\gamma_g}{T} \geq 3.29:$$

$$\gamma_g = \left(\frac{0.121 p \gamma_g}{T} - 0.236 \right)^{0.281}, \quad (16)$$

where T is in $^\circ\text{R}$.

Vasquez and Beggs Correlation

$$R_s = C_1 \gamma_g p^{C_2} \exp \left(\frac{C_3 \gamma_{API}}{T + 460} \right), \quad (17)$$

where

$$\begin{aligned} R_s &= \text{gas in solution at } p \text{ and } T, \text{ scf/STB,} \\ \gamma_g &= \text{gas gravity,} \\ p &= \text{pressure of interest, psia,} \\ \gamma_{API} &= \text{stock-tank oil gravity, } ^\circ\text{API} \\ T &= \text{temperature of interest, } ^\circ\text{F, and} \\ C_1, C_2, C_3 &= \text{are obtained from Table 22.6.} \end{aligned}$$

Example Problem 6. Estimate the solution GOR of the following oil system using the correlations of Standing, Lasater, and Vasquez and Beggs and the data: $p = 765$ psia, $T = 137^\circ\text{F}$, $\gamma_{API} = 22^\circ\text{API}$, and $\gamma_g = 0.65$.

Standing

$$\gamma_g = 0.00091(137) - 0.0125(22) = -0.15.$$

$$R_s = 0.65 \left[\frac{765}{18 \times 10^{-0.15}} \right]^{1.204} = 90 \text{ scf/STB.}$$

Lasater

$$\frac{p\gamma_g}{T} = \frac{765(0.65)}{137 + 460} = 0.833.$$

$$\gamma_g = 0.359 \ln[1.473(0.833) + 0.476] = 0.191 \text{ (Eq. 15).}$$

$$M_o = 630 - 10(22) = 410 \text{ (Eq. 7).}$$

$$\gamma_o = \frac{141.5}{131.5 + 22} = 0.922.$$

$$R_s = \frac{132755(0.922)(0.191)}{410(1 - 0.191)} = 70 \text{ scf/STB (Eq. 14).}$$

If γ_g is read from Fig. 22.7 rather than calculated from Eq. 15, a value of approximately 0.25 is obtained. This gives a value of $R_s = 100$ scf/STB. In this example, the graphical value is closer to those calculated from the other two correlations. The accuracy of the Lasater equation is much better at higher R_s values.

Vasquez and Beggs

$$R_s = 0.0362(0.65)(765)^{1.0937} \exp \left[\frac{25.724(22)}{137 + 460} \right];$$

$$R_s = 87 \text{ scf/STB.}$$

Oil FVF Correlations

The oil FVF is required for both reservoir and production system calculations. The reservoir engineer must be able to relate stock-tank volumes to reservoir volumes at various pressures and a constant reservoir temperature. Production engineering involves converting surface-measured volumetric flow rates to in-situ flow rates at various pressures and changing temperatures as the fluid is produced to the surface.

As defined previously, the oil FVF is the volume that would be occupied at some pressure and temperature by 1 STB oil plus any gas dissolved in the oil at these pressure and temperature conditions. It is a function of the composition of the system and the conditions under which the gas and liquid are separated.

Values of oil FVF at reservoir temperature and various pressures can be obtained from a standard PVT analysis of a reservoir fluid sample. However, this type of analysis is often unavailable and the engineer must then resort to empirical correlations that require only limited data. Two empirical correlations for saturated oil systems will be presented in this section. Both require values for solution GOR, R_s , which can be obtained by the methods presented in the previous section.

At pressures above the bubblepoint, the oil is undersaturated and the liquid expands as pressure is reduced. Calculation of oil FVF thus requires a value for oil compressibility. Two correlations for estimating the compressibility of an undersaturated oil system will be presented.

Saturated Systems

If an oil system is saturated with gas at given conditions of pressure and temperature, a reduction in pressure will allow solution gas to evolve, thus causing the oil to shrink. The liquid volume is also affected by temperature. Solution gas increases as temperature is decreased, but the liquid volume decreases as the oil is cooled. The correlations presented in this section can be expressed as

$$B_o = f(R_s, \gamma_{API}, \gamma_g, T).$$

Standing Correlation. Standing⁴ used the same oil systems described in the bubblepoint correlation section to develop a correlation for B_o at pressures less than p_b . The method was presented in both equation and nomograph form. In equation form,

$$B_o = 0.972 + 0.000147F^{1.175}, \dots \dots \dots (18)$$

where F is a correlating function and is determined from the equation

$$F = R_s(\gamma_g/\gamma_o)^{0.5} + 1.25T,$$

B_o = oil FVF, bbl/STB,
 R_s = solution GOR, scf/STB,
 γ_g = gas gravity,
 γ_o = oil specific gravity = $141.5/(131.5 + \gamma_{API})$,
 and
 T = temperature of interest, °F.

A nomograph that solves Eq. 18 graphically is presented in Fig. 22.9.

Example Problem 7. Use both Standing's equation and nomograph to estimate the oil FVF for the oil system described by the data $T = 200^\circ\text{F}$, $R_s = 350$ scf/STB, $\gamma_g = 0.75$, and $\gamma_{API} = 30^\circ\text{API}$.

Solution.

$$\begin{aligned} \gamma_o &= 141.5/(131.5 + 30) = 0.876. \\ F &= 350(0.75/0.876)^{0.5} + 1.25(200) = 574. \\ B_o &= 0.972 + 0.000147(574)^{1.175}; \\ B_o &= 1.228 \text{ bbl/STB.} \end{aligned}$$

A value of 1.22 bbl/STB is obtained from the nomograph, Fig. 22.9.

Vasquez and Beggs Correlation. In conjunction with development of the bubblepoint and solution GOR correlations, Vasquez and Beggs⁵ also presented an equation for oil FVF for saturated oils. To improve the accuracy of the correlation, the 600 oil systems were divided into two groups, those having API gravities ≤ 30 and those having gravities > 30 . The gas gravity used in the equation should be the corrected gravity calculated by Eq. 11 if the separator pressure is known. If separator conditions are unknown, the uncorrected gas gravity may be used. The equation is

$$B_o = 1 + C_1 R_s + C_2 (T - 60)(\gamma_{API}/\gamma_{gc}) + C_3 R_s (T - 60)(\gamma_{API}/\gamma_{gc}), \dots \dots \dots (19)$$

where

$$\begin{aligned} B_o &= \text{oil FVF at } p \text{ and } T, \text{ bbl/STB} \\ R_s &= \text{solution GOR at } p, T, \text{ scf/STB} \\ T &= \text{temperature of interest, } ^\circ\text{F} \\ p &= \text{pressure of interest, psia} \\ \gamma_{API} &= \text{stock-tank oil gravity, } ^\circ\text{API, and} \\ \gamma_{gc} &= \text{gas gravity, corrected, air} = 1. \end{aligned}$$

The constants are determined from Table 22.8.

Fig. 22.9—Chart for calculating oil-formation volume by Standing's correlation.

Example Problem 8. Use the Vasquez and Beggs equation to determine the oil FVF at bubblepoint pressure for the oil system described by $p_b = 2,652$ psia, $R_{sb} = 500$ scf/STB, $\gamma_{gc} = 0.80$, $\gamma_{API} = 30^\circ$ API, and $T = 220^\circ$ F.

Solution.

$$B_{ob} = 1 + 4.677 \times 10^{-4} (500) + 1.751 \times 10^{-5} (160) \cdot (30/0.80) - 1.811 \times 10^{-8} (500)(160) \cdot (30/0.80).$$

$$B_{ob} = 1.285 \text{ bbl/STB.}$$

Undersaturated Systems

The oil FVF decreases with pressure increase at pressures above the bubblepoint. In this case, B_o is calculated from

$$B_o = B_{ob} \exp[c_o(p_b - p)], \quad (20)$$

where

- B_{ob} = oil FVF at p_b ,
- p_b = bubblepoint pressure, psia,
- p = pressure of interest, psia, and
- c_o = oil isothermal compressibility, psi^{-1} .

Values for B_{ob} can be calculated with the Standing or Vasquez and Beggs correlation. The oil compressibility can be determined from a PVT analysis or estimated from empirical correlations. Two correlations for c_o will be presented.

TABLE 22.8—CONSTANTS FOR OIL FVF

	$^\circ\text{API} \leq 30$	$^\circ\text{API} > 30$
C_1	4.677×10^{-4}	4.670×10^{-4}
C_2	1.751×10^{-5}	1.100×10^{-5}
C_3	-1.811×10^{-8}	1.337×10^{-9}

Oil Isothermal Compressibility—Trube Method. The Trube method⁶ makes use of the following relationships.

$$c_{pr} = c_o p_{pc},$$

$$p_{pr} = \frac{p}{p_{pc}},$$

and

$$T_{pr} = \frac{T}{T_{pc}},$$

where

- c_{pr} = pseudoreduced compressibility,
- c_o = oil isothermal compressibility,
- p_{pc} = pseudocritical pressure,
- T_{pc} = pseudocritical temperature.

Fig. 22.10—Variation of pseudocritical temperature of reservoir oils with 60°F bubblepoint pressure; Trube's correlation.

p_{pr} = pseudoreduced pressure,
 T_{pr} = pseudoreduced temperature,
 p = pressure of interest, and
 T = temperature of interest.

The pseudoreduced compressibility is a function of p_{pr} and T_{pr} . Once c_{pr} is obtained, c_o is calculated from

$$c_o = c_{pr}/p_{pc} \quad (21)$$

Three graphs are required to obtain the necessary parameters to calculate c_o . The pseudocritical temperature T_{pc} is obtained from Fig. 22.10 as a function of the specific gravity of the undersaturated liquid at the bubblepoint pressure and 60°F. It also depends on the bubblepoint pressure of the oil at 60°F. Values for these parameters may be estimated using the correlations for density and bubblepoint pressure presented previously.

A value for p_{pc} is obtained from Fig. 22.11 using the liquid specific gravity at 60°F and the value of T_{pc} obtained from Fig. 22.10. Once p_{pc} and T_{pc} are known, p_{pr} and T_{pr} at the pressure and temperature of interest can be calculated. A value of c_{pr} is obtained from Fig. 22.12 using p_{pr} and T_{pr} . Then c_o is calculated by Eq. 21.

Application of the Trube method using a computer or calculator would require digitization of Figs. 22.10, 22.11, and 22.12.

Because of its complexity, no example will be given illustrating the application of this method. An example problem may be found in Ref. 6.

Oil Isothermal Compressibility—Vasquez and Beggs Method. Vasquez and Beggs⁵ used approximately 2,000 experimentally measured values of c_o from more than 600 oil systems to develop a correlation for c_o as a function of R_{sb} , T , γ_g , γ_{API} , and p . This method is much simpler to use than the Trube method and is more accurate

Fig. 22.11—Pseudocritical pressure variation with pseudocritical temperature and 60°F specific gravity of reservoir oil; Trube's correlation.

when used to predict the 2,000 measured values of c_o from which the correlation was developed. No comparison of the two methods is available using independent data. The equation for c_o is

$$c_o = \frac{5R_{sb} + 17.2T - 1,180\gamma_g + 12.61\gamma_{API} - 1,433}{p \times 10^5} \quad (22)$$

where

c_o = oil isothermal compressibility, psi^{-1}
 R_{sb} = solution GOR, scf/STB
 T = temperature of interest, °F
 p = pressure of interest, psia
 γ_g = gas gravity, and
 γ_{API} = stock-tank oil gravity, °API.

Example Problem 9. Calculate the oil FVF for the oil system described in Example Problem 8 at a pressure of 3,000 psia. Use Eq. 22 to determine a value for c_o where $p_b = 2,652$ psia, $R_{sb} = 500$ scf/STB, $\gamma_g = 0.80$, $\gamma_{API} = 30^\circ\text{API}$, $T = 220^\circ\text{F}$, and $B_{ob} = 1.285$ bbl/STB.

Solution.

$c_o =$

$$\frac{5(500) + 17.2(220) - 1,180(0.80) + 12.61(30) - 1,433}{3,000 \times 10^5};$$

$$c_o = 1.43 \times 10^{-5} \text{ psi}^{-1}.$$

With Eq. 20,

$$B_o = 1.285 \exp[1.43 \times 10^{-5}(2,652 - 3,000)];$$

$$B_o = 1.285(0.995) = 1.279 \text{ bbl/STB.}$$

Total FVF's

When material-balance calculations are made for reservoir engineering, it is often convenient to calculate the volume at reservoir conditions that is occupied by all the material associated with a stock-tank barrel of oil—i.e., the volume of the saturated oil and the volume of the evolved or liberated gas. This can be expressed as a total FVF, B_t .

The total FVF can be calculated if B_o and the amount of liberated gas is known. That is, B_t equals volume of oil plus dissolved gas/STB plus volume of liberated gas/STB.

In equation form,

$$B_t = B_o + B_g(R_{sb} - R_s), \dots\dots\dots(23)$$

where

B_t = total FVF, bbl/STB,

B_o = oil FVF, bbl/STB,

R_{sb} = solution GOR at p_b , scf/STB,

R_s = solution GOR at pressure of interest, scf/STB, and

B_g = gas FVF at pressure and temperature of interest, bbl/scf.

The gas FVF requires a value for the gas compressibility or z_g factor that may be obtained from Chap. 17.

$$B_g = \frac{0.00504 z_g T}{p}, \dots\dots\dots(24)$$

where

B_g = gas FVF, bbl/scf,

z_g = gas compressibility factor at p , T ,

p = pressure of interest, psia, and

T = temperature of interest, °R.

A nomograph for estimating total FVF was presented by Standing.³ The correlation was developed from 387 experimental data points that included the ranges given in Table 22.9.

The nomograph, on which an example calculation is worked, is shown in Fig. 22.13.

Oil Viscosity Correlations

The absolute viscosity of a fluid is a measure of the fluid's resistance to flow. The resistance to flow is caused by internal friction generated when the fluid molecules are sheared. The viscosity can be quantified as the ratio of the shearing stress required to induce a particular rate of shear in the fluid at specific conditions of pressure and temperature. The absolute viscosity of a Newtonian fluid is independent of the rate of shear. Only Newtonian fluids are considered in this section.

Fig. 22.12—Variation of pseudoreduced compressibility with pseudoreduced pressure and temperature.

Values of oil viscosity are required at various pressures and temperatures for both reservoir and production engineering calculations. If a PVT analysis is available, measured values of oil viscosity will be reported at reservoir temperature and at various pressures. However, as the fluid flows through the production system, the temperature also changes. This necessitates correcting the viscosity for temperature changes, which is usually accomplished by empirical correlations.

The absolute viscosity, which is usually referred to merely as the viscosity, can be expressed in various units. The so-called "oilfield unit" is the centipoise or poise. A relationship among various systems of units is given as 1 cp = 0.01 poise = 0.001 Pa·s = 6.72×10^{-4} lbm/(ft·sec).

The kinematic viscosity of a fluid is the absolute viscosity divided by the density, or

$$\nu = \frac{\mu}{\rho}$$

The most commonly used unit of kinematic viscosity is the centistoke (cSt), where the conversion to SI units is 1 cSt = 10^{-6} m²/s.

In addition to absolute and kinematic viscosity units, the units of Saybolt seconds universal (SSU) and Saybolt

TABLE 22.9—DATA RANGES FOR STANDING CORRELATION

Pressure, psia	400 to 5,000
GOR, scf/STB	75 to 37,000
Temperature, °F	100 to 258
Gas gravity	0.59 to 0.95
Oil gravity, °API	16.5 to 63.8

Fig. 22.13—Chart for calculating total formation volume by Standing's correlation.

seconds furol (SSF) are commonly used. An approximate conversion between centistokes and the time units can be made with the following equations.

$$\nu = 0.220t_{SU} - 180/t_{SU},$$

and

$$\nu = 2.12t_{SF} - 139/t_{SF}, \quad (25)$$

where

- ν = kinematic viscosity in cSt,
- t_{SU} = Saybolt seconds universal, and
- t_{SF} = Saybolt seconds furol.

Factors Affecting Oil Viscosity

The principal factors of interest to the petroleum engineer that affect viscosity are composition, temperature, dissolved gas, and pressure. Oil viscosity increases with a decrease in API gravity and also increases with a decrease in temperature.

The effect of dissolved gas is to lighten the oil and thus decrease its viscosity, while an increase in pressure on an undersaturated oil compresses the oil and causes the viscosity to increase.

Oil Viscosity Correlations—Saturated Systems

The most common method for obtaining the viscosity of a crude oil that contains dissolved gas is first to estimate the viscosity of the gas-free or dead oil and then to cor-

rect this value for dissolved gas. The dead-oil viscosity depends on API gravity of the stock-tank oil and the temperature of interest.

The dead-oil viscosity can be obtained from empirical correlations or, if measured values are available at two temperatures, the viscosity at any other temperature can be calculated from the equation

$$\log[\log(\nu + 0.8)] = A + B \log T, \quad (26)$$

where

- ν = kinematic viscosity at T ,
- T = temperature of interest, and
- A, B = constants for a particular oil that can be determined if two measured values of ν and T are available.

Beal's Correlation for Dead Oils. Beal⁷ presented a graphical correlation showing the effects of both oil gravity and temperature on dead-oil viscosity. The correlation was developed from measurements made on 655 oil samples. The relationship among viscosity, API gravity, and temperature is shown in Fig. 22.14.

Effect of Dissolved Gas—Chew and Connally Method.

The decrease in the dead-oil viscosity as gas goes into solution can be estimated with Fig. 22.15, which was published by Chew and Connally⁸ in 1959. The procedure for using the chart and an example problem are shown

Fig. 22.14—Gas-free crude viscosity as a function of reservoir temperature and stock-tank crude gravity.

in the figure. They also proposed an equation for correcting for the dissolved gas:

$$\mu_{os} = a\mu_{od}^b \quad (27)$$

where

μ_o = saturated oil viscosity,
 μ_{od} = gas-free or dead-oil viscosity, and
 a, b = functions of R_s , shown in Fig. 22.16.

Beggs and Robinson Correlation. A method for calculating both dead-oil and saturated-oil viscosity was presented by Beggs and Robinson⁹ in 1975. The correlation was developed from more than 2,000 measured data points using 600 oil systems. The range of variables of the data is given in Table 22.10.

The equation developed reproduced the measured data with an average error of -1.83% and a standard deviation of 27% .

The equation for dead-oil viscosity is

$$\mu_{od} = 10^x - 1.0, \quad (28)$$

where

$x = T^{-1.163} \exp(6.9824 - 0.04658\gamma_{API})$,
 μ_{od} = dead-oil viscosity, cp,
 T = temperature of interest, °F, and
 γ_{API} = stock-tank oil gravity, °API.

To correct for the effect of dissolved gas, an equation similar to Eq. 27 was developed.

$$\mu_{os} = A\mu_{od}^B, \quad (29)$$

Fig. 22.15—Viscosity and gas-saturated crude oils at reservoir temperature and pressure; Chew and Connally's correlation.

where

μ_{os} = saturated-oil viscosity

μ_{od} = dead-oil viscosity,

A, B = functions of R_s ,

$$A = 10.715(R_s + 100)^{-0.515}, \quad (30)$$

and

$$B = 5.44(R_s + 150)^{-0.338}, \quad (31)$$

where R_s is the solution GOR in scf/STB. No graphs are required to apply this method.

Example Problem 10. Calculate the viscosity of the saturated oil system described next using the Beal and Chew and Connally correlations and the Beggs and Robinson correlation where $T = 137^\circ\text{F}$, $\gamma_{API} = 22^\circ\text{API}$, and $R_s = 90$ scf/STB.

Solution—Beal with Chew and Connally. From Fig. 22.14, $\mu_{od} = 20$ cp. From Fig. 22.16, $a = 0.82$ and $b = 0.9$. $\mu_{os} = 0.82(20)^{0.9} = 12.15$ cp.

Interpolation was necessary on both Figs. 22.14 and 22.16 to obtain values for μ_{od} , a , and b . Use of Fig. 22.15 to correct for R_s gives a value of approximately 12 cp for μ_o .

Solution—Beggs and Robinson.

$$x = (137)^{-1.163} \exp[6.9824 - 0.04658(22)];$$

$$x = 1.2658.$$

$$\mu_{od} = 10^{1.2658} - 1.0 = 17.44 \text{ cp.}$$

$$A = 10.715(90 + 100)^{-0.515} = 0.719.$$

$$B = 5.44(90 + 150)^{-0.338} = 0.853.$$

$$\mu_{os} = 0.719(17.44)^{0.853} = 8.24 \text{ cp.}$$

Fig. 22.16—*a* and *b* factors for use in Chew and Connally's viscosity correlation.

TABLE 22.10—BEGGS AND ROBINSON CORRELATION DATA

R_s , scf/STB	20 to 2,070
γ_{API} , °API	16 to 58
p , psig	0 to 5,250
T , °F	70 to 295

Oil Viscosity Correlations—Undersaturated Systems

The effect of increasing the pressure on an oil system above the bubblepoint is to compress the liquid and to increase the viscosity. This effect was measured by Beal and presented graphically in Fig. 22.17. The graph gives the viscosity increase in cp/1,000-psi increase in pressure above p_b as a function of the saturated or bubblepoint viscosity, μ_{ob} .

Vasquez and Beggs⁵ extended the Beggs and Robinson correlation for undersaturated oils with the equation

$$\mu_o = \mu_{ob}(p/p_b)^m, \quad (32)$$

where

- μ_o = viscosity at $p > p_b$,
- μ_{ob} = viscosity at p_b ,
- p = pressure of interest, and
- p_b = bubblepoint pressure.

The exponent m is pressure dependent and is calculated from

$$m = C_1 p^{C_2} \exp(C_3 + C_4 p), \quad (33)$$

where

- p = pressure of interest, psia,
- $C_1 = 2.6$,
- $C_2 = 1.187$,
- $C_3 = -11.513$, and
- $C_4 = -8.98 \times 10^{-5}$.

Example Problem 11. Calculate the viscosity of the oil system described at a pressure of 4,750 psia, with $T=240^\circ\text{F}$, $\gamma_{API}=31^\circ\text{API}$, $\gamma_g=0.745$, and $R_{sb}=532$ scf/STB.

Fig. 22.17—Effect of pressure on viscosity of gas-saturated crude oils; Beal's correlation.

Solution.

From Eq. 12:

$$p_b =$$

$$\left[\frac{532}{0.0178(0.745) \exp 23.931(31)/(240+460)} \right]^{1/1.187};$$

$$p_b = 3,093 \text{ psia.}$$

From Eq. 28:

$$x = (240)^{-1.163} \exp[6.9824 - 0.04658(31)];$$

$$x = 0.4336,$$

$$\mu_{ob} = 10^{0.4336} - 1.0 = 1.71 \text{ cp.}$$

From Eqs. 29, 30, and 31:

$$A = 10.715(532+100)^{-0.515} = 0.387,$$

$$B = 5.44(532+150)^{-0.338} = 0.599,$$

and

$$\mu_{ob} = 0.387(1.71)^{0.599} = 0.53 \text{ cp.}$$

From Eqs. 32 and 33:

$$m = 2.6(4,750)^{1.187} \exp[-11.513 - 4,750(8.98 \times 10^{-5})];$$

$$m = 0.393, \text{ and}$$

$$\mu_o = 0.53(4,750/3,093)^{0.393} = 0.63 \text{ cp.}$$

Gas/Oil IFT

The interfacial or surface tension existing between a liquid and gas is required for estimating capillary-pressure

forces in reservoir engineering and is a parameter in some correlations used in wellbore hydraulics calculations. The surface tension between natural gas and crude oil ranges from zero to about 35 dyne/cm. It is a function of pressure, temperature, and compositions of the phases.

The surface tension of a hydrocarbon mixture can be calculated if the composition of the mixture at the pressure and temperature of interest is known. The parachor of each component must also be known. The parachor is the molecular weight of a liquid times the fourth root of its surface tension, divided by the difference between the density of the liquid and the density of the vapor in equilibrium with it. It is essentially constant over wide ranges of temperature. An equation for estimating surface tension is

$$\sigma^{0.25} = \sum_{i=1}^C P_{\text{chi}} \left(\frac{x_i \rho_L}{M_L} + \frac{y_i \rho_v}{M_v} \right), \quad \dots \dots \dots (34)$$

where

- σ = surface tension, dyne/cm,
- P_{chi} = parachor of i th component,
- x_i = mole fraction of i th component in the liquid phase,
- y_i = mole fraction of i th component in the vapor phase,
- ρ_L = density of the liquid phase, g/cm³,
- ρ_v = density of the vapor phase, g/cm³,
- M_L = molecular weight of liquid phase,
- M_v = molecular weight of vapor phase, and
- C = number of components.

Parachors for some hydrocarbons, nitrogen, and carbon dioxide are given in Table 22.11. A correlation of the parachor with molecular weight was presented by Katz¹⁰ and is shown in Fig. 22.18.

Empirical correlations in the form of graphs were presented by Baker and Swerdloff¹¹ where surface tension is correlated with temperature, API gravity, and pressure. The correlations are shown in Figs. 22.19 and 22.20. Equations that approximate Figs. 22.19 and 22.20 are:

$$\sigma_{68} = 39 - 0.2571 \gamma_{\text{API}}, \quad \dots \dots \dots (35)$$

and

$$\sigma_{100} = 37.5 - 0.2571 \gamma_{\text{API}}, \quad \dots \dots \dots (36)$$

where

- σ_{68} = IFT at 68°F, dyne/cm,
- σ_{100} = IFT at 100°F, dyne/cm, and
- γ_{API} = gravity of stock-tank oil, °API.

It has been suggested that if the temperature is greater than 100°F, the value at 100°F should be used. Also, if $T < 68^\circ\text{F}$, use the value calculated at $T = 68^\circ\text{F}$. For intermediate temperatures, use linear interpolation between the values obtained at 68 and 100°F. That is:

$$\sigma_T = \sigma_{68} - \frac{(T - 68^\circ\text{F})(\sigma_{68} - \sigma_{100})}{32}, \quad \dots \dots \dots (37)$$

where σ_T = IFT at $68^\circ\text{F} < T < 100^\circ\text{F}$.

Fig. 22.18—Parachors for hydrocarbons. ●, n-paraffins; ○, heptanes plus; ▲, gasolines; Δ, crude oil.

TABLE 22.11—PARACHORS FOR PURE SUBSTANCES

Methane	77.0
Ethane	108.0
Propane	150.3
Isobutane	181.5
n-Butane	190.0
Isopentane	225
n-Pentane	232
n-Hexane	271
n-Heptane	311
n-Octane	352
Nitrogen (in n-heptane)	41.0
Carbon dioxide	78.0

The effect of gas going into solution as pressure is increased on the gas/oil mixture is to reduce the IFT. The dead-end oil IFT can be corrected by multiplying it by the following correction factor.

$$F_c = 1.0 - 0.024p^{0.45}, \quad \dots \dots \dots (38)$$

where p is in psia.

The IFT at any pressure is then obtained from

$$\sigma_o = F_c \sigma_T \quad (39)$$

The IFT becomes zero at miscibility pressure, and for most systems, this will be at any pressure greater than about 5,000 psia.

Most of the correlations presented in this chapter are included in a calculator program for the HP-41C. The program is available from Hewlett-Packard.¹²

Nomenclature

- a = function of R_s in Eq. 27
- A = constant in Eq. 26
- b = function of R_s in Eq. 27

T is in K ,

ρ_o is in kg/m^3 , and

μ_o is in $\text{Pa}\cdot\text{s}$.

Glossary

These are generally accepted definitions, peculiar to reservoir engineering phase-behavior work.

Apparent liquid density is the ratio of mass to volume of a gas when dissolved in a liquid. It normally is calculated for conditions of 14.7 psia and 60°F by correcting the observed density of the system to that state and subtracting the mass and volume of the liquid component of the system.

Bubblepoint of a system is the state characterized by the coexistence of a substantial amount of liquid phase and an infinitesimal amount of gas phase in equilibrium.

Compressibility factor (gas-deviation factor, supercompressibility factor) is a multiplying factor introduced into the ideal-gas law to account for the departure of true gases from ideal behavior ($pV = nzRT$; z is the compressibility factor).

Condensate (distillate) liquids are liquids formed by condensation of a vapor or gas. The term usually identifies a light-colored liquid, usually of 50°API gravity or higher, obtained from systems that exist in the gaseous phase in the reservoir.

Critical state is the term used to identify the unique condition of pressure, temperature, and composition wherein all properties of coexisting vapor and liquid become identical.

Critical temperature T_c and/or pressure p_c is the temperature or pressure at the critical state.

Dewpoint of a system is analogous to the bubblepoint in that a large volume of gas and an infinitesimal amount of liquid coexist in equilibrium.

Dewpoint pressure p_d is the gas pressure in a system at its dewpoint.

Differential-gas liberation indicates removal of a gas phase from the system as the gas forms at bubblepoint conditions. It is generally believed that the differential-gas-liberation process is the one that predominates in solution-gas-drive reservoirs during the greater part of their producing life.

Differential process is a term used primarily in PVT work to indicate that, as a system is caused to move through a bubblepoint or dewpoint and as a result forms two phases, the minor phase is removed from further contact with the major phase. Thus, during a differential process, the "system" is continuously changing in quantity and composition.

Dissolved gas (solution gas) identifies material ordinarily gaseous at atmospheric conditions but which is part of a liquid phase at elevated pressure and temperature.

Dissolved-gas drive (solution-gas drive) is a primary recovery process whereby liquid (oil) is displaced from the reservoir rock by energy of expansion of gas components originally dissolved in the liquid.

Flash gas liberation means that a gas forms from a liquid (usually on reduction of pressure) under conditions wherein the total composition of the system remains the same in time. An example of flash gas liberation occurs during the steady-state flow of oil and gas through a gas-oil separator.

Flash process is one in which the composition of the system remains constant but the proportion of gas and liquid phases that comprise the system changes as pressure or some other independent variable is changed. For example, the determination of the PV relations of a reservoir fluid sample involves a flash process.

Formation volume factor (FVF) is a means of expressing a volumetric relation of a system. The volume of fluid, at formation pressure and temperature, that results in 1 bbl stock-tank oil is, by definition, the formation volume B . If the system is in a single condensed state in the formation, the term oil-FVF B_o is used. If two phases exist, the term used is total-FVF B_t or two-phase formation volume. Oil-formation volumes normally are between 1.1 and 2.0. Total formation volumes may be as great as 200, depending on the system composition and the pressure involved. Gas-formation volume B_g refers to the volume in the reservoir (usually expressed as barrels) per 1,000 std surface cu ft of the gas. Water-formation volume B_w designates the volume in the formation occupied by 1 surface bbl water and its attendant gases. Water-formation volumes are usually in the range of 0.99 to 1.07. In all instances, the reference state is standard surface conditions of 14.7 psia and 60°F unless specified otherwise.

Gas gravity is a simple means of expressing the molecular weight of a gas. The unit of gas gravity is dry air of molecular weight 28.97. Thus, methane (molecular weight = 16.04) has a gas gravity of $16.04/28.97 = 0.55$.

Gas-oil ratio (GOR) is a loose expression of system composition. Normally, the units involved are cubic feet of gas per 1 bbl liquid, both measured at 14.7 psia and 60°F. However, in some instances, local usage calls for measuring the gas at some pressure other than 14.7 psia. Further, the barrel of liquid may refer to some pressure other than the usual stock-tank oil. The units of reservoir oil and residual oil are encountered quite often in PVT work. Lastly, several kinds of GOR are used in reser-

voir engineering, such as solution (gas solubility in oil) R_s , producing R , and cumulative R_p . Pressure and temperature of separation and the number of stages used affect the GOR number obtained for a given system.

Mole is one molecular weight unit of any substance. For example, 16.04 lbm methane is a lbm-mol. Likewise, 16.04 g methane constitute a gmol. The lbm-mole is used for petroleum engineering work. A lbm-mol of gas (perfect) occupies 379.4 cu ft at 14.7 psia and 60°F.

Phase is a portion of a system that differs in its intensive properties from adjacent portions of the system. An interface exists between phases because of this difference in properties. Systems involved in petroleum production normally occur in not more than two phases, gas and liquid. On occasion and for hydrocarbon systems of unusual composition, two liquid phases or a solid phase may occur.

Properties, Extensive and Intensive. Properties directly proportional to the amount of material making up the system are termed extensive properties. Examples are area, mass, inertia, and volume. An intensive property is one that is independent of the amount of material. Density, pressure, temperature, viscosity, and surface tension are intensive properties. Energy is the product of an intensive property and an extensive property; for example, pressure times volume is mechanical energy.

Pseudocritical and Pseudoreduced Properties (Temperature, Pressure). Properties of pure hydrocarbons are often the same when expressed in terms of their reduced properties. The same reduced-state relationships often apply to multicomponent systems if "pseudo" critical temperatures and pressures are used rather than the true criticals of the systems. Calculation of the pseudocritical values from the composition of the system varies depending on the correlation being used. The ratio of the property to the pseudocritical property is called the pseudoreduced property, e.g., pseudoreduced pressure $p_{pr} = p/p_{pc}$.

Reduced properties (temperature, pressure, volume) are the ratio of the property to the critical property; for example, the reduced pressure $p_r = p/p_c$.

Relative oil volume is analogous to formation volume except that the reference state is other than at standard surface conditions and the oil is other than stock-tank oil. For example, the term is used often on the basis of 1 bbl bubblepoint oil, or saturated oil, as the reference volume. Relative oil volumes must specify pressure, temperature, and some composition parameter, e.g., relative oil volume = 0.7 (2,520 psia, 185°F, bubblepoint oil = 1.0).

Residual oil is a term common in PVT work to identify the liquid remaining in a PVT cell at the completion of a differential process carried out at or near the reservoir temperature. By analogy, it refers also to the liquid that remains in an oil reservoir at depletion. General usage is that residual oil volumes and gravities are reported in PVT work at 60°F and 14.7 psia. Residual oil is to a dif-

ferential gas-removal process as stock-tank oil is to a flash-gas process—the end liquid product.

Saturated liquid is a liquid in equilibrium with vapor at the saturation pressure. Likewise, saturated vapor denotes equilibrium with liquid. These terms are often used synonymously with the term "bubblepoint liquid" (dewpoint vapor) at the bubblepoint (dewpoint) pressure. Note that the terms "bubblepoint" and "dewpoint" identify the special case where the minor phase is present only in an infinitesimal amount, whereas the term "saturated liquid" does not involve the relative amounts of phases present.

Shrinkage refers to the decrease in volume of a liquid phase caused by release of solution gas and/or by the thermal contraction of the liquid. Shrinkage may be expressed (1) as a percentage of the final resulting stock-tank oil or (2) as a percentage of the original volume of the liquid. Shrinkage factor is the reciprocal of FVF expressed as barrels of stock-tank oil per barrel of reservoir oil. A reservoir oil that resulted in 0.75 bbl of stock-tank oil per 1 bbl of reservoir oil would have a shrinkage of $0.25/0.75 = 33\%$ under Definition 1, a shrinkage of $0.25/1.00 = 25\%$ under Definition 2, a shrinkage factor of 0.75, and an FVF of $1.00/0.75 = 1.33$.

Solution gas-oil ratio, R_s , expresses the amount of gas in solution, or dissolved, in a liquid. The reference oil may be stock-tank oil or residual oil. On occasion, reservoir saturated oil is used as the reference.

Standard conditions (surface) are 14.7 psia and 60°F. Gas volumes may be specified on occasion at pressures slightly removed from 14.7 psia.

Stock-tank oil is the liquid that results from production of reservoir material through surface equipment that separates normally gaseous components. Stock-tank oil may be caused to vary in composition and properties by varying the conditions of gas/liquid separation. Stock-tank oil is normally reported at 60°F and 14.7 psia but may be measured under other conditions and corrected to the standard condition.

System refers to a body or to a composition of matter that represents the material under consideration. The term "system" may be defined further as a **homogeneous system** or a **heterogeneous system**. In a homogeneous system, the intensive properties vary only in a continuous manner with respect to the extent of the system. A heterogeneous system is made up of a number of homogeneous parts, and abrupt changes in the intensive properties occur at the interface between the homogeneous parts.

Undersaturated fluid (liquid or vapor) is material capable of holding additional gaseous or liquid components in solution at the specified state.

Chapter 23

Phase Diagrams

F.M. Orr Jr., New Mexico Inst. of Mining and Technology
J.J. Taber, New Mexico Inst. of Mining and Technology*

Introduction

Petroleum reservoir fluids are complex mixtures containing many hydrocarbon components that range in size from light gases such as methane, ethane, and so on to very large hydrocarbon molecules containing 40 or more carbon atoms. Nonhydrocarbon components such as nitrogen, hydrogen sulfide (H_2S), or CO_2 also may be present. Water, of course, is usually present in large quantities in all reservoirs. At a given temperature and pressure, the components distribute between whatever *solid*, *liquid*, and *vapor* phases are present. A *phase* may be defined as that portion of a system that is homogeneous, bounded by a surface, and physically separable from other phases present. *Equilibrium phase diagrams* offer convenient representations of the ranges of temperature, pressure, and composition within which various combinations of phases coexist. Phase behavior plays an important role in a variety of reservoir engineering applications ranging from pressure maintenance to separator design to enhanced oil recovery (EOR) processes. This chapter reviews the fundamentals of phase diagrams used in such applications.

Single-Component Phase Diagrams

Fig. 23.1 summarizes the phase behavior of a single component. The saturation curves shown in Fig. 23.1 indicate the temperatures and pressures at which phase changes occur. At temperatures below the *triple point*, the component forms a vapor if the pressure is below that indicated by the *sublimation curve*, and forms a solid at pressures above the curve. At pressures and temperatures lying on the sublimation curve, solid and vapor can coexist, and on the *melting curve*, solid and liquid are in equilibrium. At higher temperatures, liquid and vapor can coexist along the vaporization or *vapor-pressure curve*. If the pressure is greater than the vapor pressure, a liquid forms, if lower, a vapor. The vapor-pressure curve

terminates at the *critical point*. At temperatures above the *critical temperature*, T_c , a single phase forms over the entire range of pressures. Thus, for a single component, the critical temperature is the maximum temperature at which two phases can exist. Critical temperatures of hydrocarbons vary widely. Small hydrocarbon molecules have low critical temperatures, while those of large ones are much higher. Critical pressures generally decline as the molecular size increases. For instance, the critical temperature and pressure of methane are -117°F and 668 psia. For decane, the values are 652°F and 304 psia. (Fig. 23.9 shows additional vapor pressure curves and critical points for several other light hydrocarbon molecules.)

For many reservoir engineering applications liquid/vapor equilibrium is of greatest interest, though liquid/liquid equilibria are important in some EOR processes. Solid/liquid phase changes, such as asphaltene or paraffin precipitation, occasionally occur in petroleum production operations. Fig. 23.2 shows typical volumetric behavior of a single component in the range of temperatures and pressures near the vapor-pressure curve in Fig. 23.1. If the substance under consideration is placed in a pressure cell at constant temperature T_1 below T_c and at a low pressure (Point A, for instance), it forms a vapor phase of high volume (low density). If the volume of the sample is decreased with the temperature held constant, the pressure rises. When the pressure reaches $p_v(T_1)$, the sample begins to condense. The pressure remains constant at the vapor pressure until the sample volume is reduced from the saturated vapor volume (V_v) to that of the saturated liquid (V_L). With further reductions in volume, the pressure rises again as the liquid phase is compressed. Note that small decreases in volume give rise to large pressure increases in the liquid phase because of the low compressibility of liquids. At a temperature T_2 above the critical temperature, no phase change is observed. Instead, the sample can be

*The chapter on this topic in 1962 edition was written by Murray F. Hawkins.

Fig. 23.1—Phase behavior of a pure component.

Fig. 23.2—Volumetric behavior of a pure component in the liquid/vapor region.

compressed from high volume (low density) and low pressure to low volume (high density) and high pressure with only one phase present.

Phase Rule

The maximum number of phases that can coexist at fixed temperature and pressure is determined by the number of components present. The phase rule states that

$$F = 2 + C - P - n_C, \quad (1)$$

where F is the number of degrees of freedom, C is the number of components, P is the number of phases, and n_C is the number of constraints. For a single-component system, the maximum number of phases occurs when there are no constraints ($n_C = 0$) and there are no degrees

Fig. 23.3—Pressure-composition phase diagram for a binary mixture at a temperature below the critical temperature of both components.

of freedom ($F=0$). Thus, the maximum number of phases possible is three. Therefore, if three phases coexist in equilibrium (possible only at the triple point), the pressure and temperature are fixed. If only two phases are present for a pure component, then either the temperature or the pressure can be chosen. Once one is chosen, the other is determined. If the two phases are vapor and liquid, for example, choice of the temperature determines the pressure to be the vapor pressure at that temperature. These permitted pressure-temperature values lie on the vapor pressure curve of Fig. 23.1.

In a binary system, two phases can exist over a range of temperatures and pressures. The number of degrees of freedom is

$$F = 2 - n_C, \quad (2)$$

and hence both the temperature and pressure can be chosen, though there is no guarantee that two phases will occur at a specific choice of T and p . For multicomponent systems, the phase rule provides little guidance, since the number of phases is always far less than the maximum number that can occur. Hence, as the number of components increases, more component concentrations must be known to determine the system.

Types of Diagrams

Binary Phase Diagrams

Fig. 23.3 shows typical vapor/liquid phase behavior for a binary system at a fixed temperature below the critical temperature of both components. Such a diagram is known as a pressure-composition phase diagram. At pressures below the vapor pressure of Component 2, p_{v2} , any mixture of the two components forms a single vapor phase. At pressures between p_{v1} and p_{v2} , two phases can coexist for some compositions. For instance, at pressure p_b two phases will occur if the mole fraction of Component 1 lies between x_B and x_E . If the mixture

Fig. 23.4—Volumetric behavior of a binary mixture at constant temperature.

Fig. 23.6—Volumetric behavior of a binary mixture at a constant temperature showing retrograde vaporization.

Fig. 23.5—Pressure-composition phase diagram for a binary mixture at a temperature above the critical temperature of Component 1.

Fig. 23.7—Regions of temperature, pressure, and composition for which two phases occur in a binary liquid/vapor system.

composition is x_B , it will be all liquid, if it is x_E , all vapor. For 1 mol of mixture of overall composition, z , between x_B and x_E , the number of moles of liquid phase is

$$L = \frac{x_E - z}{x_E - x_B} \quad (3)$$

Eq. 3 is known as an inverse lever rule because it is equivalent to a statement concerning the distances along a tie line from the overall composition to the liquid and vapor compositions; $L = ZE/BE$, where ZE and BE are lengths on the tie line shown in Fig. 23.3. Thus, the amount of liquid is proportional to the distance from the overall composition to the vapor composition divided by the length of the tie line. The line connecting the compositions of phases in equilibrium is known as a tie line. In binary phase diagrams such as Fig. 23.3, the tie lines are always horizontal.

Phase diagrams such as Fig. 23.3 can be determined experimentally by placing a mixture of fixed overall composition in a high-pressure cell and measuring the pressures at which phases appear and disappear. For example, a mixture of composition x_B would show the behavior indicated qualitatively in Fig. 23.4. At a pressure less than p_d (Fig. 23.3), the mixture is a vapor. If the mixture is compressed by injecting mercury into the cell, the first liquid, which has composition x_A , appears at the dewpoint pressure, p_d . As the pressure is further increased, the volume of liquid grows as more and more of the vapor phase condenses. The last vapor, of composition x_E , disappears at the bubblepoint pressure, p_b .

If the system temperature is above the critical temperature of one of the components, the phase diagram is similar to that shown in Fig. 23.5. (See Fig. 23.13 for additional examples of this type of phase diagram.) At the higher temperature, the two-phase region no longer extends to the pure Component 1 side of

Fig. 23.8—Projection of the vapor pressure (p_{v1} and p_{v2}) curves and locus of critical points for binary mixtures. Points C_1 and C_2 are the critical points of the pure components.

Fig. 23.10—Properties of ternary diagrams.

Fig. 23.9—Vapor pressure curves for light hydrocarbons and critical loci for selected hydrocarbon pairs.

the diagram. Instead, there is a critical point, C , at which liquid and vapor phases are identical. The critical point occurs at the maximum pressure of the two-phase region. The volumetric behavior of mixtures containing less Component 1 than the critical mixture is like that shown in Fig. 23.4. Fig. 23.6 shows the volumetric behavior of mixtures containing more Component 1. Compression of mixture of composition x_2 (in Fig. 23.5) leads to the appearance of liquid phase of composition x_1 when pressure p_{D1} is reached. The volume of liquid first grows and then declines with increasing pressure. The liquid phase disappears again when pressure p_{D2} is reached. Such behavior is called "retrograde vaporization" (or "retrograde condensation" if the pressure is decreasing).

If the system temperature is exactly equal to the critical temperature of Component 1, the critical point on the binary pressure-composition phase diagram is located at a Component 1 mole fraction of 1.0. Fig. 23.7 shows the behavior of the two-phase regions as the temperature rises. As the temperature increases, the critical point moves to lower concentrations of Component 1. As the critical temperature of Component 2 is approached, the two-phase region shrinks, disappearing altogether when the critical temperature is reached. A typical locus of critical temperatures and pressures for a pair of hydrocarbons is shown in Fig. 23.8. The critical locus shown in Fig. 23.8 is the projection of the critical curve in Fig. 23.7 onto the p - T plane. Thus, each point on the critical locus represents a critical mixture of different composition, though composition information is not shown on this diagram. For temperatures between the critical temperature of Component 1 and Component 2, the critical pressure of the mixtures can be much

Fig. 23.11—Ternary phase diagram at a constant temperature and pressure for a system that forms a liquid and a vapor.

higher than the critical pressure of either component. Thus, two phases can coexist at pressures much greater than the critical pressure of either component. If the difference in molecular weight of the two components is large, the critical locus may reach very high pressures. Fig. 23.9 gives critical loci for some hydrocarbon pairs.¹

The binary phase diagrams reviewed here are those most commonly encountered. More complex phase diagrams involving liquid/liquid and liquid/liquid/vapor equilibria do occur, however, in hydrocarbon systems at very low temperatures (well outside the range of conditions encountered in reservoirs or surface separators) and in CO₂/crude oil systems at temperatures below about 50°C. For reviews of such phase behavior see Refs. 2 and 3.

Ternary Phase Diagrams

Phase behavior of mixtures containing three components is conveniently represented on a triangular diagram such as that shown in Fig. 23.10a. Such diagrams are based on the property of equilateral triangles that the sum of the perpendicular distances from any point to each side of the diagram is a constant equal to length of any of the sides. Thus, the composition of a point in the interior of the triangle is

$$x_1 = \frac{L_1}{L_T}, x_2 = \frac{L_2}{L_T}, x_3 = \frac{L_3}{L_T},$$

where

$$L_T = L_1 + L_2 + L_3. \quad (4)$$

Several other useful properties of triangular diagrams are also a consequence of this fact. For mixtures along any line parallel to a side of the diagram, the fraction of the component of the corner opposite to that side is constant

Fig. 23.12—Ternary phase diagram for the methane/butane/decane system at 160°F [71°C].

(Fig. 23.10b). In addition, mixtures lying on any line connecting a corner with the opposite side contain a constant ratio of the components at the ends of the side (Fig. 23.10c). Finally, mixtures of any two compositions, such as A and B in Fig. 23.10d, lie on a straight line connecting the two points on the ternary diagram. Compositions represented on a ternary diagram can be expressed in volume, mass, or mole fractions. For vapor/liquid equilibrium diagrams, mole fractions are most commonly used.

Typical features of a ternary phase diagram for a system that forms a liquid and a vapor at fixed temperature and pressure are shown in Fig. 23.11. Mixtures with overall compositions that lie inside the binodal curve will split into liquid and vapor. Tie lines connect compositions of liquid and vapor phases in equilibrium. Any mixture on one tie line gives the same liquid and vapor compositions. Only the amounts of liquid and vapor change as the overall composition changes from the liquid side of the binodal curve to the vapor side. If the mole fractions of component i in the liquid, vapor, and overall mixture are x_i , y_i , and z_i , the fraction of the total moles in the mixture in the liquid phase is given by

$$L = \frac{y_i - z_i}{y_i - x_i}. \quad (5)$$

Eq. 5 is another lever rule similar to that described for binary diagrams. The liquid and vapor portions of the binodal curve meet at the plait point, a critical point where the liquid and vapor phases are identical. Thus, the plait point mixture has a critical temperature and pressure equal to the conditions for which the diagram is plotted. Depending on the pressure and temperature and components, a plait point may or may not be present.

Any one ternary diagram is given for fixed temperature and pressure. As either the temperature or pressure is varied, the location of the binodal curve and

Fig. 23.13—Pressure-composition phase diagrams for methane/butane and methane/decane binary systems at 160°F [71°C].

slopes of the tie lines may change. Fig. 23.12 shows the effect of increasing pressure on ternary phase diagrams for mixtures of methane (C_1), butane (C_4), and decane (C_{10}) at 160°F.^{4,5} The sides of the ternary diagram represent a binary system, so the ternary diagram includes whatever binary tie lines exist at the temperature and pressure of the diagram. Fig. 23.13 shows the corresponding binary phase diagrams for the C_1 - C_4 and C_1 - C_{10} pairs. The C_4 - C_{10} pair is not shown because it forms two phases only below the vapor pressure of C_4 , about 120 psia at 160°F (see Fig. 23.9).

As shown in Fig. 23.12, at 1,000 psia the two-phase region is a band that stretches from the C_1 - C_{10} side of the diagram to the tie line on the C_1 - C_4 side. If the pressure is increased above 1,000 psia, the liquid composition line shifts to higher methane concentrations; methane is more soluble in both C_4 and C_{10} at the higher pressure (see Fig. 23.13). The two-phase region detaches from the C_1 - C_4 side of the diagram at the critical pressure of the C_1 - C_4 pair (about 1,800 psia). As the pressure increases above that critical pressure, the plait point moves into the interior of the diagram (Fig. 23.12, lower diagrams). With further increases in pressure, the two-phase region continues to shrink. It would disappear completely from the diagram if the pressure reached the critical pressure of the C_1 - C_{10} system at 160°F (nearly 5,200 psia).

Reservoir Fluid Systems

Real reservoir fluids contain many more than the two or three components, so phase composition data can no longer be represented with two or three coordinates. In-

Fig. 23.14—Pressure-temperature phase diagram for a mixture of fixed composition.

stead, phase diagrams, which give more limited information, are used. Fig. 23.14 shows one such diagram for a multicomponent mixture. Fig. 23.14 gives the region of temperatures and pressures at which the mixture forms two phases. The analog of Fig. 23.14 for a binary system can be obtained by taking a slice at constant mole fraction of Component 1 through the diagram in Fig. 23.7. Also given are contours of liquid volume fractions, which indicate the fraction of total sample volume occupied by the liquid phase. Fig. 23.14 does not give any compositional information, however. In general, the compositions of coexisting liquid and vapor will be different at each temperature and pressure.

At temperatures below the critical temperature (Point C), a sample of the mixture described in Fig. 23.14 splits into two phases at the bubblepoint pressure (Fig. 23.4) when the pressure is reduced from a high level. At temperatures above the critical temperature, dewpoints are observed (Fig. 23.6). In this multicomponent system, the critical temperature is no longer the maximum temperature at which two phases can exist. Instead, the critical point is the temperature and pressure at which the phase compositions and all phase properties are identical.

The bubblepoint, dewpoint, and single-phase regions shown in Fig. 23.14 are sometimes used to classify reservoirs. At temperatures above the *cricondentherm*, the maximum temperature for the formation of two phases, only one phase occurs at any pressure. For instance, if the hydrocarbon mixture of Fig. 23.14 were to occur in a reservoir at temperature T_A and pressure p_A (Point A), a decline in pressure at approximately constant temperature caused by removal of fluid from the reservoir would not cause the formation of a second phase. While the fluid in the reservoir remains a single phase, the produced gas splits into two phases as it cools and expands to surface temperature and pressure at Point A'. Thus, some condensate would be collected at the

surface even though only one phase is present in the formation. The amount of condensate collected depends on the operating conditions of the separator (or separators). The lower the temperature at a given pressure, the larger the volume of condensate collected (Fig. 23.14).

Dewpoint reservoirs are those for which the reservoir temperature lies between the critical temperature and the cricondentherm for the reservoir fluid. Production of fluid from a reservoir starting at Point B in Fig. 23.14 causes liquid to appear in the reservoir when the dewpoint pressure is reached, and as the pressure declines further, the saturation of liquid increases because of retrograde condensation. Because the saturation of liquid is low, only the vapor phase flows to producing wells. Thus, the overall composition of the fluid remaining in the reservoir changes continuously. However, the phase diagram shown in Fig. 23.14 is for the original composition only. The preferential removal of light hydrocarbon components in the vapor phase generates new hydrocarbon mixtures which have a greater fraction of the heavier hydrocarbons. Differential liberation experiments, in which a sample of the reservoir fluid initially at high pressure is expanded through a sequence of pressures, can be used to investigate the magnitude of the effect of pressure reduction on the vapor composition. At each pressure, a portion of the vapor is removed and analyzed. Such an experiment simulates what happens when condensate is left behind in the reservoir as the pressure declines. As the reservoir fluid becomes heavier, the boundary of the two-phase region in a diagram like Fig. 23.14 shifts to higher temperatures. Thus, the composition change also acts to drive the system toward higher liquid condensation. Such reservoirs are candidates for pressure maintenance by lean gas injection to limit the retrograde loss of condensate or for gas cycling to vaporize and recover some of the liquid hydrocarbons.

Bubblepoint reservoirs are those in which the temperature is less than the critical temperature of the reservoir fluid (Point D in Fig. 23.14). These reservoirs are sometimes called "undersaturated" because there is insufficient gas for a gas phase at that temperature and pressure. Isothermal pressure reduction causes the appearance of a vapor phase at the bubblepoint pressure. Because the compressibility of the liquid phase is much lower than that of a vapor, the pressure in the reservoir declines rapidly during production in the single-phase region. The appearance of the much more compressible vapor phase reduces the rate of pressure decline. The volume of vapor present in the reservoir grows rapidly with reduction of reservoir pressure below the bubblepoint. Because the vapor viscosity is much lower than the liquid viscosity, and the gas relative permeability goes up markedly with increasing gas saturation, the vapor phase flows more easily. Hence, the produced GOR climbs rapidly. Again, pressure maintenance by water drive, water injection, or gas injection can substantially improve oil recovery over the 10 to 20% recovery typical of pressure depletion in these solution-gas-drive reservoirs. As in dewpoint reservoirs, the composition of the reservoir fluid changes continuously once the two-phase region is reached.

There is, of course, no reason why initial reservoir temperatures and pressures cannot lie within the two-phase region. Oil reservoirs with gas caps and gas reser-

Fig. 23.15—Increase in °API gravity with depth: (a) Ordovician Ellenberger reservoirs in Delaware Val Verde basin; (b) Pennsylvanian Tensleep reservoirs in Wyoming.

voirs with some liquids present are common. There also can be considerable variation in the initial composition of the reservoir fluid. The discussion of single-phase, dewpoint, and bubblepoint reservoirs was based on a phase diagram for one fluid composition. Even for one fluid, all the types of behavior occur over a range of temperatures. In actual reservoir settings, the composition of the reservoir fluid correlates with depth and temperature. Deeper reservoirs usually contain lighter oils.⁶ Fig. 23.15 shows the relationships between oil gravity and depth for two basins. The higher temperatures of deeper reservoirs alter the original hydrocarbon mixtures to produce lighter hydrocarbons over geologic time.⁶ Low oil gravity, low temperature, and relatively small amounts of dissolved gas all combine to produce bubblepoint reservoirs. High oil gravity, high temperatures, and high GOR's produce dewpoint or condensate systems.

Phase Diagrams for EOR Processes

Phase behavior plays an important role in a variety of EOR processes. Such processes are designed to overcome, in one way or another, the capillary forces that act to trap oil during waterflooding. In surfactant/polymer processes, the effects of capillary forces are reduced by injection of surfactant solutions that contain molecules with oil- and water-soluble portions. Such molecules migrate to the oil/water interface and reduce the interfacial tension, thereby reducing the magnitude of the capillary forces that resist movement of trapped oil. Miscible displacement processes are designed to eliminate interfaces between the oil and the displacing phase, thereby removing the effects of capillary forces between the injected fluid and the oil. Unfortunately, fluids that are strictly miscible with oil are too expensive for general use. Instead, fluids such as methane or methane enriched with intermediate hydrocarbons, CO₂, or nitrogen are injected, and the required miscible displacing fluid is generated by mixing of the injected fluid with oil in the reservoir.

Fig. 23.16—Ternary representation of phase diagrams.

Phase diagrams typical of those used to explain the behavior of surfactant systems are shown in Fig. 23.16.⁷ In those ternary diagrams, the components shown are no longer true thermodynamic components since they are mixtures. A crude oil contains hundreds of components, and the brine and surfactant pseudocomponents may also be complex mixtures. The simplified representation, however, has obvious advantages for describing phase behavior, and it is reasonably accurate as long as each pseudocomponent has approximately the same composition in each phase. In Fig. 23.16a for instance, the “oil” pseudocomponent can appear in an oil-rich phase or in a phase containing mostly surfactant and brine. If the oil solubilized into the surfactant/brine phase is nearly the same mixture of hydrocarbons as the original “oil,” then the representation in terms of pseudocomponents is reasonable. The compositions shown in Fig. 23.16 are in volume fractions. An inverse lever rule similar to Eqs. 3 or 5 gives the relationship between the volumes of the two phases for a given overall composition, as illustrated in Fig. 23.16.

Fig. 23.16a is a phase diagram for the liquid/liquid equilibrium behavior typical of mixtures of brines of low salinity with oil. If there is no surfactant present, the oil and brine are immiscible; mixture compositions on the base of the diagram split into essentially “pure” brine in equilibrium with “pure” oil. Addition of surfactant causes some oil to be solubilized into a microemulsion rich in brine. That phase is in equilibrium with a phase containing nearly pure oil. Thus in the low-salinity brine, the surfactant partitions into the brine phase,

Fig. 23.17—Typical pressure-composition phase diagram for a binary mixture of CO_2 with a crude oil at temperatures above 120°F [49°C].

solubilizing some oil. The plait point in Fig. 23.16a lies close to the oil corner of the diagram. Because only two phases occur and the tie lines all have negative slope, such phase is often called “Type II(-).”

Phase diagrams for high-salinity brines are often similar to Fig. 23.16c. In the high-salinity systems the surfactant partitions into the oil phase and solubilizes water into an oil-external microemulsion. In this case the plait point is close to the brine apex on the ternary diagram. For intermediate salinities, the phase behavior can be more complex, as shown in Fig. 23.16b. According to the phase rule, if the temperature and pressure are set, then up to three phases can coexist for a three component system. If three phases do occur, then the compositions of the phases are fixed at a given temperature and pressure. The three-phase region on a ternary diagram is represented as a triangle (Fig. 23.16b). Any overall composition lying within the three-phase region splits into the same three phases. Only the amounts of each phase change as the overall composition varies in the three-phase region. The edges of the three-phase region are tie lines for the associated two-phase regions. Thus, there is a two-phase region adjacent to each of the sides of the three-phase triangle. In Fig. 23.16b, the two-phase region at low surfactant concentrations is too small to show on the diagram. It must be present, however, since oil and brine form only two phases in the absence of surfactant.

Fig. 23.18—Pressure composition diagram—Gas 1 system for Rangely oil: 95% CO_2 and 5% methane gas system at 160°F [71°C].

Phase behavior of CO_2 /crude oil systems is often summarized in pressure-composition (p - x) diagrams such as those shown in Fig. 23.17. Fig. 23.18 is an example of a p - x diagram for mixtures of CO_2 (containing a small amount of methane contamination) with crude oil from the Rangely field.⁸ In such diagrams, the behavior of binary mixtures of CO_2 with a particular oil is reported for a fixed temperature. Thus, the oil is represented as a single pseudocomponent on such a diagram. Such diagrams indicate bubble- and dewpoint pressures, the regions of pressure and composition for which two or more phases exist, and information about the volume fractions of the phases. However, they provide no information about the compositions of the phases in equilibrium. The reason for the absence of composition data is illustrated in Fig. 23.19,³ which gives data reported by Metcalfe and Yarborough⁹ for a ternary system of CO_2 , C_4 , and C_{10} . Binary phase data for the CO_2 - C_4 (Ref. 10) and CO_2 - C_{10} (Ref. 11) systems also are included. Fig. 23.19 shows a triangular solid within which all possible compositions (mole fractions) of CO_2 - C_4 - C_{10} mixtures for pressures between 400 and 2,000 psia are contained. The two-phase region is bounded by a surface that connects the binary phase envelope for the CO_2 - C_{10} binary pair to that on the CO_2 - C_4 side of the diagram. That surface is divided into two parts—liquid compositions and vapor compositions. Tie lines (heavy dashed lines in Fig. 23.19) connect the compositions of liquid and vapor phases in equilibrium at a fixed pressure. Thus, the ternary phase diagram for CO_2 - C_4 - C_{10} mixtures at any pressure is just a constant

Fig. 23.19—Phase behavior of CO_2 - C_4 - C_{10} mixtures at 160°F [71°C].

pressure (horizontal) slice through the triangular prism. Several such slices at different pressures are shown in Fig. 23.19. At pressures below the critical pressure of CO_2 - C_4 mixtures (1,184 psia), both CO_2 - C_{10} mixtures and CO_2 - C_4 mixtures form two phases for some range of CO_2 concentrations. At 400 and 800 psia, the two-phase region is a band across the diagram. Above the critical pressure of CO_2 - C_4 mixtures, CO_2 is miscible with C_4 , and ternary slices at higher pressures show a continuous binodal curve on which the locus of liquid compositions meets that of vapor compositions at a plait point. The locus of plait points (labeled "P" in Fig. 23.19) connects the critical points of the two binary pairs.

To see the effect of representing the phase behavior of a ternary system on a pseudobinary diagram, consider a p - x diagram for an "oil" composed of 70 mol% C_{10} and 30 mol% C_4 . At any fixed pressure, the mixtures of CO_2 and oil which would be investigated in an experiment to determine a p - x diagram lie on a straight line (the dilution line), which connects the original oil composition with the CO_2 apex. Thus, a p - x diagram for this

Fig. 23.20— p - x diagrams for mixtures of CO₂ with Wasson oil, where L₁ is Liquid Phase 1 (oil-rich phase), L₂ is Liquid Phase 2 (CO₂-rich phase), and V is the vapor phase. Dashed lines indicate constant volume fraction of L₁ phase.

system is a vertical slice through the triangular prism shown in Fig. 23.19. The saturation pressures on a p - x diagram are those at which the dilution plane intersects the surface which bounds the two-phase region. Bubble-point pressures (B) occur where the dilution plane intersects the liquid composition side of the two-phase surface, while dewpoint pressures (D) occur at the intersection with vapor compositions. Comparison of the phase envelope on the resulting p - x diagram with binary phase diagrams yields the following observations.

1. Tie lines do not, in general, lie in the dilution plane. Instead, they pierce that plane. This means that the composition of vapor in equilibrium with a bubblepoint mixture on the p - x diagram is not the same as that of the dewpoint mixture at the same pressure.

2. The critical point on the p - x diagram occurs where the locus of plait points pierces the dilution plane. It is not, in general, at the maximum saturation pressure on the p - x diagram. The maximum pressure occurs where the binodal curve is tangent to the dilution plane. The critical point on the p - x diagram can lie on either side of the maximum pressure, depending on the position of locus of plait points on the two-phase surface.

It is apparent from Fig. 23.19 that the composition of the original oil has a strong influence on the shape of the saturation pressure curve, and on the location of the critical point on the p - x diagram. If the oil had been richer in C₄, the critical pressure and maximum pressure both would have been lower. Thus, it should be anticipated that the appearance of p - x diagrams for CO₂/crude oil systems should depend on the composition of the oil.

Figs. 23.18 and 23.20 illustrate the complexity of

phase behavior observed for CO₂/crude oil systems. Fig. 23.18 gives the behavior of mixtures of CO₂ (with about 5% methane as a contaminant) with Rangely crude oil at 160°F. The oil itself has a bubblepoint pressure of about 350 psia. Mixtures containing up to about 80 mol% CO₂ (+C₁) show bubblepoints, while those containing more CO₂ show dewpoints. At the relatively high temperature of the Rangely field, only two phases, a liquid and a vapor, form. At lower temperatures, more complex phase behavior can occur. Figs. 23.20a, b and c show the behavior of mixtures of a dead oil from the Wasson field³ with CO₂. At 90°F and 105°F, the mixtures form a liquid and a vapor at low pressures and two liquid phases at high pressures and high CO₂ concentrations. They form three phases, two liquids and a vapor, for a small range of pressures at high CO₂ concentrations. The liquid/liquid and liquid/liquid/vapor behavior disappears if the temperature is high enough. At 120°F (Fig. 23.20c), the three-phase region had disappeared. For the systems studied to date, 120°F appears to be a reasonable estimate of the maximum temperature for liquid/liquid/vapor separations. For detailed discussions of such phase behavior, see Refs. 2 and 3.

Calculation of Phase Compositions

Calculations of the compositions of phases that occur for multicomponent mixtures are important for the design of surface separators and for the design of EOR processes such as high-pressure and condensing-gas drives and CO₂ floods. There are two widely used methods for such calculations— K -value correlations and equations of state (EOS's).

The use of K -values, also called "equilibrium ratios" or "equilibrium constants," is based on the behavior of mixtures of gases at relatively low pressures and temperatures. According to Raoult's law, the partial vapor pressure p'_{vi} of component i in a liquid mixture is equal to the product of the mole fraction of component i in the liquid and its pure component vapor pressure

$$p'_{vi} = x_i p_{vi} \quad (6)$$

In addition, Dalton's law states that the partial pressure of component i in the vapor is

$$p'_{vi} = y_i p_t \quad (7)$$

where y_i is the mole fraction of component i in the vapor and p_t is the total pressure. Rearrangement of Eqs. 6 and 7 gives the definition of K -value for an ideal (low pressure) system:

$$K_i = \frac{y_i}{x_i} = \frac{p_{vi}}{p_t} \quad (8)$$

Thus, for a multicomponent mixture at low pressure, the equilibrium value can be estimated from the vapor pressure, which is a function of temperature only, and the total pressure. The assumption of an ideal gas in Raoult's and Dalton's laws is reasonable only if the pressure is below about 50 to 100 psia.¹² At higher pressures, equilibrium ratios are functions of pressure, temperature, and composition. Fig. 23.21 shows a typical set of equilibrium ratios for a hydrocarbon system containing some CO₂ at 220°F.¹³ Also shown (as dashed lines) are the ideal equilibrium ratios. At high pressures, the K -values for ethane and heavier hydrocarbons pass through a minimum and appear to converge to a value of one, in this case at 4,200 psia. This observation is the basis for a widely used empirical correlation for K -values. K -value charts for a variety of convergence pressures and a recommended technique for estimating the convergence pressure are given in GPSA's *Engineering Data Book*.¹

If K -values are known or can be estimated, then amounts of liquid and vapor and phase compositions can be calculated easily. Consider 1 mol of a mixture in which the overall mole fraction of the i th component is z_i . If the mole fractions of component i in the liquid and vapor are x_i and y_i , and the fraction of the mole of mixture that is liquid is L , then a material balance gives

$$z_i = x_i L + y_i (1 - L) \quad (9)$$

Substitution of the definition of $K_i = y_i/x_i$ into Eq. 9 and rearrangement gives

$$x_i = \frac{z_i}{K_i + (1 - K_i)L} \quad (10)$$

Similarly, Eq. 9 can be solved for y_i , giving

$$y_i = \frac{K_i z_i}{K_i + (1 - K_i)L} \quad (11)$$

Fig. 23.21—Typical equilibrium ratios at 220°F [104°C] (dashed lines are the ideal ratios).

By definition, $\sum x_i = \sum y_i = 1$, so $\sum x_i - \sum y_i = 0$ which gives the nonlinear function $f(L)$:

$$f(L) = \sum_i \frac{z_i (K_i - 1)}{K_i + (1 - K_i)L} = 0 \quad (12)$$

Eq. 12 can be solved for L by application of a Newton-Raphson iteration. If L_k is the k th estimate of the solution, an improved estimate is given by

$$L_{k+1} = L_k - \frac{f(L_k)}{\left. \frac{df}{dL} \right|_{L_k}} \quad (13)$$

where

$$\frac{df}{dL} = \sum_i \frac{z_i (1 - K_i)^2}{[K_i + (1 - K_i)L]^2} \quad (14)$$

The iterative calculation is complete when $f(L)$ as given by Eq. 12 and $\Delta L = L_{k+1} - L_k$ are both smaller than some preset tolerances. Once the liquid mole fraction has been determined, the x_i and y_i are obtained from Eqs. 10 and 11.

If the mixture is at its bubblepoint pressure, then $L = 1$ and $\sum z_i = 1$, and Eq. 12 reduces to

$$\sum (z_i K_i) = 1 \quad (15)$$

Thus, if K_i 's are known as a function of pressure, then the bubblepoint pressure can be obtained as the pressure at which Eq. 15 is satisfied. Bubblepoint pressures are generally most sensitive to the K -values of the lightest components, which are the largest. If the mixture is at its dewpoint pressure, then $L = 0$, $\sum z_i = 1$, and

$$\sum \left(\frac{z_i}{K_i} \right) = 1 \quad (16)$$

Fig. 23.22—Comparison of calculated and measured phase compositions for ternary mixtures of CO₂, methane (C₁), and decane (C₁₀), at 160°F [71°C] and 1,250 psia.

Dewpoint pressures are most sensitive to the smallest K -values, those of the heavy components, which often are least accurately known. Thus, there is often more uncertainty in calculated values of dewpoint pressure. The sums of Eqs. 15 and 16 also are useful for determining whether the mixture forms one or two phases. If $\Sigma(K_i z_i) < 1$, the mixture is all liquid. If $\Sigma(z_i/K_i) < 1$, the mixture is all vapor. If both $\Sigma(K_i z_i) > 1$ and $\Sigma(z_i/K_i) > 1$, the mixture forms two phases.

In recent years, EOS's also have been used extensively for phase equilibrium calculations. Most of the widely used EOS's are refinements of the equation proposed by van der Waals:

$$p = \frac{RT}{V-b} - \frac{a}{V^2}, \quad (17)$$

where p is the pressure, R the gas constant, T the temperature, and V the molar volume. The constants a and b can be determined for a particular component from thermodynamic constraints at the critical point, which requires that

$$(\partial p / \partial V)_{T_c} = (\partial^2 p / \partial V^2)_{T_c} = 0,$$

which gives

$$a = \frac{27}{64} \frac{R^2 T_c^2}{p_c}$$

and

$$b = \frac{RT_c}{8p_c}, \quad (18)$$

where T_c is the critical temperature and p_c is the critical pressure.

van der Waals' equation reduces to the ideal gas law if the molar volume is large (low pressure). If the molar

volume is small enough to be close to the constant b , then the pressure increases rapidly as the volume is reduced. Thus, the EOS is qualitatively consistent with liquid behavior when the pressure is high.

The calculation of phase compositions is based on the fact that, at thermodynamic equilibrium, the fugacity of each component must be the same in each phase. The fugacity of a component in a phase can be calculated if the volumetric behavior of the phase is known. It can be shown¹⁴ that the fugacity of component i , f_i , in a phase is given by

$$RT \ln f_i = \int_{V_i}^{\infty} \left[\left(\frac{\partial p}{\partial n_i} \right)_{T, V_i, n_j} - \frac{RT}{V_i} \right] dV_i - RT \ln \frac{V_i}{n_i RT}, \quad (19)$$

where T is the temperature, p the pressure, V_i the total volume, n_i the number of moles of component i , and R the gas constant. If the relationship between pressure, composition, and total volume is known from an EOS, then $(\partial p / \partial n_i)_{T, V_i, n_j}$ can be obtained and the integral evaluated. A variety of EOS's have been suggested for hydrocarbon mixtures. For example, the original Redlich-Kwong equation has the form

$$p = \frac{n_i RT}{V_i - n_i b_m} - \frac{n_i^2 a_m}{T^{1/2} V_i (V_i + n b_m)}, \quad (20)$$

where $n_i = \Sigma n_i$ is the total number of moles and a_m and b_m depend on the mixture composition and the critical properties of the components as follows.

$$a_m = \frac{(\Sigma y_i A_i^{1/2})^2 R^2 T^{5/2}}{p}, \quad (21)$$

where

$$A_i = \frac{\Omega_a (p/p_{ci})}{(T/T_{ci})^{5/2}}, \quad (22)$$

and

$$\Omega_a = \frac{1}{9(2^{1/2} - 1)} \cong 0.4275. \quad (23)$$

$$b_m = \frac{(\Sigma y_i B_i) RT}{p}, \quad (24)$$

where

$$B_i = \frac{\Omega_b (p/p_{ci})}{(T/T_{ci})}, \quad (25)$$

and

$$\Omega_b = \frac{2^{1/2} - 1}{3} \cong 0.08664. \quad (26)$$

In Eqs. 21 through 26, y_i is the mole fraction of component i in the mixture, and p_{ci} and T_{ci} are the critical pressure and temperature of component i . The constants Ω_a and Ω_b arise from the thermodynamic constraints, $(\partial p/\partial V)_{T_c} = (\partial^2 p/\partial V^2)_{T_c} = 0$, at the critical point. From Eqs. 19 through 26, an expression for the fugacity of each component in a phase can be obtained. To calculate phase compositions, the following procedure is used.

1. Estimate compositions of liquid and vapor.
2. Calculate fugacities of each component in each phase.
3. If $f_{iv} = f_{iL}$ stop. Otherwise, obtain improved phase compositions and return to Step 2.

Similar calculations can be performed for liquid/liquid and even liquid/liquid/vapor systems. Because the equations for fugacities are complex and nonlinear, computer implementation of this iterative scheme to find phase compositions is required.

The Redlich-Kwong EOS given as an example here is by no means the only equation available. Many modifications to the Redlich-Kwong equation have been proposed to improve the accuracy of the predictions of phase compositions, and equations with different analytical forms are also in use. The Soave modification of the Redlich-Kwong equation and the Peng-Robinson equation are among the most widely used. Ref. 14 gives details of a variety of EOS's, and Ref. 15 is a useful collection of papers relevant to phase equilibrium calculations for hydrocarbon systems. Computer programs for such calculations are available.*

EOS's currently in use are quite accurate for mixtures of light hydrocarbons for which critical properties are known and extensive phase behavior data are available. For instance, Fig. 23.22 shows a comparison of phase compositions calculated with the Peng-Robinson EOS with measured values for mixtures of CO₂, C₁, and C₁₀ at 1,250 psia and 160°F. For this well-characterized system, the calculated values agreed well with the measured compositions. For crude oil systems, phase behavior predictions are less reliable because the characterization of heavy components is less certain. For such systems some experimental data are required to tune the EOS to represent the particular hydrocarbon system. Improvement of the predictive power of EOS's for complex hydrocarbon systems is an area of active current research.

Nomenclature

- a_m = defined by Eq. 21
- A_i = defined by Eq. 22
- b_m = defined by Eq. 24
- B_i = defined by Eq. 25
- C = critical point when liquid and vapor phases are identical
- f_{iL} = liquid fugacity of Component i
- f_{iv} = vapor fugacity of Component i
- K_i = K-value of Component i
- L = total moles of liquid-phase in mixture
- L_k = k th estimate of L by Newton-Raphson iteration
- n_C = number of constraints

- p = pressure
- p_b = bubblepoint pressure
- p_d = dewpoint pressure
- p_t = total pressure
- p_v = vapor pressure
- p_{vi} = vapor pressure of Component i in liquid mixture
- p'_{vi} = partial vapor pressure of Component i in liquid mixture
- p_{vz} = any mixture of two components which form a single vapor phase
- p_{v1} = pressure below vapor pressure of Component z which may form a single vapor phase
- p_{v2} = pressure above vapor pressure of Component z which may form a single vapor phase

Chapter 24

Properties of Produced Waters

A. Gene Collins,* U.S. DOE Bartlesville Energy Technology Center**

Introduction and History

Early U.S. settlements commonly were located close to salt licks that supplied salt to the population. Often these salt springs were contaminated with petroleum, and many of the early efforts to acquire salt by digging wells were rewarded by finding unwanted increased amounts of oil and gas associated with the saline waters. In the Appalachian Mts., many saline water springs occurred along the crests of anticlines.¹

In 1855 it was found that distillation of petroleum produced a light oil that was similar to coal oil and better than whale oil as an illuminant.² This knowledge spurred the search for saline waters that contained oil. Using the methods of the salt producers, Col. Edward Drake drilled a well on Oil Creek, near Titusville, PA, in 1859. He struck oil at a depth of 70 ft, and this first oil well produced about 35 B/D.³

The early oil producers did not realize the significance of the oil and saline waters occurring together. In fact, it was not until 1938 that the existence of interstitial water in oil reservoirs was generally recognized.⁴ Torrey⁵ was convinced as early as 1928 that dispersed interstitial water existed in oil reservoirs, but his belief was rejected by his colleagues because most of the producing wells did not produce any water upon completion. Occurrences of mixtures of oil and gas with water were recognized by Griswold and Munn,⁶ but they believed that there was a definite separation of the oil and water, and that oil, gas, and water mixtures did not occur in the sand before a well tapped the reservoir.

It was not until 1928 that the first commercial laboratory for the analysis of rock cores was established, and the first core tested was from the Bradford third sand (from the Bradford field, McKean County, PA). The

percent saturation and percent porosity of this core were plotted vs. depth to construct a graphic representation of the oil and water saturation. The soluble mineral salts that were extracted from the core led Torrey to suspect that water was indigenous to the oil-productive sand. Shortly thereafter a test well was drilled near Custer City, PA, that encountered higher than average oil saturation in the lower part of the Bradford sand. This high oil saturation resulted from the action of an unsuspected flood, the existence of which was not known when the location for the test well had been selected. The upper part of the sand was not cored. Toward the end of the cutting of the first core with a cable tool core barrel, oil began to come into the hole so fast that it was not necessary to add water for the cutting of the second section of the sand. Therefore, the lower 3 ft of the Bradford sand was cut with oil in a hole free from water. Two samples from this section were preserved in sealed containers for saturation tests, and both of them, when analyzed, had a water content of about 20%PV. This well made about 10 BOPD and no water after being shot with nitroglycerine. Thus, the evidence developed by the core analysis and the productivity test after completion provided a satisfactory indication of the existence of immobile water, indigenous to the Bradford sand oil reservoir, which was held in its pore system and could not be produced by conventional pumping methods.⁵

Fettke⁷ was the first to report the presence of water in an oil-producing sand. However, he thought that it might have been introduced by the drilling process.

Munn⁸ recognized that moving underground water might be the primary cause of migration and accumulation of oil and gas. However, this theory had little experimental data to back it until Mills⁹ conducted several laboratory experiments on the effect of moving water and gas on water/oil/gas/sand and water/oil/sand systems. Mills concluded that "the up-dip migration of

*Now with the Natl. Inst. of Petroleum and Energy Research, Bartlesville, OK.

**The author of the original chapter on this topic in the 1962 edition was J. Wade Watkins.

oil and gas under the propulsive force of their buoyancy in water, as well as the migration of oil, either up or down dip, caused by hydraulic currents, are among the primary factors influencing both the accumulation and the recovery of oil and gas." This theory was seriously questioned and completely rejected by many of his contemporaries.

Rich¹⁰ assumed that "hydraulic currents, rather than buoyancy, are effective in causing accumulation of oil or its retention." He did not believe that the hydraulic accumulation and flushing of oil required a rapid movement of water but rather that the oil was an integral constituent of the rock fluids and that it could be carried along with them whether the movement was very slow or relatively rapid.

The effect of water displacing oil during production was not recognized in the early days of the petroleum industry in Pennsylvania. Laws were passed, however, to prevent operators from injecting water into the oil reservoir sands through unplugged wells. In spite of these laws, some operators at Bradford secretly opened the well casing opposite shallow groundwater sands to start a waterflood in the oil sands. Effect of artificial waterfloods were noted in the Bradford field in 1907, and became evident about 5 years later in the nearby oil fields of New York.¹¹ Volumetric calculations of the oil-reservoir volume that were made for engineering studies of these waterflood operations proved that interstitial water was generally present in the oil sands. Garrison¹² and Schilthuis⁴ gave detailed information concerning the distribution of water and oil in porous rocks, and of the origin and occurrence of "connate" water with information concerning the relationship of water saturation to formation permeability.

The word "connate" was first used by Lane and Gordon¹³ to mean interstitial water that was deposited with the sediments. The processes of rock compaction and mineral diagenesis result in the expulsion of large amounts of water from sediments and movement out of the deposit through the more permeable rocks. It is therefore highly unlikely that the water now in any pore is the same as that which was there when the particles that surround it were deposited. White¹⁴ redefined connate water as "fossil" water because it has been out of contact with the atmosphere for an appreciable part of a geologic time period. Thus, connate water is distinguished from "meteoric" water, which has entered the rocks in geologically recent times, and from "juvenile" water, which has come from deep in the earth's crust and has never been in contact with the atmosphere.

Meanwhile, petroleum engineers and geologists had learned that waters associated with petroleum could be identified with regard to the reservoir in which they occurred by a knowledge of their chemical characteristics. Commonly, the waters from different strata differ considerably in their dissolved chemical constituents, making the identification of a water from a particular stratum easy. However, in some areas the concentrations of dissolved constituents in waters from different strata do not differ significantly, and the identification of such waters is difficult or impossible.

The amount of water produced with the oil often increases as the amount of oil produced decreases. If this is edge water, nothing can be done about it. If it is bottom-

water, the well can be plugged back. However, it often is intrusive water from a shallow sand gaining access to the well from a leaky casing or faulty completion and this can be repaired.

Enormous quantities of water are produced with the oil in some fields, and it is necessary to separate the oil from the water. Most of the oil can be removed by settling. Often, however, an oil-in-water emulsion forms, which is very difficult to break. In such cases, the oil is heated and various surface-active chemicals are added to induce separation.

In the early days, the water was dumped on the ground, where it seeped below the land surface. Until about 1930, the oilfield waters were disposed into local drainage, frequently killing fish and even surface vegetation. After 1930, it became common practice to evaporate the water in earthen pits or inject it into the producing sand or another deep aquifer. The primary concern in such disposal practice is to remove all oil and basic sediment from the waters before pumping them into injection wells to prevent clogging of the pore spaces in the formation receiving the waste water. Chemical compatibility of waste water and host aquifer water also must be ensured.

Waters produced with petroleum are growing in importance. In years past, these waters were considered waste and had to be disposed of in some manner. Injection of these waters into the petroleum reservoir rock serves three purposes: it produces additional petroleum (secondary recovery), it utilizes a potential pollutant, and in some areas it controls land subsidence.

The volume of water produced with petroleum in the U.S. is large. In 1981 domestic oil production was about 8.6×10^6 B/D and the amount of water produced with the oil ranges from 4 to 5 times the oil production. Therefore, the water production, assuming a factor of 4.5, would be about 38.7×10^6 B/D.

Secondary and tertiary oil recovery processes that use water injection usually result in the production of even more water along with the oil. To inject these waters into reservoir rocks, suspended solids and oil must be removed from the waters to prevent plugging of the porous formations. Water injection systems require separators, filters, and, in some areas, deoxygenating and bacteria control equipment with chemical and physical methods to minimize corrosion and plugging in the injection system.

In waterflooding most petroleum reservoirs, the volume of produced water is not sufficient to recover the additional petroleum efficiently. Therefore, supplemental water must be added to the petroleum reservoir. The use of waters from the other sources requires that the blending of produced water with supplemental water must yield a chemically stable mixture so that plugging solids will not be formed. For example, a produced water containing considerable calcium should not be mixed with a water containing considerable carbonate because calcium carbonate may precipitate and prevent injection of the floodwater. The design and successful operation of a secondary or tertiary recovery operation requires a thorough knowledge of the composition of the waters used.

Chemical analyses of waters produced with oil are useful in oil production problems, such as identifying the

source of intrusive water, planning waterflood and saltwater disposal projects, and treating to prevent corrosion problems in primary, secondary, and tertiary recovery. Electrical well-log interpretation requires a knowledge of the dissolved solids concentration and composition of the interstitial water. Such information also is useful in correlation of stratigraphic units and of the aquifers within these units, and in studies of the movement of subsurface waters. It is impossible to understand the processes that accumulate petroleum or other minerals without insight into the nature of these waters.

Sampling

The composition of subsurface water commonly changes with depth and also laterally in the same aquifer. Changes may be brought about by the intrusion of other waters, and by discharge from and recharge to the aquifer. It is thus difficult to obtain a representative sample of a given subsurface body of water. Any one sample is a very small part of the total mass, which may vary widely in composition. Therefore, it is generally necessary to obtain and analyze many samples. Also, the samples may change with time as gases come out of solution and supersaturated solutions approach saturation.

The sampling sites should be selected, if possible, to fit into a comprehensive network to cover an oil-productive geologic basin.

There is a tendency for some oilfield waters to become more diluted as the oil reservoir is produced. Such dilution may result from the movement of dilute water from adjacent compacting clay beds into the petroleum reservoir as pressure declines with the continued removal of oil and brine.¹⁵

The composition of oilfield water varies with the position within the geologic structure from which it is obtained. In some cases the salinity will increase upstructure to a maximum at the point of oil/water contact.

Few of the samples collected by drillstem test (DST) are truly representative formation-water samples. During drilling, the pressure in the wellbore is intentionally maintained higher than that in the formations. Filtrate from the drilling mud seeps into the permeable strata, and this filtrate is the first liquid to enter the test tool.

The most truly representative formation-water sample usually is obtained after the oil well has produced for a period of time and all extraneous fluids adjacent to the wellbore have been flushed out. Samples taken immediately after the well is completed may be contaminated with drilling fluids and/or with well completion fluids, such as filtrate from cement, tracing fluids, and acids, which contain many different chemicals.

Sampling methods are discussed in publications of the American Petroleum Inst. (API),¹⁶ American Soc. for Testing and Materials (ASTM),¹⁷ and the Natl. Assn. of Corrosion Engineers (NACE).¹⁸

Drillstem Test

The DST, if properly made, can provide a reliable formation water sample. It is best to sample the water after each stand of pipe is removed. Normally, the total dissolved solids (TDS) content will increase downward and become constant when pure formation water is ob-

tained. A test that flows water will give even higher assurance of an uncontaminated sample. If only one DST water sample is taken for analysis, it should be taken just above the tool, since this is the last water to enter the tool and is least likely to show contamination.

Analyses of water obtained from a DST of Smackover limestone water in Rains County, TX, show how errors can be caused by improper sampling of DST water. Analyses of top, middle, and bottom samples taken from a 50-ft fluid recovery show an increase in salinity with depth in the drillpipe, indicating that the first water was contaminated by mud filtrate.¹⁹ Thus, the bottom sample was the most representative of Smackover water.

Sample Procedure

No single procedure is universally applicable for obtaining a sample of oilfield water. For example, information may be desired concerning the dissolved gas or hydrocarbons in the water or the reduced species present, such as ferrous or manganous compounds. Sampling procedures applicable to the desired information must be used.

Some of the special information and sample location cases, with appropriate procedures or references cited for proper sampling, follow.

Sample Containing Dissolved Gas. Knowledge of certain dissolved hydrocarbon gases is used in exploration.^{20,21}

Sampling at the Flowline. Another method of obtaining a sample for analysis of dissolved gases is to place a sampling device in a flowline. Fig. 24.1 illustrates such a device. The device is connected to the flowline, and water is allowed to flow into and through the container, which is held above the flowline, until 10 or more volumes of water have flowed through. The lower valve on the sample container is closed and the container removed. If any bubbles are present in the sample, the sample is discarded and a new one is obtained.

Sampling at the Wellhead. It is common practice in the oil industry to obtain a sample of formation water from a sampling valve at the wellhead. A plastic or rubber tube can be used to transfer the sample from the sample valve into the container (usually plastic). The source and sample container should be flushed to remove any foreign material before a sample is taken. After flushing the system, the end of the tube is placed in the bottom of the container, and several volumes of fluid are displaced before the tube is removed slowly from the container and the container is sealed. Fig. 24.2 illustrates a method of obtaining a sample at the wellhead. An extension of this method is to place the sample container in a larger container, insert the tube to the bottom of the sample container, allow the brine to overflow both containers, and withdraw the tube and cap the sample under the fluid.

At pumping wellheads the brine will surge out in heads and be mixed with oil. In such situations a larger container equipped with a valve at the bottom can be used as a surge tank or an oil-water separator or both. To use this device, place the sample tube in the bottom of the large container, open the wellhead valve, rinse the large container with the well fluid, allow the large container to

Fig. 24.1—Flowline sampler.

fill, and withdraw a sample through the valve at the bottom of the large container. This method will serve to obtain samples that are relatively oil-free.

Field Filtered Sample. In some studies it is necessary to obtain a field filtered sample. The filtering system shown in Fig. 24.3 was designed and has proved successful for various applications.

Fig. 24.2—Example of the method used for obtaining a sample at the wellhead.

This filtering system is simple and economical. It consists of a 50-mL disposable syringe, two check valves, and an inline-disk-filter holder. The filter holder takes size 47-mm diameter, 0.45- μ m pore size filters, with the option of a prefilter and depth prefilter.

After the oilfield brine is separated from the oil, the brine is drawn from the separator into the syringe. With the syringe, it is forced through the filter into the collection bottle. The check valves allow the syringe to be used as a pump for filling the collection bottle. If the filter becomes clogged, it can be replaced in a few minutes. About 2 minutes are required to collect 250 mL of sample. Usually two samples are taken, with the one being acidified to pH 3 or less with concentrated HCl or HNO₃. The system can be cleaned easily or flushed with brine to prevent contamination.

Sample for Stable-Isotope Analysis. Stable isotopes have been used in several research studies to determine the origin of oilfield brines.²²⁻²⁴

Sample for Determining Unstable Properties or Species. A mobile analyzer was designed to measure pH, Eh (redox potential), O₂, resistivity, S⁼, HCO₃⁻, CO₃⁼, and CO₂ in oilfield water at the wellhead. When oilfield brine samples are collected in the field and transported to the laboratory for analysis, many of the unstable constituents change in concentration. The amount of change depends on the sampling method, sample storage, ambient conditions, and the amounts of the constituents in the original sample. Therefore an analysis of the brine at the wellhead is necessary to obtain reliable data.²⁵

Sample Containers. Containers that are used include polyethylene, other plastics, hard rubber, metal cans, and borosilicate glass. Glass will adsorb various ions such as iron and manganese, and may contribute boron or silica to the aqueous sample. Plastic and hard rubber containers are not suitable if the sample is to be analyzed to determine its organic content. A metal container is used by some laboratories if the sample is to be analyzed for dissolved hydrocarbons such as benzene.

The type of container selected depends on the planned use of the analytical data. Probably the more satisfactory container, if the sample is to be stored for some time

before analysis. is the polyethylene bottle. Not all polyethylenes are satisfactory because some contain relatively high amounts of metal contributed by catalysts in their manufacture. The approximate metal content of the plastic can be determined by a qualitative emission spectrographic technique. If the sample is transported during freezing temperatures, the plastic container is less likely to break than is glass.

Tabulation of Sample Description. Information such as that in Table 24.1 should be obtained for each sample of oilfield water.

Analysis Methods for Oilfield Waters

Analytical methods for analyzing oilfield waters are improving with respect to precision, accuracy, and speed. There have been at least two groups trying to standardize methods of oilfield water analysis during the past 20 years. They are the API and ASTM. The API published Recommended Practice 45 for Analysis of Oilfield Waters.¹⁶

The ASTM's Committee D-19 standardizes methods of analyzing oilfield brines. Methods standardized by rigorous round-robin testing by several laboratories and subsequent ASTM committee balloting procedures are found in Ref. 17.

Table 24.2 illustrates the analyses for various properties or constituents of oilfield water. Methods to determine most of these properties or constituents can be found in Refs. 16, 17, and 25 through 30.

Chemical Properties of Oilfield Waters

Oilfield waters are analyzed for various chemical and physical properties. Most oilfield waters contain a variety of dissolved inorganic and organic compounds.

*Upper figure in each column is minimum value and lower figure is maximum value for number of analyses indicated.

**Not determined

However, oil producers usually are interested in only a few of the macro properties. This is understandable because oil producers wish to spend the least amount of money possible. Therefore, they will look at only the properties that are necessary to evaluate any treatment for reinjection to recover more oil or to dispose of the oilfield waters.

Composition of Oilfield Waters

The composition of oilfield waters varies from relatively dilute waters to heavy brines. Several thousand oilfield water analyses are available on computerized files.³¹ Tables 24.3 through 24.14 show characteristics of produced waters, and much of the text was taken from the 1962 edition of this book.³²

The tabulated data on water analyses following are listed alphabetically in order of general oil-productive areas of the U.S., Canada, and Venezuela, rather than by the smaller subdivisions of basins, geologic provinces, or geosynclines. An exception to this is the Illinois

basin, a large area not generally otherwise identifiable. This division has been made arbitrarily for convenience and because of the lack of a uniform system and is not intended as a precedent for any system of classification. The states or provinces from which reliable analyses were available are listed alphabetically in the tables under each area.

The reader is referred to the original indicated sources of analytical data for more complete information.

Appalachian Area. The Appalachian area was the first in the U.S. in which petroleum was produced commercially and is one of the best known and studied geologic features of North America. Table 24.3 gives the characteristics of some waters produced from Appalachian fields.³³⁻³⁹

Petroleum and associated water are produced from more than 50 strata in systems from the Cambrian to the Permian. Most of the productive strata are sandstones, although some limestones are productive. Many of the

sandstones are nonuniform and discontinuous, although the Big Injun and Berea sands have been traced across wide areas. The oil-producing states included in the Appalachian area from which analyses were available are Kentucky, Ohio, Pennsylvania, and West Virginia. The concentrations of dissolved salts in waters produced with petroleum range from a few hundred to more than 300,000 mg/L.

California. In different fields of California, oil is produced from many reservoirs, ranging in age from Cretaceous to Pleistocene. Sandstones and sands are the principal productive rocks. Many of the formations are of massive thickness, and much folding and faulting are evident. In general, mineralized water produced with petroleum from California reservoirs is by no means as concentrated as that from reservoirs in many other areas, especially the midcontinent. Table 24.4 gives the characteristics of some water produced from California fields.^{40,41}

U.S. Gulf Coast. For many years since the Spindletop dome was discovered in 1901, copious quantities of oil have been produced from Tertiary and Quaternary formations on the flanks, in the caprock, and in structures above the caprock of massive salt domes, usually considered intrusive in nature. During recent years, offshore drilling has focused attention on drilling off the coasts of Louisiana and Texas. Some waters produced from gulf coast fields are quite fresh; others have concentrations of dissolved salts as high as 170,000 mg/L (Table 24.5).⁴²⁻⁴⁴

Illinois Basin. The Illinois basin, divided roughly into halves by the LaSalle anticline, comprises much of Illinois and southwestern Indiana. Oil is produced here from many fields, principally from Pennsylvanian and Mississippian sandstones and, to a smaller extent, from limestones. TDS in the produced waters range from about 1,000 to more than 160,000 mg/L (Table 24.6).⁴⁵

TABLE 24.4—CHARACTERISTICS OF SOME WATERS PRODUCED FROM CALIFORNIA FIELDS

Midcontinent Area. The midcontinent oil productive area is the largest geographically of all oil-productive areas in the U.S. For purposes of this section, it is considered to include Arkansas, Kansas, northern Louisiana, Missouri, Nebraska, Oklahoma, and all of Texas except the gulf coast fields.

Oil and associated brines are produced from many sandstones and limestones, as well as from other types of formations, in geologic systems ranging from the Cambrian through the Upper Cretaceous. Waters produced with petroleum from midcontinent fields have a wide range of concentration of dissolved salts, from little more than 1,000 to more than 350,000 mg/L. Tables 24.7 through 24.9 present the characteristics of some produced waters from the midcontinent fields of Kansas, Oklahoma, and Texas. ⁴⁶⁻⁵⁴

Rocky Mt. Area. Petroleum is produced in Colorado, Montana, New Mexico, Utah, and Wyoming from many fields in the Rocky Mt. area. The principal production is from rocks of the Cretaceous system, although oil and

associated waters also are produced from Jurassic, Permian, Pennsylvanian, and Mississippian rocks. Produced waters from Rocky Mt. fields have comparatively low concentrations of dissolved salts and often are characterized by comparatively high concentrations of bicarbonate. Tables 24.10 and 24.11 give the characteristics of some waters produced from Rocky Mt. fields of Colorado, Montana, and Wyoming. ⁵⁵⁻⁵⁹

Canada. The principal oil-productive areas in Canada are the lower Ontario Peninsula, where oil is produced from rocks ranging from Ordovician to Devonian age, and the western provinces, principally Alberta, Saskatchewan, and the Northwest Territories. Reservoir rocks in western Canada range in age from Devonian to Cretaceous. Although many of the waters produced with petroleum have quite low concentrations of dissolved salts, others are quite concentrated. Tables 24.12 and 24.13 present the characteristics of some waters from Canadian fields in Alberta, Manitoba, and Saskatchewan. ⁶⁰⁻⁶⁵

*Upper figure in each column is minimum value and lower figure is maximum value for number of analyses indicated.⁴⁵

Venezuela. The principal productive formations in Venezuela are Tertiary sandstones and Cretaceous limestones. In general, the various waters produced with petroleum have low concentrations of dissolved salts (Table 24.14).⁶⁶⁻⁶⁹

Inorganic Constituents

Petroleum companies often analyze oilfield waters to determine their major dissolved inorganic constituents. The major constituents usually are sodium, calcium, magnesium, chloride, bicarbonate, and sulfate. The analytical data are used in studies such as water identification, log evaluation, water treatment, environmental impact, geochemical exploration, and recovery of valuable minerals.²⁶

Cations

The presence of various cations and anions in oilfield waters can cause solubility, acidity, and redox (Eh) potential changes as well as the precipitation and adsorption of some constituents. The major cations in most

oilfield waters are sodium, calcium, and magnesium. The concentrations of these ions can range from less than 10,000 mg/L for sodium, and from less than 1,000 mg/L to more than 30,000 mg/L for calcium and/or magnesium.

Other cations that often are present in oilfield waters in concentrations greater than 10 mg/L are potassium, strontium, lithium, and barium. Some oilfield waters contain concentrations in excess of 10 mg/L of aluminum, ammonium, iron, lead, manganese, silicon, and zinc.^{26,70,71}

Anions

The major anion in most oilfield waters is chloride. The chloride concentration can range from less than 10,000 to more than 200,000 mg/L. There are exceptions to this—e.g., some Venezuelan oilfield waters contain more bicarbonate than chloride.⁷²

Most oilfield waters contain bromide and iodide. The concentrations of these anions range from less than 50 to more than 6,000 mg/L for bromide and from less than 10

**Not determined

to more than 1,400 mg/L for iodide.²⁶ Bromide concentration is important in determining the origin of an oilfield brine and is an important geochemical marker constituent.⁷³ Bicarbonate and sulfate are present in many oilfield waters. Their concentrations can range from none to several thousand milligrams per liter.

Other anions found in oilfield waters include arsenate, borate, carbonate, fluoride, hydroxide, organic acid salts, and phosphates. Boron concentrations in excess of 100 mg/L can affect electric log deflections.²⁶

Physical Properties of Oilfield Waters*

Compressibility

The compressibility of formation water at pressures above the bubblepoint is defined as the change in water volume per unit water volume per psi change in pressure. This is expressed mathematically as

$$c_w = -\frac{1}{V} \left(\frac{\partial V}{\partial p} \right) T, \dots \dots \dots (1a)$$

*This section, except for the pH and Eh, was written by Howard B. Bradley.

or

$$\bar{c}_w = \frac{1}{\bar{V}} \left(\frac{V_2 - V_1}{p_1 - p_2} \right), \dots \dots \dots (1b)$$

or

$$\bar{c}_w = \frac{B_{w2} - B_{w1}}{\bar{B}_w(p_1 - p_2)}, \dots \dots \dots (1c)$$

where

c_w = water compressibility at the given pressure and temperature, bbl/bbl-psi,

\bar{c}_w = average water compressibility within the given pressure and temperature interval, bbl/bbl-psi,

V = water volume at the given pressure and temperature, bbl,

\bar{V} = average water volume within p and T intervals, bbl,

p_1 and

p_2 = pressure at conditions 1 and 2 with $p_1 > p_2$, psi,

B_{w1} and

B_{w2} = water FVF p_1 and p_2 , bbl/bbl, and

\bar{B}_w = average water FVF corresponding to \bar{V} , bbl/bbl.

In an oil reservoir, water compressibility also depends on the salinity. In contrast to the literature, laboratory measurements by Osif⁷⁴ show that the effect of gas in

solution on compressibility of water with NaCl concentrations up to 200 g/cm³ is essentially negligible. Osif's results show no effect at gas/water ratios (GWR's) of 13 scf/bbl, at GWR's of 35 scf/bbl probably no effect, but certainly no more than a 5% increase in the compressibility of brine.

Laboratory measurements⁷⁴ of water compressibility resulted in linear plots of the reciprocal of compressibility vs. pressure. The plots of $1/c_w$ vs. p have a slope of m_1 , and intercepts linear in salinity and temperature. Data points for the systems tested containing no gas in solution resulted in Eq. 2.

$$1/c_w = m_1 p + m_2 C + m_3 T + m_4, \dots \dots \dots (2)$$

where

c_w = water compressibility, psi⁻¹,

p = pressure, psi,

C = salinity, g/L of solution,

T = temperature, °F,

$m_1 = 7.033$,

$m_2 = 541.5$,

$m_3 = -537$, and

$m_4 = 403.3 \times 10^3$.

Eq. 2 was fit for pressures between 1,000 and 20,000 psi, salinities of 0 to 200 g NaCl/L, and temperatures from 200 to 270°F. Compressibilities were independent of dissolved gas.

Where conditions overlap, the agreement with the results reported by both Dorsey⁷⁵ and Dotson and Standing⁷⁶ is very good. Results from the Rowe and Chou⁷⁷

Fig. 24.4—Specific gravity of salt solutions at 60°F and 14.7 psia.

Fig. 24.5—Density of NaCl solutions at 14.7 psia vs. temperature.

equation agree well up to 5,000 psi (their upper pressure limit) but result in larger deviations with increasing pressure. In almost all cases, the Rowe and Chou compressibilities are less than that of Eq. 2.

Density

The density of formation water is a function of pressure, temperature, and dissolved constituents. It is determined most accurately in the laboratory on a representative sample of formation water.¹⁷ The formation water density is defined as the mass of the formation water per unit volume of the formation water. For engineering purposes, density in metric units (g/cm^3) is considered equal to specific gravity. Therefore, for most engineering calculations density and specific gravity are interchangeable.¹⁶

When laboratory data are not available, the density of formation water at reservoir conditions can be estimated (usually to within $\pm 10\%$) from correlations (Figs. 24.4 through 24.6). The only field data necessary are the density at standard conditions, which can be obtained from the salt content by use of Fig. 24.4. The salt content can

be estimated from the formation resistivity (obtained from electric log measurements) by use of Fig. 49.3 (see Chap. 49). The density of formation water at reservoir conditions can be calculated in four steps.

1. Using the temperature and density at atmospheric pressure, obtain the equivalent weight percent NaCl from Fig. 24.5.

2. Assuming the equivalent weight percent NaCl remains constant, extrapolate the weight percent to reservoir temperature and read the new density.

3. Knowing the density at atmospheric pressure and reservoir temperature, use Fig. 24.6 to find the increase in specific gravity (density) when compressed to reservoir pressure. Note that for oil reservoirs below the bubblepoint, the "saturated-with-gas" curves should be used; for water considered to have no solution gas, the "no-gas-in-solution" curves should be used. These curves were computed from data given by Ashby and Hawkins.⁷⁸

4. The density of formation water (g/cm^3) at reservoir conditions is the sum of the values read from Figs. 24.5 and 24.6. They can be added directly since the metric

units are referred to the common density base of water (1 g/cm³). The metric units can be changed to customary units (lbm/cu ft) by multiplying by 62.37.

Also the specific gravity of formation water can be estimated if the dissolved solids are known. The equation is

$$\gamma_w = 1 + C_{sd} \times 0.695 \times 10^{-6}, \dots \dots \dots (3)$$

where C_{sd} is the concentration of dissolved solids (mg/L).

For precise but very detailed calculations, the reader is referred to a recent paper by Rogers and Pitzer.⁷⁹ They tabulated a large number of values of compressibility, expansivity and specific volume vs. molality, temperature, and pressure. A semiempirical equation of the same type found to be effective in describing thermal properties of NaCl (0.1 to 5 molality) was used to reproduce the volumetric data from 0 to 300°C and 1 to 1,000 bars.

Formation Volume Factor (FVF)

The water FVF, B_w , is defined as the volume at reservoir conditions occupied by 1 STB of formation water plus its dissolved gas. It represents the change in volume of the formation water as it moves from reservoir conditions to surface conditions. Three effects are involved: the liberation of gas from water as pressure is reduced, the expansion of water as pressure is reduced, and the shrinkage of water as temperature is reduced.

The water FVF also depends on pressure. Fig. 24.7 is a typical plot of water FVF as a function of pressure. As the pressure is decreased to the bubblepoint, p_b , the FVF increases as the liquid expands. At pressures below the bubblepoint, gas is liberated, but in most cases the FVF still will increase because the shrinkage of the water resulting from gas liberation is insufficient to counterbalance the expansion of the liquid. This is the effect of the small solubility of natural gas in water.

The most accurate method of obtaining the FVF is from laboratory data. It also can be calculated from density correlations if the effects of solution gas have been accounted for properly. The following equation is used to estimate B_w if solution gas is included in the laboratory measurement or correlation of ρ_{rc} :

$$B_w = \frac{V_{rc}}{V_{sc}} \times \frac{\rho_{sc}}{\rho_{rc}}, \dots \dots \dots (4)$$

where

V_{rc} = volume occupied by a unit mass of water at reservoir conditions (weight of gas dissolved in water at reservoir or standard conditions is negligible), cu ft,

V_{sc} = volume occupied by a unit mass of water at standard conditions, cu ft,

ρ_{sc} = density of water at standard conditions, lbm/cu ft, and

ρ_{rc} = density of water at reservoir conditions, lbm/cu ft.

The density correlations and the methods of estimating ρ_{sc} and ρ_{rc} were described previously.

Fig. 24.6—Specific gravity increase with pressure—salt water.

Fig. 24.7—Typical plot of water FVF vs. pressure.

The FVF of water can be less than one if the increase in volume resulting from dissolved gas is not great enough to overcome the decrease in volume caused by increased pressure. The value of FVF is seldom higher than 1.06.

Resistivity

The resistivity of formation water is a measure of the resistance offered by the water to an electrical current. It can be measured directly or calculated.¹⁶ The direct-measurement method is essentially the electrical resistance through a 1-m² cross-sectional area of 1 m³ of formation water. The formation water resistivity, R_{wg} , is expressed in units of $\Omega\cdot m$. The resistivity of formation water is used in electric log interpretation and for such use the value is adjusted to formation temperature.⁸⁰ (See Chap. 49 for more information).

Surface (Interfacial) Tension (IFT)

Surface tension is a measure of the attractive force acting at a boundary between two phases. If the phase boundary separates a liquid and a gas or a liquid and a solid, the attractive force at the boundary usually is called "surface tension"; however, the attractive force at the interface between two liquids is called "IFT." IFT is an important factor in enhanced recovery processes (see Chap. 47, Chemical Flooding, describing "Low-IFT Processes" and "Phase Behavior and IFT" in the Micellar/Polymer Flooding section).

Surface tension is measured in the laboratory by a tensiometer, by the drop method, or by other methods. Descriptions of these methods are found in most physical chemistry texts.

Viscosity

The viscosity of formation water, μ_w , is a function of pressure, temperature, and dissolved solids. In general, brine viscosity increases with increasing pressure, increasing salinity, and decreasing temperature.⁸¹ Dissolved gas in the formation water at reservoir conditions generally results in a negligible effect on water viscosity. There is little information on the actual numerical effect of dissolved gas on water viscosity.

Gas in solution behaves entirely differently from gas in hydrocarbons.* In water the presence of the gas actually causes the water molecules to interact with each other more strongly, thus increasing the rigidity and viscosity of the water. However, this effect is very small and has not been measured to date. In the physical chemistry literature there is an enormous amount of indirect evidence to support this concept.

For the best estimation of the viscosity of water, the reader is referred to a paper by Kestin *et al.*⁸² Their correlating equations involve 32 parameters for calculating the numerical effect of pressure, temperature, and concentration of aqueous NaCl solutions on the dynamic and kinematic viscosity of water. Twenty-eight tables generated from the correlating equations cover a temperature range from 20 to 150°C, a pressure range from 0.1 to 35 mPa, and a concentration range from 0 to 6 molal.

Figs. 24.8 through 24.10 may be used to approximate water viscosity for engineering purposes. These figures show the effects of pressure, temperature, and NaCl content on the viscosity of water. They may be used when the primary contaminant is sodium chloride.

Some engineers assume that reservoir brine viscosity is equal to that of distilled water at atmospheric pressure and reservoir temperature. In this case it is assumed that the viscosity of brine is essentially independent of pressure (a valid premise for the pressure ranges usually encountered).

The pH

The pH of oilfield waters usually is controlled by the CO₂/bicarbonate system. Because the solubility of CO₂ is directly proportional to temperature and pressure, the pH measurement should be made in the field if a close-to-natural-conditions value is desired. The pH of the water is not used for water identification or correlation purposes, but it does indicate possible scale-forming or corrosion tendencies of a water. The pH also may indicate the presence of drilling-mud filtrate or well-treatment chemicals.

The pH of concentrated brines usually is less than 7.0, and the pH will rise during laboratory storage, indicating that the pH of the water in the reservoir probably is appreciably lower than many published values. Addition of the carbonate ion to sodium chloride solutions will raise the pH. If calcium is present, calcium carbonate precipitates. The reason the pH of most oilfield waters rises during storage in the laboratory is because of the formation of carbonate ions as a result of bicarbonate decomposition.

The Redox Potential (Eh)

The redox potential often is abbreviated "Eh," and also may be referred to as oxidation potential, oxidation-reduction potential, or pE. It is expressed in volts, and at equilibrium it is related to the proportions of oxidized and reduced species present. Standard equations of chemical thermodynamics express the relationships.

Knowledge of the redox potential is useful in studies of how compounds such as uranium, iron, sulfur, and other minerals are transported in aqueous systems. The solubility of some elements and compounds depends on the redox potential and the pH of their environment.

Some water associated with petroleum is interstitial ("connate") water, and has a negative Eh; this has been proved in various field studies. Knowledge of the Eh is useful in determining how to treat a water before it is reinjected into a subsurface formation. For example, the Eh of the water will be oxidizing if the water is open to the atmosphere, but if it is kept in a closed system in an oil-production operation the Eh should not change appreciably as it is brought to the surface and then reinjected. In such a situation, the Eh value is useful in determining how much iron will stay in solution and not deposit in the wellbore.

Organisms that consume oxygen cause a lowering of the Eh. In buried sediments, it is the aerobic bacteria that attract organic constituents, which remove the free oxygen from the interstitial water. Sediments laid down in a shoreline environment will differ in degree of oxidation

* Personal communication: Melrose, J.C., Mobil R&D Corp., Dallas (Sept. 25, 1985).

Fig. 24.8—Effect of pressure on the viscosity of water.

compared with those laid down in a deepwater environment. For example, the Eh of the shoreline sediments may range from -50 to 0 mV, but the Eh of deepwater sediments may range from -150 to -100 mV.

The aerobic bacteria die when the free oxygen is totally consumed; the anaerobic bacteria attack the sulfate ion, which is the second most important anion in the seawater. During this attack, the sulfate reduces to sulfite and then to sulfide; the Eh drops to -600 mV, H_2S is liberated, and $CaCO_3$ precipitates as the pH rises above 8.5.

Dissolved Gases

Large quantities of dissolved gases are contained in oilfield brines. Most of these gases are hydrocarbons; however, other gases such as CO_2 , N_2 , and H_2S often are present. The solubility of the gases generally decreases with increased water salinity, and increases with pressure.

Hundreds of drillstem samples of brine from water-bearing subsurface formations in the U.S. gulf coast area were analyzed to determine their amounts and kinds of hydrocarbons.²⁰ The chief constituent of the dissolved gases usually was methane, with measurable amounts of ethane, propane, and butane. The concentration of the dissolved hydrocarbons generally increased with depth in a given formation and also increased basinward with regional and local variations. In close proximity to some oilfields, the waters were enriched in dissolved hydrocarbons, and up to 14 scf dissolved gas/bbl water was observed in some locations. A more detailed discussion of this topic is given in Chap. 22.

Organic Constituents

In addition to the simple hydrocarbons, a large number of organic constituents in colloidal, ionic, and molecular form occur in oilfield brines. In recent years, some of these organic constituents have been measured quantitatively. However, many organic constituents are present that have not been determined in some oilfield

Fig. 24.9—Viscosity of sodium chloride solutions as a function of temperature and concentration at 14.7 psia.

brines primarily because the analytical problems are difficult and very time-consuming.

Knowledge of the dissolved organic constituents is important because these constituents are related to the origin and/or migration of an oil accumulation, as well as to the disintegration or degradation of an accumulation. The concentrations of organic constituents in oilfield brines vary widely. In general, the more alkaline the water, the more likely that it will contain higher concentrations of organic constituents. The bulk of the organic matter consists of anions and salts of organic acids; however, other compounds also are present.

Fig. 24.10—Effect of temperature on viscosity of water.

Knowledge of the concentrations of benzene, toluene, and other components in oilfield brines is used in exploration. The solubilities of some of these compounds in water at ambient conditions and in saline waters at elevated temperatures and pressures have been determined.^{83,84}

However, the actual concentrations of these and other organic constituents in subsurface oilfield brines is another matter. It has been shown experimentally that the solubilities of some organic compounds found in crude oil increase with temperature and pressure if pressure is maintained on the system. The increased solubilities become significant above 150°C. The solubilities decrease with increasing water salinity. Waters associated with paraffinic oils are likely to contain fatty acids, while those associated with asphaltic oils more likely contain naphthenic acids.

Quantitative recovery of organic constituents from oilfield brines is difficult. Temperature and pressure changes, bacterial actions, adsorption, and the high inorganic/organic-constituents ratio in most oilfield brines are some reasons why quantitative recovery is difficult.

Interpretation of Chemical Analyses

Oilfield waters include all waters or brines found in oilfields. Such waters have certain distinct chemical characteristics.

About 70% of the world petroleum reserves are associated with waters containing more than 100 g/L dissolved solids. A water containing dissolved solids in excess of 100 g/L can be classified as a brine. Waters associated with the other 30% of petroleum reserves contain less than 100 g/L dissolved solids. Some of these waters are almost fresh. However, the presence of fresher waters usually is attributed to invasion after the petroleum accumulated in the reservoir trap.

Examples of some of the low-salinity waters can be found in the Rocky Mt. areas in Wyoming fields such as Enos Creek, South Sunshine, and Cottonwood Creek. The Douleb oil field in Tunisia is another example.

The composition of dissolved solids found in oilfield waters depends on several factors. Some of these factors are the composition of the water in the depositional environment of the sedimentary rock, subsequent changes by rock/water interaction during sediment compaction, changes by rock/water interaction during water migration (if migration occurs), and changes by mixing with other waters, including infiltrating younger waters such as meteoric waters. The following are definitions of some types of water.

Types of Water

Meteoric Water. This is water that recently was involved in atmospheric circulation; furthermore, "the age of meteoric groundwater is slight when compared with the age of the enclosing rocks and is not more than a small part of a geologic period."¹⁴

Seawater. The composition of seawater varies somewhat, but in general will have a composition relative to the following (in mg/L): chloride—19,375, bromide—67, sulfate—2,712, potassium—387, sodium—10,760, magnesium—1,294, calcium—413, and strontium—8.

Interstitial Water. Interstitial water is the water contained in the small pores or spaces between the minute grains or units of rock. Interstitial waters are *syngenetic* (formed at the same time as the enclosing rocks) or *epigenetic* (originated by subsequent infiltration into rocks).

Connate Water. The term "connate" implies born, produced, or originated together—connascent. Therefore, connate water probably should be considered an interstitial water of syngenetic origin. Connate water of this definition is fossil water that has been out of contact with the atmosphere for at least a large part of a geologic period. The implication that connate waters are only those "born with" the enclosing rocks is an undesirable restriction.¹⁴

Diagenetic Water. Diagenetic waters are those that have changed chemically and physically, before, during, and after sediment consolidation. Some of the reactions that occur in or to diagenetic waters include bacterial, ion exchange, replacement (dolomitization), infiltration by permeation, and membrane filtration.

Formation Water. Formation water, as defined here, is water that occurs naturally in the rocks and is present in them immediately before drilling.

Juvenile Water. Water that is in primary magma or derived from primary magma is juvenile water.¹⁴

Condensate Water. Water associated with gas sometimes is carried as vapor to the surface of the well where it condenses and precipitates because of temperature and pressure changes. More of this water occurs in the winter and in colder climates and only in gas-producing wells. This water is easy to recognize because it contains a relatively small amount of dissolved solids, mostly derived from reactions with chemicals in or on the well casing or tubing.

Water analyses may be used to identify the water source. In the oil field one of the prime uses of these analyses is to determine the source of extraneous water in an oil well so that casing can be set and cemented to prevent such water from flooding the oil or gas horizons. In some wells a leak may develop in the casing or cement, and water analyses are used to identify the water-bearing horizon so that the leaking area can be repaired. With the current emphasis on water pollution prevention, it is very important to locate the source of a polluting brine so that remedial action can be taken.

Comparisons of water-analysis data are tedious and time-consuming; therefore, graphical methods are commonly used for positive, rapid identification. A number of systems have been developed, all of which have some merit.

Graphic Plots

Graphic plots of the reacting values can be made to illustrate the relative amount of each radical present. The graphical presentation is an aid to rapid identification of a water and classification as to its type. Several methods have been developed.

Tickell Diagram. The Tickell diagram was developed using a six-axis system or star diagram.⁸⁵ Percentage reaction values of the ions are plotted on the axes. The percentage values are calculated by summing the equivalent proton masses (EPM's) of all the ions, dividing the EPM of a given ion by the sum of the total EPM's, and multiplying by 100.

The plots of total reaction values, rather than of percentage reaction values, are often more useful in water identification because the percentage values do not take into account the actual ion concentrations. Water differing only in concentrations of dissolved constituents cannot be distinguished.

Reistle Diagram. Reistle devised a method of plotting water analyses by using the ion concentrations.⁸⁶ The data are plotted on a vertical diagram, with the cations plotted above the central zero line and the anions below. This type of diagram often is useful in making regional correlations or studying lateral variations in the water of a single formation because several analyses can be plotted on a large sheet of paper.

Stiff Diagram. Stiff plotted the reaction values of the ions on a system of rectangular coordinates.⁸⁷ The cations are plotted to the left and the anions to the right of a vertical zero line. The endpoints then are connected by straight lines to form a closed diagram, sometimes called a "butterfly" diagram. To emphasize a constituent that may be a key to interpretation, the scales may be varied by changing the denominator of the ion fraction, usually in multiples of 10. However, when a group of waters is being considered, all must be plotted on the same scale.

Many investigators believe that this is the best method of comparing oilfield water analyses. The method is simple, and nontechnical personnel can be easily trained to construct the diagrams.

Other Methods. Several other water identification diagrams have been developed, primarily for use with fresh waters, and they are not discussed here. The Stiff and Piper diagrams,^{87,88} were adapted to automatic data processing by Morgan *et al.*⁸⁹ and Morgan and McNellis.⁹⁰ The Piper diagram uses a multiple trilinear plot to depict the water analysis, and this quaternary diagram shows the chemical composition of the water in terms of cations and anions.⁸⁸ Angino and Morgan applied the automated Stiff and Piper diagrams to some oilfield brines and obtained good results.⁹¹

Occurrence, Origin, and Evolution of Oilfield Waters

The sedimentary rocks that now consist of stratified deposits originally were laid down as sediments in oceans, seas, lakes, and streams. Naturally, these sediments were filled with water. This water is still present in the stratified sediments and millions of years later would be considered truly connate water.

Many large sedimentary strata originally were associated with oceans and seas. The original associated water, therefore, was marine in such sediments. Sediments laid down by lakes and streams would not contain a marine water during their initial deposition.

However, with time and tectonic events plus transgression and regression of oceans and seas, even these sediments probably were subjected to marine waters by infiltration.

In any event, the petroleum, which formed from organic matter deposited with the sediments, migrated from what usually is called the "source rock" into more porous and permeable sedimentary rock. Petroleum (i.e., oil and gas) is less dense than water; therefore, it tends to float to the top of a water body regardless of whether the water is on the surface or in the subsurface.

Therefore, water associated with petroleum in a subsurface reservoir is called an "oilfield water." By this definition, any water associated with a petroleum deposit is an oilfield water.

The question of the origin of oilfield brines is difficult to answer in a general manner. The water involved and the constituents dissolved in the water to form the brine can involve divergent histories. Subsurface water is there either because it originally was there or because it infiltrated to the subsurface from the surface. If it was there originally, it would be endogenetic, whereas if it infiltrated from the surface and/or penetrated with sediment accumulations, it would be exogenetic.

Obviously these two types of waters could meet and mix in the subsurface and thus the mixture would contain water of two separate origins. The problem could multiply if more than one exogenetic water were involved.

The chemical composition of an oilfield brine is an end product of several variables. These variables include (1) dissolved ions, salts, gases, and organic matter, (2) reactions between these dissolved constituents, and (3) interaction of the brine with the surrounding rocks, petroleum, etc. There are a number of pertinent reactions that could cause the composition of a subsurface oilfield brine to change in composition, including leaching of the rocks, ion exchange between water and rock, redox, mineral hydration, mineral formation and/or dissolution, ion diffusion, gravitational segregation of ions, and membrane filtration, or other osmotic effects.

It is rather difficult to rank the factors that might be more important for general consideration. However, two of the more important factors probably are the original composition of the water and interaction of that water with the rocks. If one assumes that the original water was a marine water and that the associated sediments (subsequently sedimentary rocks) were marine, then the original composition of the marine water could be an important factor.

However, even the salinity in the various oceans and seas is not constant. For example, the salinity of the waters in the major oceans ranges from 33,000 to 38,000 mg/L, about 40,000 mg/L in the Mediterranean Sea, up to 70,000 mg/L in the Red Sea, about 18,000 to 22,000 mg/L in the Black Sea, and only about 1,000 mg/L in the Baltic Sea. Some land-locked waters, such as the Dead Sea, Great Salt Lake, etc., contain waters that are nearly saturated with dissolved solids.

Studies of formation waters in the western Canada sedimentary basin indicate that 85% of the strata were deposited under marine conditions, while 15% were deposited under brackish-water and possibly under freshwater conditions.⁹² These investigators estimated that 80% of all the sedimentary strata in Alberta were

deposited under marine conditions. This led to the conclusion that one could assume with negligible error that all sedimentary strata originally contained seawater.

Further, the study indicated that evaporites form an important volumetric part of several of the stratigraphic units. Some of the stratigraphic units possibly contain bitterns subsequent to halite precipitation but preceding precipitation of potassium salts. They calculated an average formation water salinity of about 46,000 mg/L TDS, which indicated a net gain of dissolved salts. Of the major and some minor components, all showed a net gain with the exception of Mg and SO_4 .

Factor analysis was used in interpretation of the analyses, and the following factors were considered to be major controls: composition of the original seawater, dilution by freshwater recharge, membrane filtration, solution of halite, dolomitization, bacterial reduction of sulfate, formation of chlorite, cation exchange on clays, contribution from organic matter, and solubility relationships.

It was concluded that (1) the formation waters of western Canada are ancient seawaters in which the deuterium concentration was changed because of mixing with infiltrating fresh water, (2) oxygen-18 was exchanged with carbonates in the rocks, and (3) dissolved salts are in equilibrium with the rock matrix subsequent to their redistribution by membrane filtration and/or dilution by freshwater recharge. Equilibrium was attained by such processes as dissolution of evaporates, new mineral formation, cation exchange on clays, desorption of ions from clays and organic matter, and mineral solubilities.

The majority of the published research studies seem to agree that all these controls and/or reactions are involved in establishing the composition of oilfield brines. Further, most investigators agree with the assumption that marine water usually is a part of the original material from which formation waters evolve. Opinions, however, are not unanimous with respect to how they evolved. The major disagreements are related to the membrane filtration theory and to other modes of concentrating the dissolved solids such as seawater evaporation.

It is possible to reconstruct the evolution of some oilfield brines in sedimentary basins if one reasons that they are genetically related to evaporites. For example, geochemical and geological studies of some very concentrated brines indicate that in deep quiescent bodies of water, strong bitterns can persist for long periods of time under a layer of near-normal seawater. As a result, carbonates can precipitate from the less saline water and fall through the bittern at the bottom, and, as compaction proceeds, the pore spaces remain filled with bitterns. Some fossil brines once trapped have not moved very far or very fast.

A geochemical model can be built to represent the origin and evolution of this type of brine by using the relatively simple operations and processes of (1) evaporation, (2) precipitation, (3) sulfate reduction, (4) mineral formation and diagenesis, (5) ion exchange, (6) leaching, and (7) expulsion of interstitial fluids from evaporites during compaction.

Experimental work indicated that about 14% of the bromide in seawater precipitates with the halite as seawater evaporates. The average concentration of

bromide in the Smackover brines is 3,100 mg/L. Therefore, the average degree of concentration of these brines compared to seawater is $3,100 \div 65 = 48$. Assuming that seawater is concentrated 50-fold, the approximate composition of a brine can be calculated.²⁶

Shale Compaction and Membrane Filtration

Some investigators believe that the salinity variations found in oilfield waters are the result of filtration of water through shale.⁹³ The membrane filtration theory first was suggested by De Sitter.⁹⁴ Laboratory experiments indicated that natural shales can act as semipermeable membranes.^{95,96} This system working in nature should cause a water to be more saline on one side of the shale membrane and almost fresh or less saline on the other side. This follows because the shale membrane should filter out the dissolved ions on the upflow side, causing the water on the downflow side to contain few or no dissolved ions.

Quantities of Produced Water

An analysis was made of the approximate amount of water produced with crude oil in 14 states. The states and their percent of total U.S. crude oil production in 1981 are: Alabama, 0.3%; Alaska, 19.9%; California, 11.7%; Colorado, 1.0%; Florida, 1.4%; Louisiana, 13.4%; Montana, 1.0%; Mississippi, 1.2%; Nebraska, 0.2%; New Mexico, 2.3%; North Dakota, 1.4%; Texas, 31.2%; Utah, 0.8%; and Wyoming, 4.2%.

Fig. 24.11 indicates the crude oil and water production from wells in the 14 states. The figure indicates production of about 4.3 bbl water/bbl oil. Fig. 24.12 is a similar graph for 13 states excluding Alaska. This figure indicates production of about 5.2 bbl water/bbl oil. Further, it can be shown that oil wells produce more water as cumulative oil production increases. In other words, the older the well, the higher the WOR.

Recovery of Minerals From Brines

Extraction of minerals from oilfield brines should be considered in production planning (1) to recoup exploration and development costs, (2) to prevent environmental damage from brine, (3) to produce potable water, and (4) to conserve all valuable minerals and energy.

Precipitation is the most common separation process used in separating minerals from any type of brine. Minerals recovered from brines in the U.S. include compounds of iodine, bromine, chlorine, sodium, lithium, potassium, magnesium, and calcium.

Evaporation of a saline water or brine will cause the precipitation of calcium carbonate, calcium sulfate, sodium chloride, magnesium sulfate, potassium chloride, and finally magnesium chloride. These are the major chemicals in most brines, and this is the sequence order in which these compounds will precipitate. Mere precipitation will not produce a very pure chemical from a brine; therefore, other chemical or physical processes are used.

For example, iodine, which is in the form of iodide in a brine, is recovered by these steps: (1) the iodide is oxidized to iodine, (2) the iodine is stripped from the brine, (3) the iodine then is reduced back to iodide, (4) the iodide is oxidized again to iodine, (5) the iodine is

Fig. 24.11—Crude oil and water produced ($\times 1,000$ B/D) from wells in 14 states including Alaska.

Fig. 24.12—Crude oil and water produced ($\times 1,000$ B/D) from wells in 13 states excluding Alaska.

crystallized and filtered, and (6) the iodine crystals are purified further.

Bromine is recovered by a similar though, of course, different process. It is present in a brine as bromide. The *U.S. Bureau of Mines Yearbook*⁹⁷ contains information on general recovery technology, domestic production, consumption and uses, prices, stocks, etc., of minerals recovered from brines as well as minerals recovered from other sources.

The first plant in the U.S. in more than 40 years built solely to produce iodine from brine went on stream in 1977 near Woodward, OK. It has a design capacity of 2 million lbm iodine/yr or about 30% of the annual U.S. demand. Some smaller-scale operations to recover iodine started in 1982 near Kingfisher, OK.

Several plants recover bromine and other constituents from brine near El Dorado, AR. The brine is produced from the Smackover formation.

Magnesium and other chemicals are recovered from lake brines, well brines, and seawater in plants located near Ogden, UT; Ludington, MI; Freeport, TX; and Port St. Joe, FL. Lithium is recovered from brine near Clayton Valley, NV.⁹⁸

Economic Evaluation

It is true that market demand fluctuates with supply; therefore, any company considering an enterprise to

recover minerals from brines should make an in-depth study of the current and potential economics. Some of the factors that must be determined are (1) concentrations of valuable minerals in a brine, (2) amount of brine available, (3) costs of gathering the brine, (4) costs of recovering the minerals from the brine, (5) present and potential market demand for the recovered minerals, and (6) costs of delivering the minerals to the market.²⁶

Chapter 25

Phase Behavior of Water/Hydrocarbon Systems

Riki Kobayashi, Rice U. *

Kyoo Y. Song, Rice U.

E. Dendy Sloan, Colorado School of Mines

Introduction

The occurrence of water with hydrocarbons both in the reservoir and in the produced states represents the norm. Even though streams saturated with water enter the producing tubing, subsequent cooling generally produces separate phases of low mutual solubilities. Nevertheless, the mutual solubility of water and hydrocarbons is extremely significant in the processing of produced fluids. In the reservoir, their mutual solubilities increase as the temperature increases, either as a result of reservoir depth or external heating, as in the case of a steamflooding operation. Thus, the definition of the saturated water content in the equilibrium phases is the subject of this chapter. The coexisting phases may be gas, G , hydrocarbon-rich liquid, L_{HC} , water-rich liquid, L_w , or hydrate, H , although the coexisting phases are seldom pure. The advent of EOR processes that use CO_2 gives rise to the occurrence of a CO_2 -rich liquid phase, which we designate L_{CO_2} .

General Hydrocarbon/Water Phase Diagrams and Equilibrium Data Sources

For a given mixture of oil, water, and gas, the definition of the phases in equilibrium at any given pressure and temperature is of importance to the reservoir engineer. The prediction of the extent, composition, and other equilibrium properties of the phases in equilibrium is the objective of thermodynamic calculations. Given the number of components in the mixture and the number of coexisting phases, the number of independent variables that must be specified to describe the system (thermodynamically) is given by the phase rule of Gibbs,¹

which states that the “degrees of freedom” or number of independent variables required to define the system, F , equals the number of components, C , minus the number of phases, $P+2$, or $F=C-P+2$. A few examples given this important relationship are summarized in Table 25.1.

The phase rule is essentially a “rule of algebra” applied to equations of equilibrium and as such does not specify which phases are in equilibrium or their equilibrium concentrations. Nevertheless, its value in the organization of knowledge regarding phases in equilibrium and their relationship is important and always should be respected and used.

The pressure-temperature projection of the univariant coexistence lines of binary hydrocarbon/water systems represents a unique way of summarizing the phase behavior of the system. The methane/water system is one in which the critical point of the gas falls far below the ice point. With high pressures, even at moderate temperatures, solid hydrates are formed. The pressure-temperature projection of the system is given by Fig. 25.1.² Of particular interest to petroleum production engineers is the precise location of the L_w - H - G line or the initial hydrate formation condition. Since natural gases vary in composition, the L_w - H - G line is usually compositionally dependent.

Fig. 25.2 shows a constant-pressure trace of the saturation conditions of the methane/water binary system at a constant pressure exceeding the critical pressure of methane. Among the important features of this diagram are the dissolved gas concentration of the water-rich liquid phase (e.g., at Point 4), the equilibrium dewpoint locus, the initial hydrate formation temperature along the horizontal line 7-2-5-6, and the equilibrium and

*Authors of the original chapter on this topic in the 1962 edition were John J. McKetta and Albert H. Wehe.

3	4	1

metastable dewpoint locus (Line 7-8) below the initial hydrate formation temperature and below the stable dewpoint line. The definition of the equilibrium dewpoint water content for methane has been determined by Olds *et al.*³ and the initial hydrate formation condition by Villard,⁴ Deaton and Frost,⁵ Kobayashi and Katz,² and Marshall *et al.*⁶

The definition of the gas-hydrate equilibrium locus, as distinguished from the metastable equilibrium locus erroneously reported in most dewpoint charts, has been reported by Sloan *et al.*⁷ The measurement of the gas hydrate compositions or hydrate numbers for methane was conducted successfully by Galloway *et al.*⁸ and found in essential agreement with the statistical

mechanical theory of van der Waals and Platteeuw,⁹ as applied by Saito *et al.*²⁰⁰ as well as Parrish and Prausnitz,¹⁰ and other subsequent workers.

The second type of pressure-temperature projection presented is for the propane-water system in which the critical temperature of the hydrocarbon exceeds the ice point. Since the aqueous and hydrocarbon-rich phases exhibit low mutual solubilities, a three-phase $H-L_w-G$ condition occurs in the neighborhood of the vapor pressure of condensable hydrocarbons such as propane.

Fig. 25.4 presents a constant-pressure trace of Fig. 25.3 at a pressure less than the critical pressure of propane (Kobayashi¹¹). The principal qualitative difference between Figs. 25.2 and 25.4 is the existence of the $L_{HC}-G$ region in the latter that is absent in the former, at least at moderate temperatures. Note that in the $L_{HC}-G$ region of Fig. 25.4, the water concentration of the gas phase is larger than in the equilibrium liquid phase at the same temperature. On the contrary, in the $G-L_w$ region, the water concentration in the saturated gas is rather less than in the equilibrium water-rich liquid phase.

Owing to the differences in the molecular sizes of methane and propane, the hydrate structures of methane hydrate (Structure I) and of propane hydrate (Structure II) are quite different.

By using phase diagrams such as Figs. 25.2 and 25.4, it is possible to trace the phase transitions one would expect to encounter for various composition mixtures as the temperature of the system is lowered. It is important to note that hydrates can form directly from the fluid hydrocarbon phase (i.e., in the absence of free liquid

Fig. 25.1—Pressure-temperature projection of univariant heterogeneous equilibrium in the methane-water system.

Fig. 25.2—Constant-pressure trace of the methane/water system at a pressure greater than the methane critical pressure.

Fig. 25.3—Pressure-temperature projection of univariant heterogeneous equilibrium in the propane-water system.

Fig. 25.4—Constant-pressure trace of the propane/water system at a pressure less than the propane critical pressure.

water at low water compositions) provided that the temperature is sufficiently low and turbulence is present or the equilibration times are large, as shown by Cady.¹² The metastable dewpoint line shown in Fig. 25.2 (Line 7-8) rather than the true equilibrium state may be attained under certain situations to give a false or metastable indication of equilibrium (Kobayashi and Katz¹³).

References for aqueous/volatile-gas systems related to petroleum production are listed in the references at the end of the chapter. These are for methane/water system (Refs. 3 and 14 through 44), natural-gas/water (Refs. 13 and 45 through 52), CO₂/water (Refs. 31, 44, and 53 through 96), and for nitrogen/water (Refs. 24, 31, 33 through 36, 62, and 97 through 120). References for other binary and ternary hydrocarbon/water systems are listed in the general references.

References for hydrate/volatile-gas systems are for methane/water (Refs. 2, 4, 6 through 8, and 121 through 129), natural-gas/water (Refs. 126 and 130 through 135), CO₂/water (Refs. 5 and 136 through 139), and nitrogen/water (Refs. 6, 140, and 201). References for other binary and ternary hydrocarbon/hydrate systems are listed in the general references.

As shown in Figs. 25.1 through 25.4 for the methane/water and propane/water systems, the phase behavior of such systems is complicated by the existence of multiphase equilibria, including solid phases such as hydrate or ice. The former phase is particularly troublesome in petroleum production since solid hydrates can form at temperature above the ice point wherein the concentration of water in the system is quite low. Fig. 25.5 presents the univariant three-phase loci for various binary hydrocarbon/water systems and shows their critical hydrate formation loci (solid lines).

The variability of the water content of hydrocarbon-rich phases for a condensable system perhaps is illustrated best by Fig. 25.6, which shows the concentration of water in the propane-rich phases in the propane/water system. In the low-pressure gaseous region the water content is determined primarily by the vapor pressure of water, whereas in the condensed propane region the solubility of water in the propane-rich liquid phase is determined by the strong repulsion of water by the hydrocarbon owing to the thorough hydrogen-bond-breaking ability of the condensed hydrocarbon phase. This phenomenon can be illustrated further by Fig. 25.7, a composite plot of the activity coefficient of water at

Fig. 25.5—Hydrate-forming conditions for paraffin hydrocarbons.

moderate pressures from hydrocarbon molecules vs. temperature for molecules ranging from propane to liquids as heavy as naphtha and SAE 20 lubricating oil.¹⁴¹ Fig. 25.7 also shows that at higher temperatures water becomes increasingly miscible with hydrocarbons, with total miscibility conditions having been reported for intermediate-range hydrocarbons. This phenomenon, which is relevant to high-pressure steamfloods, also is illustrated by Fig. 25.8, which gives their three-phase miscibility conditions.¹⁴²

In addition to fluid condensed phases, as the pressure is increased and the temperature decreased, nonpolar molecules and weakly ionizing molecules of appropriate molecular sizes form solid gas hydrates. Davidson¹⁴³ presents the approximate molecular diameters and structure type of the hydrate formers and their theoretical hydrate chemical formulas.

Hydrate Stability Conditions

Table 25.2 presents the physical data of the two known hydrate lattices, the diamond type or structure II hydrate, and the body-centered type or Structure I hydrate. Owing to their critical sizes, some molecules, such as cyclopropane, stabilize both hydrate Structures I and II at higher temperatures but only Structure II at lower temperatures with a phase transition temperature in between (see Sloan¹⁴⁴).

Fig. 25.7—Composite activity coefficient plot for water in hydrocarbon systems.

Estimating Initial Hydrate Formation

The estimation for the stability conditions of the hydrates when liquid water is present, the L_w - H - G equilibrium locus, can be estimated by various means.

Sweet Natural Gas Systems Method. The initial hydrate formation condition can be estimated for sweet natural gas systems by using pressure, temperature, and gas gravity as parameters (see Katz^{145,146}) as shown in Figs. 25.9 and 25.10. These figures should be confined for usage when the natural gas mixtures are similar to those used in developing them, with data taken from Deaton and Frost,⁵ Wilcox *et al.*,¹³⁵ Kobayashi and Katz,² and Katz.¹⁴⁵ Typical compositions of natural gases corresponding to gas gravities of Fig. 25.9 are given in Table 25.3. It should be noted that no H_2S or CO_2 content is tolerated by the correlations.

Vapor/Solid Equilibrium Ratios Method. The second approach involves the development and application of vapor/solid equilibrium ratios for gas/liquid/hydrate equilibrium (Carson and Katz,¹⁴⁷ Unruh and Katz,¹³⁹ Noaker and Katz,¹⁴⁸ Robinson,¹⁴⁹ and Robinson and Ng¹⁵⁰), as shown in Figs. 25.11 through 25.16. The development of the vapor/solid K -values involved experimental hydrate formation conditions for mixtures of methane with other gas(es) and the hypothesis that hydrates could be treated as solid solutions, in hindsight a brilliant hypothesis. The vapor/solid $K_{i(v-s)}$ values are used to calculate the hydrate "frost point" in direct analogy with dewpoint calculations:

$$K_{i(v-s)} \equiv \frac{y_i}{x_i}$$

where $K_{i(v-s)}$ is the vapor/solid equilibrium values of component i , y_i is the mole fraction of component i in the vapor phase, and x_i is the mole fraction of component i in the solid phase, so that

$$\sum_{i=1}^n y_i / K_{i(v-s)} = 1.0. \quad (1)$$

An example calculation for a complex mixture is presented in Table 25.4.¹⁴⁴ As suggested, the K -value of n -butane is taken numerically as that for ethane.

Statistical Mechanics for Adsorption Approach. A third method of estimating initial hydration formation involves the application of statistical mechanics (van der Waals and Platteeuw¹⁵¹) in well-defined hydrate cages as determined by X-ray crystallography by von Stackelberg and Müller^{152,153} and others. The theory of van der Waals and Platteeuw was applied to predict the initial hydrate formation of pure gases at temperature above the ice point by Marshall *et al.*⁶ and later to binary mixtures by Saito and Kobayashi.¹⁵⁴ Nagata and Kobayashi¹⁵⁵ used the Kihara potential to calculate the dissociation pressures of hydrates, following the earlier work of McKoy and Sinanoglu.¹⁵⁶ A more convenient estimation method for hydrate decomposition conditions

Fig. 25.8—Composition of hydrocarbon-rich phase at three-phase critical conditions.

was developed by Parrish and Prausnitz,¹⁰ using the Kihara potential and the method of van der Waals and Platteeuw.⁹

Computer Method For Hydrate Dissociation Predictions. Parrish and Prausnitz Development.¹⁰ The method of van der Waals and Platteeuw as developed by Parrish and Prausnitz is slightly more complex than the previous method, but it has two considerable advantages: (1) the equations are related to the microscopic hydrate structure, and (2) the theoretical nature of the model allows it to be extended beyond the G - L_w - H region.

Fig. 25.9—Initial hydrate-formation conditions for natural gases with varying gas gravities.

In the late 1940's and early 1950's the molecular structures of hydrates, shown in Table 25.2, were studied through the use of X-ray diffraction.^{152,153} The structural determination enabled van der Waals and Platteeuw⁹ to develop a model for the prediction of hydrate dissociation pressure at any temperature. Their basic equation looks complex until one considers it as being very similar to the basic equation for the chemical potential of Component 1 in a mixture of Components 1 and 2. This equation, which relates the chemical potential of

component i , μ_i , to the activity of a component is

$$\mu_i = \mu_i^0 + RT \ln a_i, \dots \dots \dots (2)$$

where

μ_i^0 = chemical potential of pure component i ,

R = universal gas constant,

T = absolute temperature, and

a_i = activity of component i in mixture.

Van der Waals and Platteeuw used theory to derive a similar equation for the chemical potential of water in the hydrate structure as follows.

$$\mu_{wH} = \mu_{wMT} + RT \sum_i n_{ci} \ln \left(1 - \sum_j y_{ji} \right), \dots \dots (3)$$

where

μ_{wH} = chemical potential of water in filled hydrate,

μ_{wMT} = chemical potential of water in empty hydrate,

n_{ci} = number of cavities of type i per water molecule in basic lattice, and

y_{ji} = fractional occupancy of type i cavity by type j molecule.

Fig. 25.16—Vapor/solid equilibrium constants for hydrogen sulfide.

The second term on the right accounts for hydrocarbon filling of the lattice. The term y_{ji} is given by

$$y_{ji} = \frac{C_{ji}f_j}{1 + \sum_k C_{ki}f_k}, \quad \dots \dots \dots (4)$$

where C_{ji} is a unique function of temperature for each guest molecule in each size cavity, f_j and f_k are the fugacities of j and k in the gas phase, and k is ordered from one to the number of components.

The fugacity term is determined by an equation of state (EOS), such as Peng-Robinson (PREOS).¹⁵⁷ The C_{ji} functions may be calculated using the Lennard-Jones-Devonshire spherical cell model. The interaction between the guest molecule and a uniform spherical surface representing the cage commonly is described by a Kihara potential function. The method is described by Parrish and Prausnitz.¹⁰ The Kihara parameters are determined from single or binary gas dissociation conditions and then may be used to predict dissociation conditions for multicomponent gases. A fit of C_{ji} for common gases is given in Table 25.5.

To predict hydrate formation conditions from liquid water and gas, the following conditions must be satisfied.

$$\mu_{wL} = \mu_{wH} = \mu_{wg}, \quad \dots \dots \dots (5a)$$

$$T_L = T_H = T_g, \quad \dots \dots \dots (5b)$$

and

$$p_L = p_H = p_g, \quad \dots \dots \dots (5c)$$

where p is the absolute pressure and subscripts L , H , and g are liquid water, hydrate, and gas, respectively.

*Dharmawardhana.¹⁵⁶**Weiler.¹⁵⁹

Eq. 5a may be combined with Eqs. 3 and 2 to obtain

$$\Delta\mu_w = \mu_{wMT} - \mu_{wL} = -RT \sum_i n_{ci} \ln \left(1 - \sum_j y_{ji} \right) + RT \ln a_i, \dots\dots\dots(6)$$

where $\Delta\mu_w$ is the difference in chemical potential of pure water and a_i accounts for the normally small solubility of the guest gas in the aqueous phase. Now given T , p , and f_j , one may calculate $\Delta\mu_w$ in Eq. 6 by using Eq. 3 and the Kihara potential. However, the $\Delta\mu_w$ obtained are useless until they are matched to the $\Delta\mu_w$ from the following equation.

$$\frac{\Delta\mu_w(T, p)}{RT} = \frac{\Delta\mu_w(T_o, p_o)}{RT} - \int_{T_o}^T \frac{\Delta h_w}{RT^2} dT + \int_{p_o}^p \frac{\Delta v_w}{RT} dp, \dots\dots\dots(7)$$

where

- T_o = reference temperature,
- p_o = reference pressure,
- Δh_w = specific enthalpy difference, and
- Δv_w = specific volume difference.

Eq. 7 corrects a chemical potential difference at a standard T_o (0°C) and p_o (0 atm), $\Delta\mu_w(T_o, p_o)$ for the change in temperature and pressure of the hydrate of interest. The constants $\Delta\mu_w(T_o, p_o)$ and $\Delta h_w(T_o)$, measured recently by Dharmawardhana¹⁵⁸ and Weiler,¹⁵⁹ and parameters for Langmuir constants are given in Table 25.5.

Procedure for Determining Hydrate Formation Pressure. The procedure for determining hydrate formation pressures for a given gas at a given temperature is as follows.

1. Estimate a pressure, p .
2. At the estimated pressure, for the given temperature and gas mole fraction of component j , determine the fugacity of j from an EOS, such as PREOS.¹⁵⁷
3. By using C_{ji} values from the Kihara potential and y_{ji} values from Eq. 4, determine $\Delta\mu_w$ from Eq. 3.
4. By using constants from Table 25.5, calculate $\Delta\mu_w$ from Eq. 7 at the temperature and estimated pressure.
5. If the $\Delta\mu_w$ values for Eqs. 6 and 7 are equal, then the p value is correct for hydrate formation. If not, estimate a new value of p and return to Step 2.

A computer program that performs the above procedure has been written by Ng and Robinson and is available commercially through the Gas Processors Assn. (GPA). A second hydrate program generated by Erickson and Sloan¹⁶⁰ at the Colorado School of Mines is also available through GPA.

That the model predicts the three-phase data accurately is demonstrated in Fig. 25.17 for the methane/propane system. The dramatic decrease of dissociation pressure for a 1% addition of propane is evidence that the hydrate has changed structure (from I to II) as mentioned earlier. In other words, as small amounts of propane are added, a greater temperature at constant pressure is tolerated for hydrate formation.

Fig. 25.18 also demonstrates the accuracy of the model while indicating that hydrates denude the gas of propane. At 5 atm, while the gas phase has about 8% propane, the solid phase has 50% propane. From Figs. 25.17 and 25.18 and typical earth temperature gradients, Davidson¹⁶¹ proposed the following in-situ, onshore hydrate conditions.

Going toward the center of the earth, one may encounter Structure II hydrate at relatively shallow depths until the point at which the hydrate denudes the gas of propane. No more hydrate is encountered until the range of Structure I stability conditions is obtained. Continuing downward from the Structure I region no hydrates are encountered. Finally, a Structure II region is realized for gases rich in propane.

Fig. 25.17—Hydrate formation conditions for the methane/propane/water system.

Fig. 25.18—Pressure-composition diagram for the methane/propane/water system.

Determining the Water Content of Gas (or Hydrocarbon-Rich Liquid) in Equilibrium with Hydrates

The position of lines $G-H$ and $L_{HC}-H$ in Figs. 25.2 and 25.4 determines the extent to which the hydrocarbon must be dried to prevent the formation of hydrate from the gas phase. The water content in this region is relatively small and difficult to measure. Until recently, straight lines (log water content vs. $1/T$ from the gas/liq-uid region were extrapolated into the gas/hydrate region with only limited experimental justification. However, as indicated by Kobayashi and Katz,¹³ thermodynamics tells us that such concentration extrapolations across phase boundaries yield severe errors. This observation, that straight-line extrapolation into the gas hydrate region represents gas in equilibrium with metastable liq-uid water, explains the field data anomalies observed by

Records and Seely.¹⁶² Laboratory confirmation that the water content of gas in equilibrium with hydrate should be much different from the extrapolated values has been verified by Sloan *et al.*⁷ for methane hydrates, and Song and Kobayashi¹⁶³ for methane/propane hydrates.

When one predicts the water content of a single fluid phase, such as a fluid, in equilibrium with hydrates, the basic equation is as follows.

$$f_{wf} = f_{wH}, \quad (8)$$

where f_{wf} is the fugacity of water in the fluid phase and f_{wH} is the fugacity of water in the hydrate phase.

In this equation the fugacity of water in the fluid phase is determined from

$$f_{wf} = y_w K_{wf} p, \quad (9)$$

Fig. 25.19—Structure I empty hydrate vapor pressure as a function of reciprocal temperature.

Fig. 25.20—Structure II empty hydrate vapor pressure as a function of reciprocal temperature.

where K_{wf} is the fugacity coefficient* of water (determined by an EOS) and y_w is the mole fraction of water in the hydrocarbon.

The value y_w is the solution to this problem, stated as: given a flowing hydrocarbon at T and p , determine how much the fluid should be dried to prevent hydrate formation.

The quantity f_{wH} in Eq. 8 is determined by

$$f_{wH} = f_{wMT} \exp(-\Delta\mu_w/RT), \quad \dots\dots\dots (10)$$

where f_{wHT} is the fugacity of water in empty hydrate.

Ng and Robinson¹⁶⁴ give an expression for f_{wMT} in both structures, obtained by fitting the vapor/hydrate data of Kobayashi *et al.*^{7,121,165} Therefore, their method may be considered a correlation of existing two-phase (vapor/hydrate) data.

By equating the fugacity of hydrate to ice in three-phase data, Dharmawardhana¹⁵⁸ showed that f_{wMT} of Eq. 10 can be expressed as an empty hydrate vapor pressure as follows:

$$p_{vI} K_{fI} \exp \frac{V_I(p - p_I)}{RT} = p_{vMT} K_{fMT} \exp(\Delta\mu/RT), \quad \dots\dots\dots (11)$$

where

- p_{vI} = vapor pressure of ice,
- K_{fI} = fugacity coefficient of ice,
- V_I = volume of ice,
- p_I = vapor pressure of ice,
- p_{vMT} = vapor pressure of empty hydrate, and
- K_{fMT} = fugacity coefficient of empty hydrate.

*In some prior publications, ϕ was used as the symbol for fugacity coefficient.

In this equation, all of the ice properties are well known, the $\Delta\mu$ is obtained from three-phase data fit to Eqs. 3 and 4; the only unknown is p_{vMT} , which was fit to a number of hydrates' three-phase data below 273 K and found to be a single function of temperature; Figs. 25.19 and 25.20 show these values for empty hydrate vapor pressure as determined from a number of hydrates. Recent work at the Colorado School of Mines has shown the method represented by Eqs. 9 and 10 and Figs. 25.19 and 25.20 to represent the water-in-liquid hydrocarbon/hydrate equilibria accurately.

Hydrate Formation on Expansion of Gases

The simultaneous solution of the isenthalpic (throttling) expansion of natural gases with initial hydrate formation conditions, Fig. 25.9 yields a first approximation of the prediction of permissible expansions. Katz¹⁴⁵ presented a useful chart for various gas gravities of natural gases.

Definition of the Saturated Water Content of Natural Gases in Equilibrium With Aqueous Phases

The saturated water content of natural gases in equilibrium with aqueous phases generally is presented in the familiar dewpoint chart. Fig. 25.21 presents a dewpoint chart for methane-rich gases synthesized from several sources of data. The upper limit of the dewpoint chart given in Fig. 25.21 is defined by the properties of steam. Fig. 25.22 presents a correction to Fig. 25.21 caused by the hydrate formation of methane gas, and a mixture of methane and propane gas. The water content at temperatures above the hydrate stability conditions up to 10,000 psia are based primarily on the data of Olds *et al.*³ At temperatures below the initial hydrate formation

Fig. 25.21—Dewpoint water content chart for methane-rich gas.

conditions, the data are primarily those measured by Skinner.¹⁶⁶ However, below the initial hydrate formation conditions, as initially observed (in the gas fields) by Records and Seely,¹⁶² Fig. 25.21 presents metastable values. Using the hydrate theory discussed previously, and recent measurements on the water content of two gases (a methane/5.31-mol% propane and a pure methane in the gaseous state in equilibrium with hydrates), a corrective correlation to Fig. 25.21 in the gas/hydrate region was developed.

A typical replacement chart is shown in Fig. 25.22.¹⁶³ In this figure the high-temperature vapor/liquid-water region is separated from the low-temperature vapor/hydrate region by a line representing the three-phase (vapor/liquid-water/hydrate) boundary. The isobaric data in the vapor/hydrate region follow semilogarithmic straight lines when plotted against reciprocal temperature, but these lines have slopes different from the straight lines in the vapor/liquid-water region. In addition, the three-phase lines are indicated to be a function of gas composition, so that the change in the slope of an isobar from the vapor/liquid region occurs at different temperatures. With the above complexities, a comprehensive water content chart (or series of charts) for gases of differing compositions would be cumbersome. Instead, a mathematical method for determining the water content of gases in the vapor/hydrate region is used.

Fig. 25.22—Depression of metastable dewpoint below initial hydrate temperature.

Steps in Determining the Water Content of Vapor in Equilibrium with Hydrates

The method for determining the water content of vapor in equilibrium with hydrates, at a given temperature and pressure, is composed of six steps.

1. Calculate the metastable water content at the temperature and pressure of interest by using Eq. 12.
2. Calculate the three-phase temperature at the pressure and gas gravity of interest by using Eq. 13. Obtain the temperature difference (ΔT) by subtracting the temperature of interest from the calculated three-phase temperature.
3. Calculate the displacement from the metastable water content (ΔW) at the above ΔT and pressure of interest using both Eq. 14a for methane and Eq. 14b for a 94.69-mol% methane/5.31-mol% propane mixture.
4. Calculate the ΔW for the gas composition of interest by a linear interpolation between the ΔW for methane (gravity=0.552) and the ΔW for the mixture containing 5.31% propane (gravity=0.603), using gravity as an interpolation parameter.
5. Calculate the equilibrium water content by subtracting the ΔW value obtained in Step 4 from the metastable water value obtained in Step 1.
6. Consider the range of data used to fit Eqs. 12, 13, 14a, and 14b, as discussed later, to determine whether the answer obtained in Step 5 is within the bounds of the correlation.

Equations for Determining the Water Content of Vapor in Equilibrium with Hydrates

In the following equations, the pressure is expressed in psia, the temperature in degrees Rankine, and the water content is expressed in pounds of water per million cubic feet of gas at 1 atm and 60°F. A listing of the coefficients in each equation is found in Table 25.6.

Fit of Methane-Rich Gas (Fig. 25.21). The following equation, which is a fit of Fig. 25.21, is in the pressure range of 200 to 2,000 psia, and in the temperature range of -40 to 120°F, for metastable water content, W_{ms} , as a function of temperature, T , and pressure, p :

$$W_{ms} = \exp[C_1 + C_2/T + C_3(\ln p) + C_4/T^2 + C_5(\ln p)/T + C_6(\ln p)^2], \dots (12)$$

where $C_1 \dots C_6$ are obtained from Table 25.6.

Fit of Three-Phase (Vapor/Liquid/Hydrate) Formation Conditions. The three-phase condition was fit in the temperature range of 34 to 62°F, the pressure range of 65 to 1,500 psia, and the gas gravity, γ , range from 0.552 to 0.9. Only hydrocarbons were used in the fit, and gases containing CO₂ and hydrogen sulfide were excluded specifically.

$$T = 1/[C_1 + C_2(\ln p) + C_3(\ln \gamma) + C_4(\ln p)^2 + C_5(\ln p)(\ln \gamma) + C_6(\ln \gamma)^2 + C_7(\ln p)^3 + C_8(\ln p)^2(\ln \gamma) + C_9(\ln p)(\ln \gamma)^2 + C_{10}(\ln \gamma)^3 + C_{11}(\ln p)^4 + C_{12}(\ln p)^3(\ln \gamma) + C_{13}(\ln p)^2(\ln \gamma)^2 + C_{14}(\ln p)(\ln \gamma)^3 + C_{15}(\ln \gamma)^4], \dots (13)$$

where $C_1 \dots C_{15}$ are obtained from Table 25.6.

Fit of Water Content Suppression. The suppression of the water content from the metastable region, ΔW , was

fit as a function of pressure and of the temperature difference from the three-phase condition, ΔT , for both methane and a mixture containing 5.31 mol% propane. The fit for methane was in the pressure range of 500 to 1,500 psia and in the temperature range of -28 to 26°F; coefficients for methane in the following equation are labelled Eq. 14a in Table 25.6. The fit for the mixture was in the pressure range of 500 to 1,500 psia, and in the temperature range of -38 to 40°F; coefficients for the mixture are labelled Eq. 14b in Table 25.6. The general regression equation for both gases is:

$$\begin{aligned} \Delta W = & \exp[C_1 + C_2(\ln p) + C_3(\ln \Delta T) + C_4(\ln p)^2 \\ & + C_5(\ln p)(\ln \Delta T) \\ & + C_6(\ln \Delta T)^2 + C_7(\ln p)^3 \\ & + C_8(\ln p)^2(\ln \Delta T) \\ & + C_9(\ln p)(\ln \Delta T)^2 + C_{10}(\ln \Delta T)^3 + C_{11}(\ln p)^4 \\ & + C_{12}(\ln p)^3(\ln \Delta T) + C_{13}(\ln p)^2(\ln \Delta T)^2 \\ & + C_{14}(\ln p)(\ln \Delta T)^3 + C_{15}(\ln \Delta T)^4], \dots (14) \end{aligned}$$

Example Calculation of Water Content of a Vapor in Vapor/Hydrate Region. Determine the water content of a gas whose gravity is 0.575 in equilibrium with hydrate at 1,000 psia and 8.4°F.

1. The metastable water content of the gas is calculated from Eq. 12 at 1,000 psia and 8.4°F as 2.745 lbm/10⁶ scf.

2. The three-phase temperature at 1,000 psia is calculated to be 60.35°F from Eq. 13. The ΔT value is 51.95°F.

3. The displacement from the metastable condition is calculated for methane to be 0.653 lbm/10⁶ scf from Eq. 14a. The displacement from the metastable condition is calculated for the mixture containing 5.31 mol% propane as 1.55 lbm/10⁶ scf from Eq. 14b.

4. An interpolation between the values obtained in Step 3 (based on gas gravity) is done to determine the displacement for a gas with a gravity of 0.575. The resulting displacement is 1.0575 lbm/10⁶ scf.

Fig. 25.23—Depression of metastable dewpoint below ice temperature.

Fig. 25.24—Correction to water content for natural gas in equilibrium with brines.

Fig. 25.25—Water content per cubic feet of volume occupied by various gases at system pressure and temperature.

5. The displacement in Step 4 is subtracted from the metastable value in Step 1 to obtain a water concentration of $1.687 \text{ lbm}/10^6 \text{ scf}$. The 0.575-gravity gas must be dried to less than $1.687 \text{ lbm}/10^6 \text{ scf}$ to prevent hydrate formation at 1,000 psia and 8.4°F .

6. A check of the conditions of regression of Eqs. 12 through 14 indicates that the correlation should apply for the conditions of the example.

Fig. 25.23 presents the corrective correlation below the ice/gas region. Fig. 25.24 gives corrections to Fig. 25.21 from the salinity of the aqueous phase. The work of Deaton and Frost⁵ indicated that the water content of gases in equilibrium with liquid water fall in the order

$$y_{\text{He}} < y_{\text{Air}} < y_{\text{CH}_4} < y_{\text{NG}} < y_{\text{CO}_2}$$

where y is the mole fraction of water in each subscripted gas at the same pressure and temperature as shown in Fig. 25.25. The water content of nitrogen up to moderate pressures has been reported by Rigby and Prausnitz.³⁴ No data exist, however, on the water content of nitrogen in equilibrium with hydrates.

The water content of liquid and gaseous CO_2 in equilibrium with hydrates has become increasingly more important in the development of EOR technology.

Fig. 25.26 presents a pressure-temperature projection of the univariant loci for the CO_2 /water system. It defines both the univariant and two-phase regions presently being studied and the regions over which the various combinations of binary equilibrium exist. Like

propane, the location of the critical point of CO₂ relative to the $H-L_w-G$ line results in an invariant quadruple point in which $H-L_w-L_{CO_2}-G$ coexist, the hub from the other four univariant three-phase lines emanate.

A second quadruple point involving $H-I-L_w-G$ exists at lower pressure in the neighborhood of the ice point.

The pioneering work of Wiebe and Gaddy provides extensive data on the solubility of CO₂ in water^{90,91} and the vapor-phase composition of CO₂/water mixtures.⁹² The measurements were confined to temperatures exceeding the initial hydrate formation condition. Measurement of the water concentration of gas and liquid in equilibrium with hydrates currently is being pursued by Song and Kobayashi.^{137,138} By using the vapor pressure of water or metastable liquid water given in Table 25.7, the experimental data from several sources have been presented as enhancement of the vapor pressure resulting from the CO₂ pressure on the system (Fig. 25.27). In Fig. 25.27, p is the total pressure, p_w^0 is the saturation pressure of water, and y_w is the mole fraction of water. The water content of coexisting CO₂-rich liquid and gas along the three-phase region is shown as a loop terminating at its three-phase critical point in the neighborhood of the critical temperature of CO₂. Fig. 25.27 shows that the enhancement of the water vapor pressure is favored by lower temperatures and high pressure, variables that also favor a substantial increase in the density of fluid CO₂. It is noted that the solubility of water in liquid CO₂ is greater than in gaseous CO₂ at the same pressure and temperature, precisely the reverse of the solubility sequence for liquid and gaseous hydrocarbons. This phenomenon is related to the excessive collection of water in the middle of a distillation column separating a CO₂-rich feed from its associated LPG constituents.

Fig. 25.28 presents the water content of CO₂ vs. inverse absolute temperature along isobars demonstrating the complexity of the system. The curves show a break downward at the initial hydrate formation conditions as methane and natural gases.

Fig. 25.28—Water content of CO₂ vs. inverse absolute temperature along isobars.

Fig. 25.29—The effect of molecular weight on the water content in the vapor phase (from Ref. 167).

Quantitative Prediction of Water Content in Light Hydrocarbon Systems

A systematic study of the effect of molecular weight on the water content of the vapor phase made by McKetta and Katz^{52,167} is given in Fig. 25.29. The effect of molecular weight is seen to be most pronounced at the highest temperature of the study, 280°F.

The solubility of water in various liquid hydrocarbons at their vapor pressures is presented in Fig. 25.30.

Fig. 25.30—The solubility of water in various liquid hydrocarbons at their vapor pressures.

In recent years estimations of water in both the non-aqueous and aqueous phases in both the two- and three-phase regions have been carried out successfully by Peng and Robinson,¹⁶⁸ Baumgaertner *et al.*,¹⁶⁹ and Moshfeghian *et al.*¹⁷⁰ In these exercises various EOS's were used—the PREOS (Peng-Robinson equation of state),¹⁵⁷ the Schmidt-Wenzel EOS,¹⁶⁹ and the PFGC-MES (Parameter from Group Contribution—Moshfeghian, Erbar, Shariot) EOS.¹⁷⁰ Collectively, these correlation procedures are able to describe vapor/liquid equilibria in systems as diverse as $\text{CH}_4/\text{H}_2\text{O}$, $\text{C}_2\text{H}_6/\text{H}_2\text{O}$ through $\text{n-C}_8\text{H}_{18}/\text{H}_2\text{O}$, $\text{N}_2/\text{H}_2\text{O}$, $\text{CO}_2/\text{H}_2\text{O}$, $\text{CO}/\text{H}_2\text{O}$, $\text{O}_2/\text{H}_2\text{O}$, $\text{H}_2/\text{H}_2\text{O}$, $\text{C}_6\text{H}_6/\text{H}_2\text{O}$, air/ H_2O , $\text{H}_2\text{S}/\text{H}_2\text{O}$, and $\text{NH}_3/\text{H}_2\text{O}$. Both the PREOS and PFGC-MES EOS require temperature-dependent interaction parameters, while the method of Baumgaertner *et al.*¹⁶⁹ describes the water structure in terms of its degree of polymerization in the liquid as a function of the temperature. Examples of the successful application of the calculational method to multicomponent systems by Moshfeghian *et al.*¹⁷⁰ are reported.

Quantitative Predictions of Solute Concentrations in the Aqueous Phase

General references are presented for the solubility of various gases in water, along with other types of data on aqueous systems. The low-pressure references are included because of their contributions to calculational methods for sour water systems.

Fig. 25.31—The solubility of methane in water.

Fig. 25.31 presents the volumetric solubility of methane in water to 10,000 psia as measured by Culbertson and McKetta.¹⁷ The solubility of methane increases monotonically with pressure but shows a relative minimum with respect to temperature as do the Henry's law constants.¹⁴² Dodson and Standing,⁴⁵ on the other hand, presented the solubility of a typical natural gas in water and gave corrections for the solubility due to brine salinity, Fig. 25.32. The relative solubility of gas in brine relative to its solubility in pure water is given in Fig. 25.32.

The analytical prediction of the solubility of nonpolar or low-polarity solutes in water can be used by the application of the relationships introduced by Krichevskii and Kasarnovskii¹⁷¹ and Wiebe and Gaddy,⁹⁰ which were later applied by Kobayashi and Katz¹⁴² and Leland *et al.*¹⁷² to condensing light-hydrocarbon systems.

The expression is given as follows.

$$\ln \left(\frac{\hat{f}_1}{x_1} \right) - \ln K_H = \frac{\hat{V}_{M1}}{RT} p_t p_{vs}, \dots (15)$$

where

\hat{f}_1 = partial fugacity of the solute in water at T and p_t ,

K_H = an empirical constant that is a function of temperature only but is equal numerically to Henry's law constant for noncondensable gases and a hypothetical Henry's law constant for condensable gases,

x_1 = mole fraction of the dissolved solute,

R = gas constant per mole,

\hat{V}_{M1} = partial molal volume of components in the solution,

T = absolute temperature,

p_t = total pressure, and

p_{vs} = vapor pressure of the solvent for a noncondensable gas, but equal to some constant pressure slightly above the three-phase pressure determined from experimental data.

The usual absence of values for the partial volume of the solute \hat{V}_m precludes the application of Eq. 15. However, given a good set of experimental data to moderate pressures, Eq. 15 provides a good method of extending the solubility data to higher pressures, particularly if the solute remains essentially pure at the higher pressures. Fig. 25.33 gives an application of Eq. 15 to the aqueous phase of the propane/water system.¹⁴²

Examples of the agreement in the experimental and predicted water compositions are given for the methane/water^{38,40} and ethane/water^{173,174} and propane/water¹⁴² systems in Figs. 25.34 through 25.36 by Peng and Robinson.¹⁶⁸

Both the Peng-Robinson¹⁶⁸ and the Baumgaertner *et al.*¹⁶⁹ methods present successful predictions of the aqueous-phase concentrations as well as in the nonaqueous phase.

Sour Water Stripper Correlations

With the development of a collective environmental consciousness, waste disposal has become an integral part of

Fig. 25.32—Solubility of natural gas in water with correction for brine salinity.

Fig. 25.33—Solubility of propane in water to determine partial molar volume and Henry's law constant.

Fig. 25.34—Experimental and predicted vapor and liquid phase compositions for methane/water system at 250°C.

Fig. 25.36—Experimental and predicted water content of propane liquid and vapor phases along three-phase locus.

petroleum production and processing. From an experimental standpoint the developments have been spurred by the accumulation of experimental data typically encountered in sour water processes.¹⁷⁵⁻¹⁷⁸ Meanwhile, basic theoretical work had been laid for the interpretation of such data.¹⁷⁹⁻¹⁸² Interpretations of these and other theories are reviewed by Friedman and Krishnan,¹⁷⁹ Newman,¹⁸³ and Knapp and Sandler.¹⁸⁴

Thus, predictive methods have been developed to estimate vapor/liquid equilibria in complex mixtures containing such components as $\text{NH}_3/\text{CO}_2/\text{H}_2\text{S}$ (Wilson¹⁷⁵), $\text{N}_2/\text{CO}_2/\text{H}_2\text{S}/\text{CH}_4\text{OH}$ (Moshfeghian *et al.*¹⁷⁰), $\text{NH}_3/\text{H}_2\text{S}/\text{H}_2\text{O}$, $\text{NH}_3/\text{SO}_2/\text{H}_2\text{O}$, and $\text{NH}_3/\text{CO}_2/\text{H}_2\text{O}$ (Renon¹⁸⁵), $\text{NH}_3/\text{CO}_2/\text{H}_2\text{S}/\text{H}_2\text{O}$ (Mauerer¹⁸⁶), $\text{CO}_2/\text{NaCl}/\text{KCl}/\text{H}_2\text{O}$ (Chen *et al.*¹⁸⁷), and many others.¹⁸³ The calculations now enable the estimation of physical and chemical equilibria from purely aqueous to strong electrolyte solutions.

Oil and Gas Reservoirs That Exist in the Gas Hydrate Region

In recent years an increasing number of oil and gas reservoirs in the hydrated state have been discovered by Katz,¹⁸⁸ Stoll *et al.*,¹⁸⁹ Makogon *et al.*,¹⁹⁰ Bily and Dick,¹⁹¹ Verma *et al.*,¹⁹² Holder *et al.*,¹⁹³ and Trofimuk *et al.*¹⁹⁴ In fact, hydrate cores have been recovered from below the ocean floor in the Mid-American Trench off Central America.¹⁹⁵ A review of geologic occurrences of hydrates is presented by Kvenvolden and McMenamin.¹⁹⁶

In Feb. 1982 a hydrate core was recovered by the Deep Sea Drilling Project from the Mid-American Trench off Guatemala in 1718 m of water. All evidence to date indicates that these hydrates are of biogenic origin, since they are composed mainly of products from anaerobic digestion. These hydrates are of the Structure I form.

In May 1983 a second hydrate core was recovered by a Getty drilling operation from the Gulf of Mexico in 530 m of water. These hydrates are thermogenic in origin with probable prior biogenesis and have substantial amounts of ethane, propane, and isobutane. These hydrates are of the Structure II form.

Fig. 25.37—Effect of GOR on hydrate formation conditions for a 46.8°API oil in the presence of excess fluid brine.

Fig. 25.39—Crystallization temperatures of aqueous diethylene glycol solutions.

These natural hydrates bring many implications to mind; however, only a few will be outlined.

1. The simultaneous solution of hydrate formation for the occurrence of hydrates and earth temperature gradients yields possible environments for the occurrence of hydrates.

2. The potential reserve of natural gas existing in nature as solid hydrates is probably very enormous.

3. Petroleum reservoirs existing in the hydrate region may be denuded of a substantial amount of the lighter constituents and, thus, will be energy deficient for production by a gas-drive mechanism.

4. Waterflooding of dissolved gas reservoirs with near-freezing water may cause hydrate formation in the reservoir.

5. A tremendous amount of technological development will be necessary to unleash hydrocarbons from hydrated reservoirs.

Hydrate Inhibition

While crude oils may not inhibit hydrate formation per se, their oils with dissolved gases affect the initial hydrate formation significantly, as shown in Fig. 25.37.¹⁹⁷

Under some circumstances it may be advantageous to inhibit hydrate formation rather than dehydrate oil and/or gas streams. While many ionic and hydrogen-bonding substances inhibit hydrate formation, the two compounds that are used most frequently for hydrate inhibition are methanol and ethylene glycol. Natural brines cause only a few degrees of hydrate depression.¹³⁴ Figs. 25.38 through 25.40 present the freezing points of aqueous glycol solutions showing their eutectics in the absence of gas.¹⁹⁸ Fig. 25.41 presents the freezing point depression of diethylene/glycol/water solutions.¹⁹⁷

Fig. 25.38—Crystallization temperatures of aqueous ethylene glycol solutions.

Fig. 25.40—Crystallization temperatures of aqueous triethylene glycol solutions.

Fig. 25.41—Effect of diethylene glycol on conditions for hydrate formations.

The inhibition effect of methanol and ethylene glycol on the hydrate formation condition of a methane/12-mol% propane mixture is currently under study at Rice U.

Recently, Ng and Robinson¹⁹⁹ have presented the hydrate formation conditions of methane, ethane, propane, CO₂, hydrogen sulfide, methane/10.49-mol% ethane, 90.09-mol% methane/9.91-mol% CO₂, 95.01-mol% methane/4.99-mol% propane, a synthetic natural mixture, and a synthetic natural gas mixture containing CO₂, each in the presence of methanol solutions of 10 to 20 wt% methanol in water. With the increasing amount of oil and gas transmission along ocean floors prior to dehydration, such data are of increasing usefulness.

Nomenclature

- a_i = activity of component i in mixture
 C_{ji} = a unique function of temperature for each guest molecule in each size cavity
 f_j = fugacity of j in the gas phase
 \hat{f}_1 = partial fugacity of the solute in water at T and p_t
 f_{wf} = fugacity of water in the fluid phase
 Δh_w = enthalpy difference
 K_1 = an empirical constant that is a function of temperature only but is equal numerically to Henry's law constant for noncondensable gases and a hypothetical Henry's law constant for condensable gases
 K_{fl} = fugacity coefficient of ice

- K_{fMT} = fugacity coefficient of empty hydrate
 $K_{i(v-s)}$ = vapor/solid equilibrium values of Component i
 K_{wf} = fugacity coefficient of water
 n_{ci} = number of cavities of type i per water molecule in basic lattice
 p_o = reference pressure
 p_{vl} = vapor pressure of ice
 p_{vMT} = vapor pressure of empty hydrate
 p_{vs} = vapor pressure of the solvent for a noncondensable gas, but equal to some constant pressure slightly above the three-phase pressure determined from experimental data
 T_o = reference temperature
 Δv_w = specific volume difference
 \hat{V}_{M1} = partial molal volume of components in the solution
 W_{ms} = metastable water content
 x_1 = mole fraction of the dissolved solute
 y_{ji} = fractional occupancy of type i cavity by type j molecule
 μ_i = chemical potential of Component i
 μ_i^o = chemical potential of pure Component i
 $\Delta \mu_w$ = difference in chemical potential of water
 μ_{wH} = chemical potential of water in filled hydrate
 μ_{wMT} = chemical potential of water in empty hydrate

Subscripts

- L = liquid water
 H = hydrate
 g = gas

Chapter 26

Properties of Reservoir Rocks

Daniel M. Bass Jr., Colorado School of Mines*

Introduction

This chapter deals with the fundamental properties of reservoir rocks. The properties discussed are (1) *porosity*—a measure of the void space in a rock; (2) *permeability*—a measure of the fluid transmissivity of a rock; (3) *fluid saturation*—a measure of the gross void space occupied by a fluid; (4) *capillary-pressure relations*—a measure of the surface forces existing between the rock and the contained fluids; and (5) *electrical conductivity of fluid-saturated rocks*—a measure of the conductivity of the rock and its contained fluids to electric current. These properties constitute a set of fundamental parameters by which the rock may be described quantitatively.

Typical core-analysis data are presented to illustrate the description of porous media by these fundamental properties.

Porosity

Porosity is defined as the ratio of the void space in a rock to the bulk volume (BV) of that rock, multiplied by 100 to express in percent. Porosity may be classified according to the mode of origin as primary and secondary. An original porosity is developed during the deposition of the material, and later compaction and cementation reduce it to the primary porosity. Secondary porosity is that developed by some geologic process subsequent to deposition of the rock. Primary porosity is typified by the intergranular porosity of sandstones and the intercrystalline and oolitic porosity of some limestones. Secondary porosity is typified by fracture development as found in some shales and limestones and the vugs or solution cavities commonly found in limestones. Rocks having primary porosity are more uniform in their

characteristics than rocks in which a large part of the porosity is induced. For direct quantitative measurement of porosity, reliance must be placed on formation samples obtained by coring.

Unit cells of two systematic packings of uniform spheres are shown in Fig. 26.1. The porosity for cubical packing (the least compact arrangement) is 47.6% and for rhombohedral packing (the most compact arrangement) is 25.96%.¹ Considering cubical packing, the porosity may be calculated as follows. The unit cell is a cube with sides equal to $2r$ where r is the radius of the sphere. Therefore, $V_b = (2r)^3 = 8r^3$, where V_b is the bulk volume. Since there are $8\frac{1}{8}$ spheres in the unit cell, the sand-grain volume, V_s , is given by

$$V_s = \frac{4\pi r^3}{3}$$

The porosity, ϕ , is given by

$$\phi = \frac{V_p}{V_b} \times 100 = \frac{V_b - V_s}{V_b} \times 100,$$

where V_p is PV. Therefore,

$$\begin{aligned} \phi &= \frac{8r^3 - 4/3\pi r^3}{8r^3} \times 100 = \left(1 - \frac{\pi}{2 \times 3}\right) \times 100 \\ &= 47.6\%. \end{aligned}$$

Of particular interest is the fact that the radii cancel and the porosity of uniform spheres is a function of packing only.

*This author also wrote the original chapter on this topic in the 1962 edition with coauthor James W. Amyx (deceased). D.M. Bass Jr. is currently a petroleum consultant.

Fig. 26.1—Unit cells and groups of uniform spheres for cubic and rhombohedral packing.

Fig. 26.2—Variation of porosity with skewness of grain-size distribution.

Tickell *et al.*² has presented experimental data indicating that, for packings of Ottawa sand, porosity was a function of skewness of the grain-size distribution (see Fig. 26.2). Skewness is a statistical measure of the uniformity of distribution of a group of measurements. Other investigators have measured the effects of distribution, grain size, and grain shape. In general, greater angularity tends to increase the porosity, while an increase in range of particle size tends to decrease porosity.

In dealing with reservoir rocks (usually consolidated sediments), it is necessary to define total porosity and effective porosity because cementing materials may seal off a part of the PV. *Total porosity is the ratio of the total void space in the rock to the BV of the rock, while effective porosity is the ratio of the interconnected void space in the rock to the BV of the rock, each expressed in percent.* From the reservoir-engineering standpoint, effective porosity is the desired quantitative value because it represents the space that is occupied by mobile fluids. For intergranular materials, poorly to moderately well cemented, the total porosity is approximately equal to the effective porosity. For more highly cemented materials and for limestones, significant differences in total-porosity and effective-porosity values may occur.

Photographs of oilwell cores are presented in Fig. 26.3.³ The pore configuration of the sandstones shown is complex, but the pores are distributed relatively uniformly. Complex pore configurations arise from the interaction of many factors in the geologic environment of the deposit. These factors include the packing and particle-size distribution of the framework fraction, the type of interstitial material, and the type and degree of cementation. The influence of these various factors may be evaluated as statistical trends.

Material having induced porosity, such as the carbonate rocks shown in Fig. 26.3, have even more complex pore configurations. In fact, two or more systems of pore openings may occur in such rocks. The basic rock material is usually finely crystalline and is called the "matrix." The matrix contains uniformly small pore openings that comprise one system of pores. One or more systems of larger openings usually occur in carbonate rocks as a result of leaching, fracturing, or dolomitization of the primary rock material. Vugular pore openings are frequently as large as an ordinary lead pencil and usually are attributed to leaching of the rock subsequent to deposition. Fractures also may be quite large and contribute substantially to the volume of pore openings in the rock.

Fig. 26.3—Oilwell cores. Consolidated sandstone: (a) wireline core, Lower Frio; (b) whole core, Seven Rivers. Vugular, solution cavities, and crystalline limestone and dolomite: (c) whole core, Devonian; (d) whole core, Hermosa.

Laboratory Measurement of Porosity

Numerous methods have been developed for the determination of the porosity of consolidated rocks having intergranular porosity. Most of the methods developed have been designed for small samples, roughly the size of a walnut. Since the pores of intergranular material are quite small, determining the porosity of such a sample involves measuring the volume of literally thousands of pores. The porosity of larger portions of the rock is represented statistically from the results obtained on numerous small samples.

In the laboratory measurement of porosity, it is necessary to determine only two of the three basic parameters (BV, PV, and grain volume). In general, all methods of BV determination are applicable to determining both total and effective porosity.

BV. Usual procedures use observation of the volume of fluid displaced by the sample. This procedure is particularly desirable because the BV of specially shaped samples may be determined as rapidly as that of shaped samples.

The fluid displaced by a sample may be observed either volumetrically or gravimetrically. In either procedure, it is necessary to prevent fluid penetration into the pore space of the rock. This may be accomplished by (1) coating the rock with paraffin or a similar substance, (2) saturating the rock with the fluid into which it is to be immersed, or (3) using mercury, which by virtue of its surface tension and wetting characteristics does not tend to enter the small pore spaces of most intergranular materials.

Gravimetric determinations of BV may be accomplished by observing the sample's weight loss when immersed in a fluid or the difference in weight of a pycnometer when filled with a fluid and when filled with fluid and the core sample. The details of gravimetric determinations of BV are best summarized by Example Problems 1 through 3.

Example Problem 1—Coated Sample Immersed in Water.

Given that the weight of dry sample in air, $A=20.0$ g, weight of dry sample coated with paraffin, $B=20.9$ g (density of paraffin $=0.9$ g/cm³), and weight of coated sample immersed in water at 40°F, $C=10.0$ g (density of water $=1.00$ g/cm³),

we can then calculate that

$$\text{weight of paraffin} = B - A = 20.9 - 20.0 = 0.9 \text{ g,}$$

$$\text{volume of paraffin} = \frac{0.9}{0.9} = 1 \text{ cm}^3,$$

$$\text{weight of water displaced} = B - C = 20.9 - 10.0 = 10.9 \text{ g,}$$

$$\text{volume of water displaced} = \frac{10.9}{1.0} = 10.9 \text{ cm}^3,$$

$$\begin{aligned} \text{volume of water displaced} - \text{volume of paraffin} \\ = 10.9 - 1.0 = 9.9 \text{ cm}^3, \text{ and} \\ \text{BV of rock, } V_b, = 9.9 \text{ cm}^3. \end{aligned}$$

Example Problem 2—Water-Saturated Sample Immersed in Water.

Given that weight of saturated sample in air, $D=22.5$ g, and weight of saturated sample in water at 40°F, $E=12.6$ g,

we can calculate that

$$\begin{aligned} \text{weight of water displaced} &= D - E = 22.5 - 12.6 \\ &= 9.9 \text{ g, and} \end{aligned}$$

$$\text{volume of water displaced} = \frac{9.9}{1.0} = 9.9 \text{ cm}^3.$$

Therefore,

$$\text{BV rock, } V_b, = 9.9 \text{ cm}^3.$$

Example Problem 3—Dry Sample Immersed in Mercury Pycnometer.

Given A from Example Problem 1 and the following values,

weight of pycnometer filled with mercury at 20°C, $F=350.0$ g and

weight of pycnometer filled with mercury and sample at 20°C, $G=235.9$ g (density of mercury $=13.546$ g/cm³),

we can calculate that

$$\text{weight of sample + weight of pycnometer filled with mercury} = A + F = 20 + 350 = 370 \text{ g,}$$

$$\text{weight of mercury displaced} = A + F - G = 370 - 235.9 = 134.1 \text{ g, and}$$

$$\text{volume of mercury displaced} = \frac{134.1}{13.546} = 9.9 \text{ cm}^3.$$

Therefore,

$$\text{BV of rock} = 9.9 \text{ cm}^3.$$

Determinations of BV volumetrically use a variety of specially constructed pycnometers or volumeters. An electric pycnometer from which the BV may be read directly is shown in Fig. 26.4. The sample is immersed in the core chamber, causing a resulting rise in the level of the connecting U tube. The change in mercury level is measured by a micrometer screw connected to a low-voltage circuit. The electric circuit is closed as long as the measuring point is in contact with the mercury. The travel of the measuring point is calibrated in volume units such that the difference in the open-circuit readings with and without the sample in the core chamber represents the BV of the sample. Either dry or saturated samples may be used in the device.

Sand-Grain Volume (GV). The various porosity methods usually are distinguished by the means used to determine the GV or PV. Several of the oldest methods of porosity measurement are based on the determination of GV.

The GV may be determined from the dry weight of the sample and the sand-grain density. For many purposes, results of sufficient accuracy may be obtained by using the density of quartz (2.65 g/cm³) as the sand-grain density.

For more rigorous determinations either the A.F. Melcher-Nutting⁴ or Russell⁵ method may be employed. The BV of a sample is determined; then this sample, or an adjacent sample, is reduced to grain size and the GV is determined. In the Melcher-Nutting technique, all the measurements are determined

TABLE 26.1—METHODS OF DETERMINING POROSITY

	Effective Porosity Methods

Fig. 26.4—Electric pycnometer.

gravimetrically, using the principle of buoyancy (Example Problem 2). The Russell method uses a specially designed volumeter, and the BV and GV are determined volumetrically. The porosity determined is total porosity, ϕ_t . Thus,

$$\phi_t = \frac{V_b - V_s}{V_b} \times 100.$$

From the data of Example Problem 2 and using a sand-grain density of 2.65 g/cm^3 ,

$$V_b = 9.9 \text{ cm}^3,$$

$$V_g = \frac{20}{2.65} = 7.55 \text{ cm}^3,$$

and

$$\phi_t = \frac{9.9 - 7.55}{9.9} \times 100 = 23.8\%.$$

The Stevens⁶ porosimeter is a means of determining the "effective" GV. The porosimeter (Fig. 26.5) consists of a core chamber that may be sealed from atmospheric pressure and closed from the remaining parts of the porosimeter by a needle valve. The accurate volume of the core chamber is known. In operation, a core is placed in the core chamber; a vacuum is established in the

Possible incomplete saturation.	Obtain excess water from shales. Loss of vapors through condensers.	Possible leaks in system; incomplete evacuation caused by rapid operation or tight sample.	Possible loss of sand grains in crushing. Can be reproduced most accurately.

*Best method

system by manipulating the mercury reservoir; the air in the core chamber is expanded repeatedly into the evacuated system and measured at atmospheric pressure in the graduated tube. The Stevens method is an adaptation of the Washburn-Bunting⁷ procedure, which will be discussed with the measurement of PV.

Example Problem 4—Determination of Grain Volume by Gas Expansion (Stevens Porosimeter).

Given that

volume of core chamber, $H = 15 \text{ cm}^3$

and

total reading, $I = 7.00 \text{ cm}^3$

where

volume of air (first reading) = 6.970,

volume of air (second reading) = 0.03, and

volume of air (third reading) = 0,

we can calculate

effective grain volume = $H - I = 8 \text{ cm}^3$,

bulk volume of sample (from pycnometer) = 10 cm^3 ,

and effective porosity, $\phi_e = [(10 - 8)/10] \times 100 = 20\%$.

PV. All methods of measuring PV yield "effective" porosity. The methods are based on either the extraction of a fluid from the rock or the introduction of a fluid into the pore space of the rock.

The Washburn-Bunting⁷ porosimeter measured the volume of air extracted from the pore space by creating a partial vacuum in the porosimeter by manipulation of the attached mercury reservoir. In the process, the core is exposed to contamination by mercury and, therefore, is

Fig. 26.5—Stevens porosimeter.

TABLE 26.2—CHARACTERISTICS OF SAMPLES USED IN POROSITY-MEASUREMENT COMPARISONS

*Highest reported porosity value for the sample.

**Lowest reported porosity value for the sample.

not suitable for additional tests. The previously described Stevens method is a modification of the Washburn-Bunting procedure especially designed to prevent mercury contamination of the samples.

A number of other devices have been designed for measuring PV; these include the Kobe⁸ porosimeter, the Oilwell Research porosimeter, and the mercury-pump porosimeter. Kobe and Oilwell Research porosimeters are Boyle's-law-type porosimeters designed for use with nitrogen or helium with negligible adsorption on rock surfaces at room temperature. The mercury-pump porosimeter is designed so that the BV may be obtained as well as the PV.

The saturation method of determining porosity consists of saturating a clean dry sample with a fluid of known density and determining the PV from the gain in weight of the sample. The sample usually is evacuated in a vacuum flask to which the saturation fluid may be admitted by means of a separatory funnel. If care is exercised to achieve complete saturation, this procedure is believed to be one of the best available techniques for intergranular materials. Example Problem 5 illustrates the saturation technique of measuring PV.

Example Problem 5—Effective Porosity by the Saturation Method. From the data of Example Problems 1 and 2, we can calculate

$$\begin{aligned}\text{weight of water in pore space} &= D - A = 22.5 - 20 \\ &= 2.5 \text{ g,}\end{aligned}$$

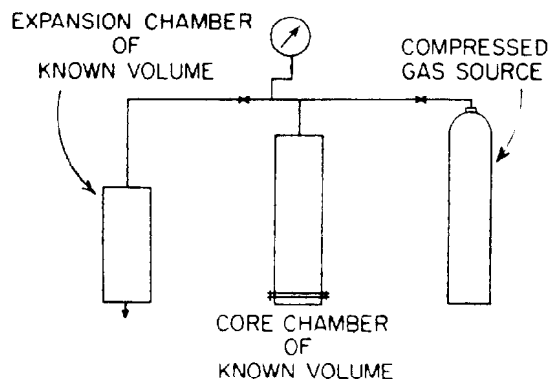

Fig. 26.6—Gas-expansion porosimeter for large cores.

$$\text{volume of water in pore space} = \frac{2.5 \text{ g}}{1 \text{ g/cm}^3} = 2.5 \text{ cm}^3,$$

$$\text{effective PV} = 2.5 \text{ cm}^3, \text{ and}$$

$$\text{BV (Example Problem 2)} = 9.9 \text{ cm}^3.$$

Therefore,

$$\phi_e = \frac{2.5}{9.9} \times 100 = 25.3\%.$$

Several methods of determining effective porosity are compared in Table 26.1.

Precision of Porosity Measurements. A group⁹ of major company laboratories conducted a series of tests to determine the precision of porosity measurements. The method used was either gas expansion or a saturation technique. Table 26.2 summarizes the results of these tests. Note that the gas-expansion method is consistently higher than the saturation method. This undoubtedly results from the fact that the errors inherent to each tend to be in opposite directions. In the case of the gas-expansion method, errors caused by gas adsorption would cause high values to be obtained while, for the saturation techniques, incomplete saturation of the sample would result in low values. The difference in the average values obtained by the two methods is about 0.8% porosity, which is approximately a 5% error for a 16% porosity sample. However, it is felt that all the methods commonly used to determine effective porosity yield results with the desired degree of accuracy if carefully performed.

Carbonate Rocks. Small samples, such as used in the routine techniques already discussed, yield values of porosity that do not include the effect of vugs, solution cavities, etc. The saturation methods of determining PV and BV are unsatisfactory because drainage will occur from the larger pore spaces. Therefore, it is necessary to use larger core samples and to determine the BV by measurement of the core dimensions or after coating the sample. The effective grain volume is obtained by using a large gas-expansion porosimeter of the type shown in Fig. 26.6. This porosimeter is based on Boyle's law in

Fig. 26.7—Effect of natural compaction on porosity.

which high-pressure gas is equalized between two chambers. The porosity may be calculated from the measured pressures, the volume of either chamber, and the bulk-sample volume by the use of Boyle's law.

Kelton¹⁰ reported results of whole-core analysis, a method utilizing large sections of the full-diameter core. The following table of matrix vs. whole-core data summarizes a part of Kelton's work.¹⁰

	Group			
	1	2	3	4
Matrix porosity, % bulk	1.98	1.58	2.56	7.92
Total porosity, % bulk	2.21	2.62	3.17	8.40

Matrix porosity is that determined from small samples; total porosity is that determined from the whole core. Whole-core analysis satisfactorily evaluates most carbonate rocks. However, no satisfactory technique is available for the analysis of extensively fractured materials because the samples cannot be put together in their natural state.

Compaction and Compressibility of Porous Rocks

The porosity of sedimentary rocks has been shown by Krumbein and Sloss¹¹ to be a function of the degree of compaction of the rock. The compacting forces are a function of the maximum depth of burial of the rock. The effect of natural compaction on porosity is shown in Fig. 26.7. This effect is caused principally by the resulting packing arrangement after compaction; thus, sediments that have been buried deeply, even if subsequently uplifted, exhibit lower porosity values than sediments that have not been buried at great depth.

Geertsma¹² states that three kinds of compressibility must be distinguished in rocks: (1) rock-matrix compressibility, (2) rock-bulk compressibility, and (3) pore compressibility. Rock-bulk compressibility is a combination of pore and rock matrix compressibility.

Rock-matrix compressibility is the fractional change in volume of the solid rock material (grains) with a unit change in pressure. Pore compressibility is the fractional change in PV of the rock with a unit change in pressure.

Fig. 26.8—Effective reservoir-rock compressibilities.

The depletion of fluids from the pore space of a reservoir rock results in a change in the internal stress in the rock, thus causing the rock to be subjected to a different resultant stress. This change in stress results in changes in the GV, PV, and BV of the rock. Of principal interest to the reservoir engineer is the change in the PV of the rock. The change in rock-bulk compressibility may be of importance in areas where surface subsidence could cause appreciable property damage.

Hall¹³ reported PV compressibility as a function of porosity. These data are summarized in Fig. 26.8. The effective rock compressibility in Fig. 26.8 results from the change in porosity caused by grain expansion and decrease in pore space because of compaction of the matrix.

Fatt¹⁴ indicates that the pore compressibility is a function of pressure. Within the range of his data, he was unable to find a correlation with porosity.

Fig. 26.9—Depth vs. formation compressibility in abnormally pressured segment of an abnormally pressured reservoir.

Fig. 26.10—PV compressibility at 75% lithostatic pressure vs. initial sample porosity for limestones.

Fig. 26.12—PV compressibility at 75% lithostatic pressure vs. initial sample porosity for friable sandstones.

Fig. 26.11—PV compressibility at 75% lithostatic pressure vs. initial sample porosity for consolidated sandstones.

The additional significance of changes in porosity with the discovery of oil at deeper depths and new geological areas resulted in the need for a better understanding of the changes in porosity with the depletion of reservoir fluid pressure.

Hammerlindl¹⁵ developed a correlation from measured field data that indicates the change in porosity compressibility with depth of burial of an unconsolidated sand (Fig. 26.9). Similar correlations have also been presented by others in the technical literature.

Considerable laboratory work has been performed recently in an attempt to understand better the effect of formation compaction on porosity. Newman¹⁶ performed measurements on samples of limestone and consolidated, friable, and unconsolidated sandstones. He compared his results with those of Hall¹³ and van der Knaap,¹⁷ as illustrated in Figs. 26.10 through 26.13. As noted in his data, an approximate correlation may exist between PV compressibility and porosity for limestones and consolidated sandstones. Little or no correlation exists between PV compressibility and porosity for friable and unconsolidated sandstones. By averaging the PV compressibility in 5% ranges of porosity, Newman attempted to correlate all four types of porous media. The results of this averaging technique are presented in Fig. 26.14.

The methods used to measure PV compressibility have come under discussion. PV compressibility can be measured in the laboratory by the hydrostatic (same pressure in all three directions) or the triaxial (different pressure in the z direction than in the x and y directions) techniques. The test samples also can be stress cycled

Fig. 26.13—PV compressibility at 75% lithostatic pressure vs. initial sample porosity for unconsolidated sandstones.

Fig. 26.14—Class averages of PV compressibility vs. initial sample porosity.

until the strain resulting from a supplied stress is constant, or the sample can be placed under stress and the strain measured for purposes of calculating PV compressibility.

Krug¹⁸ and Graves¹⁹ demonstrated that when a formation sample was stress cycled to a stable strain condition, the sample gave repeatable values of PV compressibility even when the sample was left in an unstressed condition for 30 days or more. The data reported by Newman were for samples that were not stress cycled.

Lachance²⁰ compared PV compressibilities obtained by the hydraulic and triaxial methods. The reported results (Fig. 26.15) indicate a large difference in the magnitude of PV compressibilities obtained by the two methods. The triaxial data indicate that PV compressibility is essentially independent of the sample porosity. Newman's¹⁶ data were obtained by the hydrostatic method, whereas Krug's¹⁸ and Graves'¹⁹ data were obtained by the triaxial method.

In summary, rock compressibility is an important factor in reservoir evaluation. Oil reservoirs with high initial pressures and low fluid bubblepoint pressures are sensitive to the true value of PV compressibility. Gas reservoirs with initial reservoir pressures in excess of 6,000 psi are also sensitive to the value of PV compressibility. Newman,¹⁶ Krug,¹⁸ and Graves¹⁹ all recommend that PV compressibility be measured on

Fig. 26.15—Calculated PV compressibility (porosity $\geq 8\%$).

Fig. 26.16—Schematic of Henry Darcy's experiment on flow of water through sand.

samples from the reservoir in question when the PV compressibility may be significant in reservoir evaluation.

Permeability

Introductory Theory

It is the purpose of this section to discuss the ability of the formation to conduct fluids. In the introduction to API Code 27,²¹ it is stated that permeability is a property of the porous medium and a measure of the medium's capacity to transmit fluids. The measurement of permeability, then, is a measure of the fluid conductivity of the particular material. By analogy with electrical conductors, the permeability represents the reciprocal of the resistance that the porous medium offers to fluid flow.

The following equations for flow of fluids in circular conduits are well known.

Poiseuille's equation for viscous flow:

$$v = \frac{d^2 \Delta p}{32 \mu L}, \quad (1)$$

Fanning's equation for viscous and turbulent flow:

$$v^2 = \frac{2 d \Delta p}{f \rho L}, \quad (2)$$

where

- v = fluid velocity, cm/s,
- d = diameter of conductor, cm,
- Δp = pressure loss over length L , dynes/cm²,
- L = length over which pressure loss is measured, cm,
- μ = fluid viscosity, Pa·s,
- ρ = fluid density, g/cm³, and
- f = friction factor, dimensionless.

A more convenient form of Poiseuille's equation is

$$q = \frac{\pi r^4 \Delta p}{8 \mu L}, \quad (3)$$

where r is the radius of the conduit, cm, q is the volume rate of flow, cm³/s, and the other terms are as previously defined.

If a porous medium is conceived to be a bundle of capillary tubes, the flow rate q_t through the medium is the sum of the flow rates through the individual tubes. Thus,

$$q_t = \frac{\pi \Delta p}{8 \mu L} \sum_{j=1}^k n_j r_j^4, \quad (4)$$

where n_j is the number of tubes of radius r_j . If

$$(\pi/8) \sum_{j=1}^k n_j r_j^4$$

is treated as a flow coefficient for the particular grouping of tubes the equation reduces to

$$q_t = C \frac{\Delta p}{\mu L}, \quad (5)$$

where

$$C = \frac{\pi}{8} \sum_{j=1}^k n_j r_j^4. \quad (6)$$

The pore structure of rocks does not permit simple classification of the flow channels. Therefore, empirical data are required in most cases.

In 1856, Darcy investigated the flow of water through sand filters for water purification. His experimental apparatus is shown schematically in Fig. 26.16.²² Darcy interpreted his observations to yield results essentially as given in Eq. 7.

$$q = KA \frac{h_1 - h_2}{L}. \quad (7)$$

q represents the volume rate of flow of water downward through the cylindrical sandpack of cross-sectional area A and length L . h_1 and h_2 are the heights above the standard datum of the water in manometers located at the input and output faces and represent the hydraulic head at

Points 1 and 2. K , a constant of proportionality, was found to be characteristic of the sandpack. Darcy's investigations were confined to flow of water through sandpacks that were 100% saturated with water.

Later investigators found that Darcy's law could be extended to fluids other than water and that the constant of proportionality K could be written as k/μ , where μ is the viscosity of the fluid and k is a proportionality constant for the rock. The generalized form of Darcy's law as presented in API Code 27 is presented in Eq. 8.

$$u_s = -\frac{k}{\mu} \left(\frac{dp}{ds} - g\rho \frac{dz}{ds} \right), \quad (8)$$

where

s = distance in direction of flow, always positive,

u_s = volume flux across a unit area of the porous medium in unit time along flow path s ,

z = vertical coordinate, considered positive downward, cm,

ρ = density of the fluid,

g = acceleration of gravity,

$\frac{dp}{ds}$ = pressure gradient along s at the point to which u refers,

μ = viscosity of the fluid,

k = permeability of the medium, and

$\frac{dz}{ds} = \sin \theta$, where θ is the angle between s and the horizontal.

u_s may further be defined as q/A where q is the volume rate of flow and A is the average cross-sectional area perpendicular to the lines of flow.

The portion of Eq. 8 in parentheses may be interpreted as the total pressure gradient minus the gradient caused by a head of fluid. Thus, if the system is in hydrostatic equilibrium, there is no flow and the quantity inside the parentheses will be zero. Eq. 8 may be rewritten as

$$u_s = -\frac{k}{\mu} \frac{d}{ds} (\rho g z - p). \quad (9)$$

The quantity $d(\rho g z - p)/ds$ may be considered to be the negative gradient of a potential function Φ , where

$$\Phi = p - \rho g z. \quad (10)$$

The potential function is defined such that flow will be from higher to lower values.

The dimensions of permeability may be established from an analysis of Eq. 8 as $k = L^2$. In the cgs system of units, the unit of permeability would be cm^2 , a large unit for common usage; therefore, the petroleum industry adopted the darcy as the standard unit of permeability, which is defined as follows.

A porous medium has a permeability of one darcy when a single phase fluid of one centipoise viscosity that completely fills the voids of the medium, will flow through it under conditions of viscous flow at a rate of one cubic centimeter per second per square centimeter cross sectional area under a pressure or equivalent hydraulic gradient of one atmosphere per centimeter.²¹

Fig. 26.17—Sand model for rectilinear flow of fluids.

Conditions of viscous flow mean that the rate of flow will be sufficiently low to be directly proportional to the potential gradient.

Darcy's law holds only for conditions of viscous flow as defined. Further, for the permeability k to be a proportionality constant of the porous medium, the medium must be 100% saturated with the flowing fluid when the determination of permeability is made. In addition, the fluid and the porous medium must not react—i.e., by chemical reaction, adsorption, or absorption. If a reactive fluid flows through a porous medium, it alters the porous medium and, therefore, changes the permeability of the medium as flow continues.

Flow Systems of Simple Geometry

Horizontal Flow. Horizontal rectilinear steady-state flow is common to virtually all measurements of permeability. If a rock is 100% saturated with an incompressible fluid and is horizontal (Fig. 26.17), then $dz/ds = 0$, $dp/ds = dp/dx$, and Eq. 8 reduces to

$$u_x = \frac{q}{A} = -\frac{k}{\mu} \frac{dp}{dx},$$

which on integration becomes

$$q = \frac{kA(p_1 - p_2)}{\mu L}, \quad (11)$$

where k is the specific permeability.

If a compressible fluid flows through a porous medium, Darcy's law, as expressed in Eq. 8, is still valid. However, for steady flow, the mass rate of flow rather than the volume rate of flow is constant through the system. Therefore, the integrated form of the equation differs. Considering steady rectilinear flow of compressible fluids, Eq. 8 becomes

$$\rho u_x = -\frac{k\rho}{\mu} \frac{dp}{dx}, \quad (12)$$

or, for steady-state flow,

$$\rho u_x = \rho \frac{q}{A} = \text{constant}.$$

Fig. 26.18—Sand model for vertical flow.

The density-pressure relationship for isothermal conditions of a slightly compressible fluid may be expressed as

$$\rho = \rho_o e^{cp}$$

and

$$\frac{\partial \rho}{\partial p} = \frac{\rho}{cp}, \quad (13)$$

where c is the fluid compressibility. Thus,

$$\frac{\rho_o q_o}{A} = \frac{-k\rho}{\mu} \frac{dp}{dx} = \frac{-k}{\mu c} \frac{d\rho}{dx},$$

where q_o is the volume rate of flow of a fluid of density ρ_o .

On integration,

$$\rho_o q_o = \frac{kA(\rho_1 - \rho_2)}{\mu c L}, \quad (14)$$

If terms of cp of second and higher order are neglected, the density can be expressed as

$$\rho = \rho_o(1 + cp),$$

such that Eq. 14 reduces to

$$q_o = \frac{kA(p_1 - p_2)}{\mu L}.$$

The density-pressure relationship for isothermal conditions of an ideal gas may be expressed as

$$\frac{p}{p_b} = \frac{\rho}{\rho_b} \text{ or } \rho = \frac{p\rho_b}{p_b}, \quad (15)$$

Thus,

$$\frac{\rho_b q_b}{A} = -\frac{k\rho}{\mu} \frac{dp}{dx},$$

where ρ_b and q_b are the density and volume rate of flow, respectively, at the base pressure, p_b .

Substituting for ρ

$$\frac{p_b q_b}{A} = -\frac{k}{\mu} p \frac{dp}{dx}, \quad (16)$$

which on integration yields

$$q_b = \frac{kA}{2\mu L} \frac{p_1^2 - p_2^2}{p_b}, \quad (17)$$

Define \bar{p} as $(p_1 + p_2)/2$, and q_p as the volume rate of flow at \bar{p} such that $p q_p = p_b q_b$; then

$$q_p = \frac{kA(p_1 - p_2)}{\mu L}. \quad (18)$$

Therefore, flow rates of ideal gases may be computed from the equations for incompressible liquids so long as the volume rate of flow is defined at the algebraic mean pressure.

Vertical Flow. Fig. 26.18 shows three sandpacks in which linear flow occurs in the vertical direction.

First consider Case 1 (Fig. 26.18)—when the pressure at the inlet and outlet are equal (free flow), such that only the gravitational forces are driving the fluids. Given

$$s = z, \quad \frac{dz}{ds} = 1, \text{ and } \frac{dp}{ds} = 0,$$

the flow is then defined by

$$q = \frac{kA}{\mu} \rho g. \quad (19)$$

Next consider Case 2—the case of downward flow when the driving head (difference in hydraulic head of inlet and outlet) is h (Fig. 26.18). We know that

$$\frac{dz}{ds} = 1 \text{ and } \frac{dp}{ds} = \frac{-\rho g h}{L}.$$

Therefore, from Eq. 8,

$$q = \frac{kA}{\mu} \rho g \left(\frac{h}{L} + 1 \right). \quad (20)$$

When the flow is upward and the driving head is h , Case 3 (Fig. 26.18), and z is defined as positive downward,

$$\frac{dz}{ds} = -1, \quad \frac{dp}{ds} = -\frac{dp}{dz} = \left(-\frac{\rho gh}{L} - \rho g \right),$$

and

$$u = +\frac{k}{\mu} \left(+\frac{\rho gh}{L} + \rho g - \rho g \right),$$

then

$$q = \frac{kA\rho gh}{\mu L} \quad (21)$$

Radial Flow. A radial-flow system, analogous to flow into a wellbore, is idealized in Fig. 26.19. If flow is considered to occur only in the horizontal plane under steady-state conditions, an equation of flow may be derived from Darcy's law to be

$$q = \frac{2\pi kh(p_e - p_w)}{\mu \ln r_e/r_w} \quad (22)$$

where r_e is the radius at the external boundary at which p_e (pressure at the external boundary) is measured, and r_w is the radius of the wellbore at which p_w (pressure at the wellbore) is measured. All other terms are as defined for linear flow.

Eq. 22 may be modified appropriately for the flow of compressible fluids. The details of modifying this equation are omitted because they are essentially the same as the ones used in the horizontal rectilinear flow systems.

After modification for variations in flowing volumes with changing pressures, Eq. 22 becomes for slightly compressible fluids

$$w = \frac{2\pi kh(\rho_e - \rho_w)}{c\mu \ln r_e/r_w} \quad (23)$$

where w is the mass rate of flow, g/s, or

$$q_o = \frac{2\pi kh(p_e - p_w)}{\pi \rho_o \ln r_e/r_w},$$

where q_o is defined at the pressure p_o where the density is ρ_o .

For ideal gases, Eq. 22 becomes

$$q_b = \frac{\pi kh(p_e^2 - p_w^2)}{\mu p_b \ln r_e/r_w} \quad (24)$$

or

$$q_p = \frac{2\pi kh(p_e - p_w)}{\mu \ln r_e/r_w} \quad (25)$$

where q_p is the volume rate of flow at the algebraic mean pressure $(p_e + p_w)/2$.

Fig. 26.19—Sand model for radial flow of fluids to central wellbore.

Conversion of Units in Darcy's Law

It is convenient in many applications of Darcy's law to introduce commonly used oilfield units. The following is a summary of the more common equations with the conversion factors to convert to oilfield terminology.

Linear-Flow Liquids (or Gases with Volume at Mean Pressure). Rate, B/D, is given by

$$q = 1.1271 \frac{kA(p_1 - p_2)}{\mu L} \quad (26)$$

Rate, cu ft/D, is given by

$$q = 6.3230 \frac{kA(p_1 - p_2)}{\mu L} \quad (27)$$

Radial-Flow Liquids (or Gases with Volume at Mean Pressure). Rate, liters per day, is given by

$$q = 92.349 \times 10^3 \frac{kh(p_e - p_w)}{\mu \ln r_e/r_w} \quad (28)$$

Rate, cu ft/D, is

$$q = 92.349 \times 10^3 \frac{kh(p_e - p_w)}{\mu \ln r_e/r_w} \quad (29)$$

Gases at Base Pressure, p_b , and Average Flowing Temperature, \bar{T}_f . Linear flow rate, cu ft/D, is given by

$$q_b = \frac{3.1615 T_b k A (p_1^2 - p_2^2)}{\bar{T}_f \mu_g L p_b} \quad (30)$$

Fig. 26.20—Linear flow—parallel combination of beds.

and radial flow rate, cu ft/D, is given by*

$$q_b = \frac{19.88 T_b k h (p_e^2 - p_w^2)}{\bar{T}_f \bar{z} \mu_g p_b \ln r_e / r_w}, \quad (31)$$

where k is in darcies; A is in sq ft; h is in ft; p_1 , p_2 , p_e , p_w , and p_b are in psia; μ is in cp; L is in ft; and r_e and r_w are in consistent units.

Since the previous equations describe the flow in the medium, appropriate volume factors must be introduced to account for changes in the fluids caused by any decrease in pressure and temperature from that of the medium to standard or stock-tank conditions.

Permeability Conversion Factors. Following is a list of various unit conversions from darcy units to other systems of units.

$$k = \frac{q\mu}{A(p/L)}$$

1 darcy (d) = 1,000 millidarcies (md)

$$\begin{aligned} &= \frac{(\text{cm}^3/\text{s})\text{cp}}{\text{cm}^2(\text{atm}/\text{cm})} \\ &= 9.869 \times 10^{-7} \frac{(\text{cm}^3/\text{s})\text{cp}}{\text{cm}^2 \left(\frac{\text{dyne}/\text{cm}^2}{\text{cm}} \right)} \\ &= 9.869 \times 10^{-9} \text{ cm}^2 \\ &= 1.062 \times 10^{-11} \text{ sq ft} \\ &= 7.324 \times 10^{-5} \frac{(\text{cu ft}/\text{sec})\text{cp}}{\text{sq ft}(\text{psi}/\text{ft})} \\ &= 9.697 \times 10^{-4} \frac{(\text{cu ft}/\text{sec})\text{cp}}{\text{cm}^2(\text{cm water}/\text{cm})} \\ &= 1.127 \frac{(\text{B}/\text{D})\text{cp}}{\text{sq ft}(\text{psi}/\text{ft})} \\ &= 1.424 \times 10^{-2} \frac{(\text{gal}/\text{min})\text{cp}}{\text{sq ft}(\text{ft water}/\text{ft})} \end{aligned}$$

*Because pseudosteady rather than steady state normally exists in the reservoir, average reservoir pressure is used instead of external boundary pressure. Therefore, the $\ln(r_e/r_w)$ term becomes $\ln(r_e/r_w) - 0.75$. See Chaps. 32 and 35 for further discussion. Also, if there is a large temperature difference between the base temperature and flowing temperature, then the z at both conditions should be used.

Fig. 26.21—Radial flow—parallel combination of beds.

Flow Systems of Combinations of Beds

Consider the case where the flow system comprises layers of porous rock separated from each other by infinitely thin, impermeable barriers as shown in Fig. 26.20. The average permeability \bar{k} may be evaluated by Eq. 32.

$$\bar{k} = \frac{\sum_{j=1}^n k_j h_j}{\sum_{j=1}^n h_j} \quad (32)$$

Fig. 26.21 shows that the same terms appear in the radial flow network as in the linear system. The only difference in the two systems is the manner of expressing the length over which the pressure drop occurs. Because all these terms are the same in each of the parallel layers, an evaluation of the parallel radial system yields the same solution as obtained in the linear case.

Example Problem 6—Average Permeability of Beds in Parallel. What is the equivalent linear permeability of four parallel beds having equal widths and lengths under the following conditions?

Bed	Pay Thickness (ft)	Horizontal Permeability (md)
1	20	100
2	15	200
3	10	300
4	5	400

$$\begin{aligned} \bar{k} &= \frac{\sum_{j=1}^n k_j h_j}{\sum_{j=1}^n h_j} ; \\ k &= \frac{(100 \times 20) + (200 \times 15) + (300 \times 10) + (400 \times 5)}{20 + 15 + 10 + 5} \end{aligned}$$

$$= \frac{10,000}{50} = 200 \text{ md.}$$

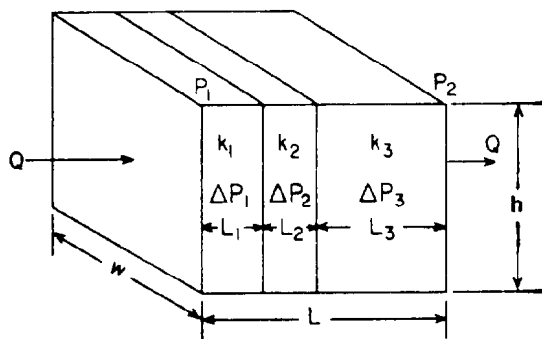

Fig. 26.22—Linear flow—series combination of beds.

Another possible combination for flow systems is to have the beds of different permeabilities to be arranged in series as shown in Fig. 26.22. In the case of linear flow, the average series permeability may be evaluated by Eq. 33.

$$\bar{k} = \frac{L}{\sum_{j=1}^n L_j/k_j} \quad \dots \dots \dots (33)$$

The same reasoning can be used in the evaluation of the average permeability for the radial system (Fig. 26.23) so as to yield

$$\begin{aligned} \bar{k} &= \frac{\ln r_e/r_w}{\sum_{j=1}^n \frac{\ln r_j/r_{j-1}}{k_j}} \\ &= \frac{\log r_e/r_w}{\sum_{j=1}^n \frac{\log r_j/r_{j-1}}{k_j}} \quad \dots \dots \dots (34) \end{aligned}$$

Example Problem 7—Average Permeability of Beds in Series. What is the equivalent permeability of four beds in series, having equal formation thicknesses under the following conditions?

Assume Bed 1 adjacent to the wellbore (1) for a linear system and (2) for a radial system if the radius of the penetrating wellbore is 6 in., and the radius of effective drainage is 2,000 ft.

Bed	Length of Bed (ft)	Horizontal Permeability (md)
1	250	25
2	250	50
3	500	100
4	1,000	200

For a linear system,

$$\bar{k} = \frac{L}{\sum_{j=1}^n L_j/k_j}$$

Fig. 26.23—Radial flow—series combination of beds.

Therefore,

$$\begin{aligned} \bar{k} &= \frac{250 + 250 + 500 + 1,000}{\frac{250}{25} + \frac{250}{50} + \frac{500}{100} + \frac{1,000}{200}} \\ &= \frac{2,000}{10 + 5 + 5 + 5} = 80 \text{ md.} \end{aligned}$$

For a radial system,

$$\begin{aligned} k &= \frac{\log 2,000/0.5}{\frac{\log 250/0.5}{25} + \frac{\log 500/250}{50} + \frac{\log 1,000/500}{100} + \frac{\log 2,000/1,000}{200}} \\ &= 30.4 \text{ md.} \end{aligned}$$

Permeability of Channels and Fractures

Only the matrix permeability has been discussed in the analysis to this point. In some sand and carbonate reservoirs, the formation frequently contains solution channels and natural or artificial fractures. These channels and fractures do not change the permeability of the matrix but do change the effective permeability of the flow network.

Circular Channel. Equating Darcy's and Poiseuille's equations for fluid flow in a tube, the permeability may be expressed as a function of the tube radius.

$$k = \frac{r^2}{8} \quad \dots \dots \dots (35)$$

where k and r are in consistent units.

If r is in centimeters, then k in darcies is given by

$$k = \frac{r^2}{8(9.869 \times 10^{-9})} \approx 12.50 \times 10^6 r^2,$$

where 9.869×10^{-9} is a conversion factor from the previous list. Then, if r is in inches,

$$\begin{aligned} k &= 12.50 \times 10^6 (2.54)^2 r^2 \\ &= 80 \times 10^6 r^2 = 20 \times 10^6 d^2, \end{aligned}$$

where d is the diameter of the opening in inches.

Fig. 26.24—Plot of experimental results for calculation of permeability—(a) from $k/\mu = qL/[A(p_1 - p_2)]$; (b) from $k/\mu = 2qBp_B L/[A(p_1^2 - p_2^2)]$.

Therefore, the permeability of a circular opening 0.005 in. in radius is 2,000,000 md.

Fracture. For flow through slots of fine clearances and unit width, Buckingham²⁵ reports that

$$\Delta p = \frac{12\mu vL}{h^2},$$

such that the permeability of the slot is given by

$$k = \frac{h^2}{12} \dots \dots \dots (36)$$

When h is in centimeters and k in darcies, the permeability of the slot is given by

$$k = \frac{h^2}{12(9.869 \times 10^{-9})} = 84.4 \times 10^5 h^2,$$

and when h is in inches and k is in darcies, permeability is given by

$$k = 54.4 \times 10^6 h^2,$$

so that the permeability of a fracture 0.01 in. in thickness would be 5,440 darcies or 5,440,000 md.

Physical Analogies to Darcy's Law

Ohm's law as commonly written is

$$I = \frac{E}{r},$$

where

- I = current, A,
- E = voltage drop, V, and
- r = resistance of the circuit, Ω ,

but

$$r = \rho \frac{L}{A} \text{ or } r = \frac{L}{\sigma A},$$

where

- ρ = resistivity, $\Omega\text{-cm}$,
- $\sigma = 1/\rho$ = conductivity,
- L = length of flow path, cm, and
- A = cross-sectional area of conductor, cm^2 .

Therefore,

$$I = \frac{AE}{\rho L}.$$

Comparing with Darcy's law for a linear system,

$$q = -\frac{k}{\mu} A \frac{\Delta p}{L}.$$

Note that

$$\begin{aligned} q &\approx I, \\ \frac{k}{\mu} &\approx \frac{1}{\rho}, \text{ and} \\ \frac{\Delta p}{L} &\approx \frac{E}{L}. \end{aligned}$$

The Fourier heat equation may be written as

$$\dot{Q} = k_h A \frac{\Delta T}{L},$$

where

- \dot{Q} = rate of heat flow, Btu/hr,
- A = cross-sectional area, sq ft,
- ΔT = temperature drop, $^{\circ}\text{F}$,
- L = length of the conductor, ft, and
- k_h = thermal conductivity, Btu/(ft-hr- $^{\circ}\text{F}$).

A comparison with Darcy's law indicates that

$$\begin{aligned} q &\approx \dot{Q}, \\ \frac{k}{\mu} &\approx k_h, \text{ and} \\ \frac{\Delta p}{L} &\approx \frac{\Delta T}{L}. \end{aligned}$$

Electrical and heat models (based on these analogies) of rock and well systems frequently are used to solve fluid-flow problems involving complex geometry.

Measurement of Permeability

The permeability of a porous medium may be determined from samples extracted from the formation or by in-place testing. The procedures discussed in this section pertain to the permeability determinations on small samples of extracted media.

Two methods are used to evaluate the permeability of cores. The method most used on clean, fairly uniform formations uses small cylindrical samples called perm plugs that are approximately $\frac{3}{4}$ in. in diameter and 1 in. in length. The second method uses full-diameter core samples in lengths of 1 to $1\frac{1}{2}$ ft. The fluids used with either method may be gas or any nonreactive liquid.

Perm-Plug Method. As core samples ordinarily contain residual oil, water, and gas, it is necessary that the sample be subjected to preparation before the determination of the permeability. The residual fluids normally are extracted by retorting or solvent extraction. The core is dried before permeability measurements are taken. Air commonly is used as the fluid in permeability measurements. The requirement that the permeability be determined for conditions of viscous flow is best satisfied by obtaining data at several flow rates and plotting results, as shown in Fig. 26.24, based on either Eq. 17 or 18. For conditions of viscous flow, the data should plot a straight line, passing through the origin. Turbulence is indicated by curvature of the plotted points. The slope of the straight-line portion of the curve is equal to k/μ , from which the permeability may be computed. To obtain k in darcies, q must be in cm^3/s , A in cm^2 , p_1 and p_2 in atm, L in cm, and μ in cp.

A permeameter designed for the determination of the permeability of rocks with either gas or liquid is illustrated in Fig. 26.25. Data ordinarily are taken from this device at only one flow rate. To assure conditions of viscous flow, the lowest possible rate that can be measured accurately is used.

Example Problem 8—Permeability Measurement. The following data were obtained during a routine permeability test. Compute the permeability of this core.

1. Flow rate = $1,000 \text{ cm}^3$ of air at 1 atm absolute and 70°F in 500 seconds.
2. Pressure, downstream side of core = 1 atm absolute; flowing temperature, 70°F .
3. Viscosity of air at test temperature = 0.02 cp .
4. Cross-sectional area of core = 2.0 cm^2 .
5. Length of core = 2 cm.
6. Pressure, upstream side of core = 1.45 atm absolute.

$$p_1 V_1 + p_2 V_2 = \bar{p} \bar{V}$$

where 1 is upstream conditions and 2 is downstream conditions, and

$$\bar{p} = \frac{p_1 + p_2}{2} = \frac{1.45 + 1}{2} = 1.225,$$

Fig. 26.25—Ruska universal permeameter.

and

$$1 \times 1,000 = 1.225 \bar{V}.$$

$$\bar{V} = 816 \text{ cm}^3,$$

$$\bar{q} = \frac{\bar{V}}{t} = \frac{816}{500} = 1.63,$$

$$k = \frac{\bar{q} L}{A \Delta p} \mu \times 1,000$$

$$= \frac{1.63 \times 2 \times 0.02}{2 \times 0.45} \times 1,000$$

$$= 72.5 \text{ md.}$$

Assuming that the data indicated were obtained, but water was used as the flowing medium, compute the permeability of the core. The viscosity of water at test temperature was 1.0 cp .

$$\bar{q} = \frac{\bar{V}}{t} = \frac{1,000}{500} = 2.0$$

and

$$k = \frac{\bar{q} \mu L}{A \Delta p} \times 1,000 = \frac{2 \times 1 \times 2}{2 \times 0.45} \times 1,000 = 4,444 \text{ md.}$$

Whole-Core Measurement. The core must be prepared in the same manner as perm plugs. The core is then mounted in special holding devices as shown in Fig. 26.26. The measurements required are the same as the perm plugs but the calculations are slightly different.

Fig. 26.26—Clamp-type permeameter for large cores.

In the case of the clamp-type permeameter, the geometry of the flow paths is complex, and an appropriate shape factor must be applied to the data to compute the permeability of the sample. The shape factor is a function of the core diameter and the size of the gasket opening. The shape factor affects the quantity L/A in the previous equations.

Factors Affecting Permeability Measurements

In the techniques of permeability measurement previously discussed, certain precautions must be exercised to obtain accurate results. When gas is being used as the measuring fluid, corrections must be made for gas slippage. When liquid is the testing fluid, care must be taken that it does not react with the solids in the core sample. Also, corrections may be applied for the change in permeability because of the reduction in confining pressure on the sample.

Effect of Gas Slippage on Permeability Measurements

Klinkenberg²⁴ has reported variations in permeability determined by using gases as the flowing fluid from that determined by using nonreactive liquids. These variations were ascribed to slippage, a phenomenon well known with respect to gas flow in capillary tubes. The phenomenon of gas slippage occurs when the diameter of the capillary openings approaches the mean free path of the gas.

Fig. 26.27 is a plot of the permeability of a porous medium as determined at various mean pressures using hydrogen, nitrogen, and carbon dioxide as the flowing fluids. Note that for each gas a straight line is obtained for the observed permeability as a function of the reciprocal of the mean pressure of the test. The data obtained with the lowest-molecular-weight gas yield the straight line with the greatest slope, indicative of a greater slippage effect. All the lines when extrapolated to infinite mean pressure ($1/\bar{p}=0$) intercept the permeability axis at a common point. This point is designated as the equivalent liquid permeability, k_L . Klinkenberg and

Fig. 26.27—Permeability constant of core sample L to hydrogen, nitrogen, and CO_2 at different pressures (permeability constant to iso-octane, 2.55 md).

others established that the permeability of a porous medium to a nonreactive homogeneous single-phase liquid was equal to the equivalent liquid permeability.

The linear relationship between the observed permeability and the reciprocal of mean pressure may be expressed as follows.

$$k_L = \frac{k_g}{1 + b/\bar{p}} = k_g - m \frac{1}{\bar{p}}, \quad \dots \dots \dots (37)$$

where

k_L = permeability of the medium to a single liquid phase completely filling the pores of the medium,

k_g = permeability of the medium to a gas completely filling the pores of the medium,

\bar{p} = mean flowing pressure of the gas at which k_g was observed,

b = constant for a given gas in a given medium, and

m = slope of the curve.

Reactive Fluids. While water commonly is considered to be nonreactive in the ordinary sense, the occurrence of swelling clays in many reservoir rock materials results in water's being the most frequently occurring reactive liquid in connection with permeability determinations. Reactive liquids alter the internal geometry of the porous medium. This phenomenon does not vitiate Darcy's law but rather results in a new porous medium, the permeability of which is determined by the new internal geometry.

While fresh water may cause the cementation material in a core to swell because of hydration, it is a reversible process. A highly saline water may be flowed through the core and return the permeability to its original value. The effect of water salinity on permeability is shown in Table 26.3.²⁵

TABLE 26.3—EFFECT OF WATER SALINITY ON PERMEABILITY OF NATURAL CORES (Grains/gal Chloride ion*)

Field	Zone	k_a	$k_{1,000}$	k_{500}	k_{300}	k_{200}	k_{100}	k_w

T	36	3,090	2,080	1,900	1,750	1,630	1,490	1,040

*For example, k_a means permeability to air, k_{500} means permeability to 500-grain/gal chloride solution, and k_w means permeability to fresh water.

Care must be taken that laboratory permeability values are corrected to liquid values obtained with water whose salinity corresponds to formation water.

Overburden Pressure. When the core is removed from the formation, all the confining forces are removed. The rock matrix is permitted to expand in all directions, partially changing the shapes of the fluid-flow paths inside the core.

Compaction of the core caused by overburden pressure may cause as much as a 25% reduction in the permeability of various formations, as observed in Fig. 26.28.²⁶ Note that some formations are much more compressible than others; thus, more data are required to develop empirical correlations that will permit the correction of surface permeability for overburden pressures.

Factors in Evaluation of Permeability From Other Parameters

Permeability, like porosity, is a variable that can be measured for each rock sample. To aid in understanding fluid flow in rocks and possibly to reduce the number of measurements required on rocks, correlations among porosity, permeability, surface area, pore size, and other variables have been made. The reasoning behind some of the correlations among porosity, permeability, and surface area is presented here to enable the reader to gain some understanding of the interrelation of the physical properties of rocks. Although these relations are not quantitative, they are indicative of the interdependence of rock characteristics.

Use of Capillary Tubes for Flow Network. The permeability of a tube derived from Darcy's and Poiseuille's equation is

$$k = \frac{r^2}{8}$$

If a porous system is conceived to be a bundle of capillary tubes, then it can be shown that the permeability of the medium depends on the pore-size distribution and porosity. A flow network of tubes would be similar to layers of different permeability in parallel, such that the average permeability could be calculated by adapting Eq. 32 to read

$$\bar{k} = \frac{\sum_{j=1}^m k_j A_j}{\sum_{j=1}^m A_j}, \dots \dots \dots (38)$$

where k_j is the permeability of one capillary tube and A_j is the area of flow represented by a bundle of tubes of permeability k_j .

Fig. 26.28—Change in permeability with overburden pressure.

The quantities k_j and A_j can be defined in terms of the radius of capillary tubes.

$$A_j = \pi n_j r_j^2$$

and

$$k_j = \frac{r_j^2}{8},$$

where n_j is the number of tubes of radius r_j .

$$\sum_{j=1}^m A_j = \phi A_t,$$

where ϕ is the porosity of the flow network and A_t is the total cross-sectional area of the flow network. By substitution, Eq. 38 reduced to

$$\bar{k} = \frac{\phi}{8} \frac{\sum_{j=1}^m n_j r_j^4}{\sum_{j=1}^m n_j r_j^2}, \quad (39)$$

where \bar{k} is the average permeability of the tube bundle.

Note that the permeability of a bundle of tubes is a function not only of the pore size but of the arrangement or porosity of the system.

Consider a system that comprises a bundle of capillary tubes of the same radii and length; k , the permeability, may be written from Eq. 39 as

$$k = \frac{\phi r^2}{8}. \quad (40)$$

The internal surface area per unit PV, A_s , may be defined in terms of the tube radius by

$$A_s = \frac{2}{r}. \quad (41)$$

Combining Eqs. 40 and 41 gives the permeability as a function of porosity and internal surface area. This function is

$$k = \frac{4\phi}{8A_s^2} = \frac{\phi}{2A_s^2}.$$

If $1/K_z$ is substituted for the constant $1/2$, the resulting expression is Kozeny's equation wherein K_z is defined as the Kozeny's constant.

$$k = \frac{\phi}{K_z A_s^2}. \quad (42)$$

Wyllie²⁷ derived the Kozeny equation from Poiseuille's law by using a specified flow network. The resulting permeability for this flow network is given by Eq. 43.

$$k = \frac{\phi}{F_s A_s^2} \left(\frac{L}{L_a} \right)^2, \quad (43)$$

where

k = permeability of the porous medium,

F_s = shape factor,

L = length of the sample, and

L_a = actual length of the flow path.

If

$$\left(\frac{L_a}{L} \right)^2 = \tau = \text{tortuosity of the porous medium}$$

and $K_z = F_s \tau$ = Kozeny constant, then Wyllie's equation will reduce to the same form as Eq. 42.

Fluid Saturations

In the previous sections of this chapter, the storage and the conduction capacity of a porous rock were discussed. To the engineer there is yet another important factor to be determined—i.e., the fluid content of the rock. In most oil-bearing formations, it is believed that the rock was completely saturated with water before the invasion of the rock by petroleum. The oil will not displace all the water from the pore space. Therefore, to determine the quantity of hydrocarbons accumulated in a porous rock formation, it is necessary to determine the fluid saturation (oil, water, and gas) of the rock.

There are two approaches to the problem of determining the fluid saturations within a reservoir rock. The direct approach is to measure, in the laboratory, the saturations of selected rock samples recovered from the parent formation. The indirect approach is to determine the fluid saturation by measuring some related physical property of the rock.

Factors Affecting Fluid Saturations of Cores

The core samples delivered to the laboratory for fluid-saturation determinations are obtained from the ground by either rotary, sidewall, or cable-tool coring. In all cases, the fluid content of these samples has been altered by two processes. First, in the case of rotary drilling, the mud column exerts a greater pressure at the formation wellbore surface than the fluid in the formation. The differential pressure between the mud column and the formation fluids causes mud and mud filtrate to invade the formation, thus flushing the formation with mud and its filtrate. The filtrate displaces some of the original fluids. This displacement process changes the original fluid contents of the in-place rock. Second, as the sample is brought to the surface, the confining pressure of the fluid column is constantly decreasing. The reduction of pressure permits the expansion of the entrapped water, oil, and gas. Gas, having the greater coefficient of expansion, expels oil and water from the core. Thus, the content of the core at the surface has been changed from that which existed in the formation. Because the invasion

of the filtrate precedes the core bit, it is not possible to use pressurized core barrels to obtain undisturbed samples.

Drill cuttings, chips, or cores from cable-tool drilling also have undergone definite physical changes. If little or no fluid is maintained in the wellbore, the formation adjacent to the well surface is depleted because of pressure reduction. As chips are formed in the well, they may or may not be invaded, depending on the fluids in the wellbore and the physical properties of the rock. In all probability, fluid will permeate this depleted sample, resulting in flushing. Thus, even cable-tool cores undergo the same two processes as was noted in the case of rotary coring, although in reverse order.

Sidewall cores from either rotary- or cable-tool-drilled holes are subjected to these same processes.

In an attempt to understand better the overall effect of the physical changes that occur in the core because of flushing and fluid expansion, Kennedy *et al.*²⁸ undertook a study to simulate rotary-coring techniques. The effects of both invasion and expansion because of pressure reduction were measured.

Schematics of the changes in saturation resulting from these two processes for oil- and water-based muds are shown in Fig. 26.29. For the water-based mud, the original displacing action of the water filtrate reduced the oil saturation by approximately 14%. The expansion to surface pressure displaced water and additional oil. The final water saturation was greater than the water saturation before coring. With oil-based mud, wherein the filtrate is oil, the displacing action did not alter the initial water saturations but did result in replacement of approximately 20% of the initial oil. On pressure depletion, a small fraction of the water was expelled, reducing the water saturation from 49.1 to 47.7%. The oil saturation was reduced by both processes from 50.9 to 26.7%. Thus, even when high water saturations are involved, up to approximately 50%, the water-saturation values obtained with oil-based muds may be considered to be representative of the initial water saturations in the reservoir. Hence, it is possible to obtain fairly representative values of in-place water saturations by using oil-based muds.

Attempts have been made to use tracers in the drilling fluid to determine the amount of water in the core that is caused by mud-filtrate invasion. The theory was that mud filtrate displaced only oil. Thus, upon recovering the core to the surface, the salt concentration of the core water could be determined. Thus, if the salt concentration in the reservoir water and the tracer concentration in the drilling fluid were known, the volume of filtrate and reservoir water in the core could be calculated. Because a large fraction of the initial reservoir water may have been displaced by the invading filtrate, the tracer method results in incorrect values for reservoir-water saturation.

To obtain realistic values of fluid saturation, it is necessary to choose the proper drilling fluid or to use indirect methods of saturation determination.

Determination of Fluid Saturations from Rock Samples

One of the most popular means of measuring fluid saturations of cores is the retort method. This method takes a small rock sample and heats the sample to

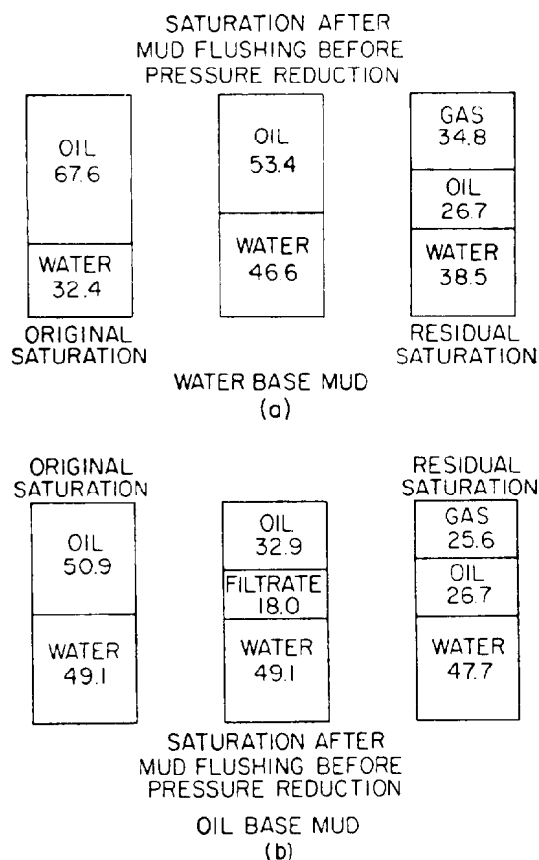

Fig. 26.29—Typical changes in saturations of cores flushed with water-based and oil-based muds.

vaporize the water and the oil, which is condensed and collected in a small receiving vessel. The retort method has several disadvantages as far as commercial work is concerned. The water of crystallization within the rock is driven off, causing the water-recovery values to be too high. The second error that occurs from retorting samples is that the oil, when heated to high temperatures, has a tendency to crack and coke. This change of hydrocarbon molecules tends to decrease the liquid volume. The fluid wetting characteristics of the sample surface may be altered during the retorting process as a result of the two previous factors. Before retorts can be used, calibration curves must be prepared for water and oils of various gravities to correct for losses and other errors. These curves can be obtained by running "blank" runs (retorting known volumes of fluids of known properties). The retort is a rapid method for determining fluid saturations and, if the corrections are used, yields satisfactory results. It gives both water and oil volumes such that the oil and water saturations can be calculated from the following equations.

$$S_w = \frac{V_w}{V_p},$$

$$S_o = \frac{V_o}{V_p},$$

Fig. 26.30—Laboratory layout for performing routine core analysis

and

$$S_g = 1 - S_w - S_o$$

{ live

- S_w water saturation,
- S_o oil saturation,
- S_g gas saturation,
- V_w water volume, cm^3 ,
- V_p pore volume, cm^3 , and
- V_o oil volume, cm^3 .

The other method of determining fluid saturation is by extraction with a solvent. Extraction may be accomplished by a modified ASTM distillation method or a centrifuge method. In the standard distillation test, the core is placed such that a vapor of either toluene, pentane, octane, or naphtha rises through the core. This process leaches out the oil and water in the core. The water and extracting fluid are condensed and collected in a graduated receiving tube. The water settles to the bottom of the receiving tube because of its greater density, and the extracting fluid refluxes over the core and into the main heating vessel. The process is continued until no more water is collected in the receiving tube. The water saturation may be determined directly by

$$S_w = \frac{V_w}{V_p}$$

The oil saturation is an indirect determination. The oil saturation as a fraction of PV is given by

$$S_o = \frac{W_{cw} - W_{cd} - W_w}{V_p - \rho_o},$$

where

- W_{cw} = weight of wet core, g,
- W_{cd} = weight of dry core, g,
- W_w = weight of water, g,
- V_p = PV, cm^3 , and
- ρ_o = density of oil, g/cm^3 .

The gas saturation is obtained in the same manner as the retort.

Another method of determining water saturation is to use a centrifuge. A solvent is injected into the centrifuge just off center. Because of centrifugal force, it is thrown to the outer radii and forced to pass through the core sample. The outflow fluid is trapped and the quantity of water in the core is determined. The use of the centrifuge provides a very rapid method because of the high forces that can be applied. In both extraction methods, at the same time that the water content is determined, the core is cleaned in preparation for the other measurements such as porosity and permeability.

There is another procedure for saturation determination that is used in conjunction with either of the extraction methods. The core as received from the well is placed in a modified mercury porosimeter in which the BV and gas volume are measured. The volume of water is determined by one of the extraction methods. The fluid saturations can be calculated from these data.

In connection with all procedures for determination of fluid content, a value of PV must be established in order that fluid saturations may be expressed as percent of PV. Any of the porosity procedures previously described may be used. Also, the BV and gas volume determined from the mercury porosimeter may be combined with the oil and water volumes obtained from the retort to calculate PV, porosity, and fluid saturations.

Porosity, permeability, and fluid-saturation determinations are the measurements commonly reported in routine core analysis. A laboratory equipped for such determinations is shown in Fig. 26.30.

Interstitial Water Saturations

Essentially, three methods are available to the reservoir engineer for the determination of interstitial water saturations. These methods are (1) determination from cores cut with oil-based muds, (2) determination from capillary-pressure data, and (3) calculation from electric-log analysis (see Chap. 49).

Oil-Based Mud. The obtaining of water saturations by using oil-based muds has been discussed. A correlation between water saturation and air permeability for cores obtained with oil-based muds is shown in Fig. 26.31.²⁹

A general trend of increasing water saturation with decreasing permeability is indicated. It is accepted from field and experimental evidence that the water content determined from cores cut with oil-based mud reflects closely the water saturation as it exists in a reservoir, except in transition zones where some of the interstitial water is replaced by filtrate or displaced by gas expansion.

Fig. 26.32 shows permeability/interstitial-water relationships reported in the literature for a number of fields and areas. There is no general correlation applicable to all fields; however, an approximately linear correlation between interstitial water and the logarithm of permeability exists for each individual field. The general trend of the correlation is decreasing interstitial water with increasing permeability.

Capillary Pressure. Capillary pressure may be thought of as a force per unit area resulting from the interaction of surface forces and the geometry of the medium in which they exist. Capillary pressure for a capillary tube is defined in terms of the interfacial tension between the fluids, σ , the angle of contact of the interface of these two fluids and the tube, θ_c , and the radius of the tube, r_t .

This relationship is expressed in Eq. 44.

$$P_c = \frac{2\sigma \cos \theta_c}{r_t} \quad (44)$$

where the angle θ_c is measured through the more dense fluid.

In a packing of spheres, the capillary pressure is expressed in terms of any two perpendicular radii of cur-

Fig. 26.31—Relation of air permeability to the water content of the South Coles Levee cores.

vature (these radii touch at only one point), r_1 and r_2 , and the interfacial tension of the fluids. This relationship is given in Eq. 45.

$$P_c = \sigma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (45)$$

Comparing Eq. 45 with the equation for capillary pressure as determined by the capillary-tube method, it is found that the mean radius \bar{r} is defined by

$$\frac{1}{\bar{r}} = \frac{1}{r_1} + \frac{1}{r_2} = \frac{2 \cos \theta_c}{r_t};$$

$$\bar{r} = \frac{r_1 r_2}{r_1 + r_2} = \frac{r_t}{2 \cos \theta_c} \quad (46)$$

Fig. 26.32—Interstitial water vs. permeability relationships.

Fig. 26.33—Schematic of porous-diaphragm method of capillary pressure.

It is practically impossible to measure the values of r_1 and r_2 ; hence, they generally are referred to by the mean radius of curvature and empirically determined from other measurements on a porous medium.

The distribution of the liquid in a porous system depends on the wetting characteristics. It is necessary to determine which is the wetting fluid so as to ascertain which fluid occupies the small pore spaces. From packings of spheres, the wetting-phase distribution within a porous system has been described as either funicular or pendular in nature. In funicular distribution, the wetting phase is continuous, completely covering the surface of the solid. The pendular ring is a state of saturation in which the wetting phase is not continuous and the nonwetting phase is in contact with some of the solid surface. The wetting phase occupies the smaller interstices. As the wetting-phase saturation progresses from the funicular to the pendular-ring distribution, the volume of the wetting phase decreases and the mean radius of curvature or the values of r_1 and r_2 tend to decrease in magnitude. Referring to Eq. 46, we see that if r_1 and r_2 decrease in size, the magnitude of the capillary pressure would have to increase in value. Since r_1 and r_2 can be related to the wetting-phase saturation, it is possible to express the capillary pressure as a function of fluid saturation when two immiscible phases are within the porous matrix.

Laboratory Measurements of Capillary Pressure

Essentially, five methods of measuring capillary pressure on small core samples are used. These methods are (1) the desaturation or displacement process, through a porous diaphragm or membrane (restored-state method of Welge³⁰), (2) the mercury-injection method, (3) the centrifuge or centrifugal method, (4) the dynamic-capillary-pressure method, and (5) the evaporation method.*

Porous Diaphragm. The first of these, illustrated in Fig. 26.33, is the displacement or diaphragm method. The essential requirement of the diaphragm method is a

permeable membrane of uniform pore-size distribution containing pores of such size that the selected displacing fluid will not penetrate the diaphragm when the pressures applied to the displacing phase are below some selected maximum pressure of investigation. Various materials including fritted glass, porcelain, and cellophane have been used successfully as diaphragms. Pressure applied to the assembly is increased by small increments. The core is allowed to approach a state of static equilibrium at each pressure level. The saturation of the core is calculated at each point defining the capillary-pressure curve. Any combination of fluids may be used: gas, oil, and/or water. Although most determinations of capillary pressure by the diaphragm method are drainage tests, by suitable modifications imbibition curves similar to Leverett's may be obtained.

Mercury Injection. The mercury-capillary-pressure apparatus was developed to accelerate the determination of the capillary-pressure/saturation relationship. Mercury is normally a nonwetting fluid. The core sample is inserted in the mercury chamber and evacuated. Mercury is forced into the core under pressure. The volume of mercury injected at each pressure determines the nonwetting-phase saturation. This procedure is continued until the core sample is filled with mercury or the injection pressure reaches some predetermined value. Two important advantages are gained by this method: (1) the time for determination is reduced to a few minutes, and (2) the range of pressure investigation is increased because the limitation of the diaphragm's properties is removed. Disadvantages are the difference in wetting properties and permanent loss of the core sample.

Centrifuge Method. A third method for determining capillary properties of reservoir rocks is the centrifuge method.³¹ The high accelerations in the centrifuge increase the field of force on the fluids, in effect subjecting the core to an increased gravitational force. By rotating the sample at various constant speeds, a complete capillary-pressure curve may be obtained. The speed of rotation is converted into force units in the center of the core sample, and the fluid saturation is read visually by the operator. The advantage of the method is the increased speed of obtaining the data. A complete curve may be established in a few hours, while the diaphragm method requires days.

Dynamic Method. Brown³² reported the results of determining capillary-pressure/saturation curves by a dynamic method. Simultaneous steady-state flow of two fluids is established in the core. By the use of special wetted disks that permitted hydraulic pressure transmission of only the selected fluid phase, the difference in the resulting measured pressures of the two fluids in the core is the capillary pressure. The saturation is varied by regulating the quantity of each fluid entering the core. Thus, it is possible to obtain a complete capillary-pressure curve.

Comparison of Methods of Measurement

Intuitively, it appears that the diaphragm method (restored state) is superior in that oil and water are used; therefore, actual wetting conditions are more nearly ap-

*Since this method is seldom used today, it will not be discussed. The procedure consists of continuously monitoring the decrease in weight caused by evaporation of a core sample initially 100% saturated with a wetting fluid. See Messner, E.S.: "Interstitial Water Determination By An Evaporation Method," *Trans., AIME* (1951) 192, 269-74.

proached. Hence, the diaphragm method is used as the standard to which all other methods are compared. The mercury-injection test data must be corrected for wetting conditions before they can be compared with results from the restored-state method. If it is assumed that the mean curvature of an interface in rock is a unique function of fluid saturation, then the ratio of mercury to water capillary-pressure data is given by

$$\frac{P_{cm}}{P_{cw}} = \frac{\sigma_m}{\sigma_w} = \frac{480}{70} = 6.57, \quad (47)$$

where σ_m is the surface tension of mercury and σ_w is the surface tension of water. Experimentation has shown the ratio to vary between 5.8 (for limestones) and 7.5 (for sandstones). Thus, no conversion factor can be defined that will apply to all rocks.

Good agreement of centrifuge data with those from the diaphragm method was reported by Slobod.³¹ Unlike the mercury-injection method, there is no need of conversion factors to correct for wetting properties. The same fluids are used in the centrifugal and diaphragm methods.

Excellent correlation was obtained by Brown³² between the diaphragm and dynamic methods. The dynamic data were obtained by simultaneous steady flow of oil and gas through the porous sample at a predetermined level of pressure difference between the fluids. Care was taken to maintain uniform saturations throughout the core as well as to conduct the test such that a close correspondence to drainage conditions existed.

If capillary-pressure data are to be used for determining fluid saturations, the values obtained should be comparable with those of other methods. Water distributions, as determined from electric logs, and capillary-pressure data are normally in good agreement. A comparison of these methods is shown in Fig. 26.34.³³ Shown also is the approximate position of the gas/oil contact as determined from other test data. In the gas-bearing portion of the formation there is no significant variation in water saturation with depth or method of determination. However, in a thin oil zone, such as that shown in Fig. 26.34, there is a significant variation in the water saturation with depth. Variations in water saturations with depth within an oil zone must be taken into account to determine accurately average reservoir interstitial-water saturations.

Water Saturation from Capillary-Pressure Data. In oilfield terms, the capillary pressure may be stated as

$$P_c = \frac{h}{144} (\rho_1 - \rho_2), \quad (48)$$

where h is in feet and ρ_1 and ρ_2 are the densities of Fluids 1 and 2, respectively, in lbm/cu ft at the conditions of the capillary pressure.

Converting Laboratory Data. To use laboratory capillary-pressure data, it is necessary to convert them to reservoir conditions. Laboratory data are obtained with a

Fig. 26.34—Comparison of water saturation from capillary pressure and electric log.

gas/water or an oil/water system that normally does not have the same physical properties as the reservoir water, oil, and gas.

Essentially two techniques, differing only in the initial assumptions, are available for correcting laboratory capillary-pressure data to reservoir conditions.

$$P_{c,R} = \frac{\sigma_{wo} \cos \theta_{cwo}}{\sigma_{wg} \cos \theta_{cwg}} P_{c,L}$$

or

$$P_{c,R} = \frac{\sigma_R}{\sigma_L} P_{c,L}, \quad (49)$$

where

- σ_{wo} = interfacial tension water/oil,
- σ_{wg} = interfacial tension water/gas,
- θ_{cwo} = water/oil contact angle,
- θ_{cwg} = water/gas contact angle,
- subscript
- R = reservoir conditions, and
- subscript
- L = laboratory conditions.

Since the interfacial tensions enter as a ratio, pressure in any consistent units may be used together with the interfacial tension in dynes/cm.

Averaging Capillary-Pressure Data. Two methods have been proposed for correlating capillary-pressure data of similar geologic formations. The first correlating procedure is a dimensionless grouping of the physical properties of the rock and the saturating fluids. This function is called a J function³⁴ and is expressed as

$$J(S_w) = \frac{P_c}{\sigma} \left(\frac{k}{\phi} \right)^{1/2}, \quad (50)$$

where

- S_w = water saturation, fraction of PV,
- P_c = capillary pressure, dyne/cm²,
- σ = interfacial tension, dyne/cm,
- k = permeability, cm², and
- ϕ = fractional porosity.

Fig. 26.35—Series of capillary-pressure curves as a function of permeability.

Some authors alter the above expression by including the $\cos \theta_c$ (where θ_c is the contact angle) as follows.

$$J(S_w) = \frac{P_c}{\sigma \cos \theta_c} \left(\frac{k}{\phi} \right)^{1/2}$$

The J function originally was proposed as a means of converting all capillary-pressure data to a universal curve. There exist significant differences in correlation of the J function with water saturation from formation to formation such that no universal curve may be obtained, but the J function may be used to correlate the data from one formation.

The second method of evaluating capillary-pressure data is to analyze a number of representative samples and treat the data statistically to derive correlations that, together with the porosity and permeability distribution data, may be used to compute the interstitial-water saturations for a field. A first approximation for the correlation of capillary-pressure data is to plot water saturation against the logarithm of permeability for constant values of capillary pressure. A straight line may be fitted to the data for each value of capillary pressure, and average-capillary-pressure curves may be computed from permeability-distribution data for the field. The resulting straight-line equation takes the general form of

$$S_w = m \log k + b \quad (51)$$

Fluid-distribution curves are reported for several values of permeability, ranging from 10 to 900 md in Fig. 26.35.³⁵ These data also may be considered to be capillary-pressure curves. The ordinate on the right reflects values of capillary pressure determined by displacing water with air in the laboratory. The ordinates on the left include the corresponding oil/water capillary pressure that would exist at reservoir conditions and the fluid distribution with height above the free-water surface.

The results of the statistical correlation previously discussed applied to the capillary-pressure data presented in Fig. 26.35 are shown in Fig. 26.36. The reader should note the linearity of the curves for each value of capillary pressure and the tendency of all capillary-pressure curves to converge at high permeability values. This behavior is what normally would be expected because of the larger capillaries associated with high permeabilities.

To convert capillary-pressure saturation data to height saturation, it is necessary only to rearrange the terms in Eq. 48 so as to solve for the height instead of the capillary pressure—i.e.,

$$h_{fw} = \frac{P_c \times 144}{\rho_w - \rho_o} \quad (52)$$

where

h_{fw} = height above the free-water surface, ft,

ρ_w = density of water at reservoir conditions, lbm/cu ft,

ρ_o = density of oil at reservoir conditions, lbm/cu ft, and

P_c = capillary pressure at some particular saturation for reservoir conditions (it must be converted from laboratory data first, psi).

Example Problem 9—Calculation of Saturation Plane From Laboratory Capillary-Pressure Data. If

$P_{c,L} = 18$ psi for $S_w = 0.35$,

$\sigma_{wo} = 24$ dynes,

$\rho_w = 68$ lbm/cu ft,

$\sigma_{wg} = 72$ dynes, and

$\rho_o = 53$ lbm/cu ft,

then, from Eq. 49,

$$P_{c,R} = 18(24/72) = 18/3 = 6 \text{ psi,}$$

and

$$h = \frac{P_{c,R} \times 144}{\rho_w - \rho_o} = \frac{6 \times 144}{68 - 53} = 58 \text{ ft.}$$

Thus, a water saturation of 35% exists at a height of 58 ft above the free-water surface.

To calculate the fluid saturation in the gas zone, it is necessary to consider all three phases: oil, water, and gas. If all three phases are continuous, it can be shown that

$$P_{c,wg} = P_{c,wo} + P_{c,og},$$

where

$P_{c,wg}$ = capillary pressure at a given height above the free-water surface determined by using water and gas,

$P_{c,wo}$ = capillary pressure at a given height above the free-water surface, using water and oil, and

$P_{c,og}$ = capillary pressure at a given height above the free-oil surface, using oil and gas.

If the wetting phase becomes discontinuous, then the wetting-phase saturation takes on a minimum value, and, at all heights above the point of discontinuity, the wetting-phase saturation cannot be less than this minimum value. It is then possible to calculate the fluid saturations above the free-oil surface by the following relations.

1. S_w at h is calculated using oil and water as the continuous phases.

2. S_L at h is calculated using oil and gas as the continuous phases and height denoted by the free-oil surface.

3. $S_g = 1 - S_L$ and $S_o = S_L - S_w$, where S_L is the total liquid saturation, oil plus water, fraction.

Example Problem 10—Calculation of Water and Oil Saturation in Gas Zone From Capillary-Pressure Data. Let oil-zone thickness, h_o , equal 70 ft and

$$\begin{aligned}\sigma_{wg} &= 72 \text{ dynes,} \\ \sigma_{og} &= 50 \text{ dynes,} \\ \sigma_{wo} &= 25 \text{ dynes,} \\ \rho_w &= 68 \text{ lbm/cu ft} \\ \rho_g &= 7 \text{ lbm/cu ft, and} \\ \rho_o &= 53 \text{ lbm/cu ft.}\end{aligned}$$

From Fig. 26.28 for a 900-md sample, let

$P_{c,L} = 54$ psi by the method illustrated in

Example Problem 9,

$P_{c,R} = 18$ psi,

$h_{fw} =$ height above free-water level = 120 ft, and

$S_w = 16\%$ at a height of 70 ft or greater (read from curve).

Since the oil zone is only 70 ft thick, the height of 120 ft above the free-water surface must be at least 50 ft into the gas-saturated zone. The first step is to calculate the total fluid saturation, S_L , using gas and oil as the continuous phases.

$$h_{fo} = h_{fw} - h_o = 120 - 70 = 50 \text{ ft;}$$

$$P_{c,R} = \frac{h_{fo}}{144} (\rho_o - \rho_g),$$

where h_{fo} is the height above free-oil level, ft.

$$P_{c,R} = 50/144 \times (53 - 7) = 50/144 \times 46,$$

$$P_{c,R} = 15.97,$$

and

$$P_{c,L} = P_{c,R} \frac{\sigma_{wg}}{\sigma_{og}} = 15.97 \times 72/50 = 23 \text{ psi.}$$

From Fig. 26.35, for a laboratory capillary pressure of 23 psi and a permeability of 900 md, the total wetting saturation, S_L , equals 18%. Therefore,

$$S_o = S_L - S_w = 18 - 16 = 2\%$$

Fig. 26.36—Correlation of water saturation with permeability for various capillary pressures.

and

$$S_g = (100 - S_L) = 100 - 18 = 82\%.$$

It must be understood that the relationships used in Example Problem 10 for calculating the fluid saturations in the gas zone were based on continuity of all three phases. Since this is not normally the case, it might be expected that saturations somewhat different from the calculated values exist. Because the capillary pressure for a discontinuous phase could vary from pore to pore, it is impossible to ascertain the exact relationships that should exist. Hence, the preceding method of calculating fluid distributions is not exact but is usually as accurate as the data available for making the computation.

Electrical Conductivity of Fluid-Saturated Rocks

Porous rocks comprise an aggregate of minerals, rock fragments, and void space. The solids, with the exception of certain clay minerals, are nonconductors of electricity. The electrical properties of a rock depend on the geometry of the voids and the fluids that fill the voids. The fluids of interest in petroleum reservoirs are oil, gas, and water. Oil and gas are nonconductors. Water is a

Fig. 26.37—Core-sample resistivity cell.

conductor when it contains dissolved salts. Current is conducted in water by movement of ions and therefore may be termed electrolytic conduction. The resistivity of a material is the reciprocal of conductivity and commonly is used to define the ability of a material to conduct current. The resistivity of a material is defined by the following equation.

$$\rho = \frac{rA}{L}, \quad (53)$$

where

- ρ = resistivity,
- r = resistance,
- A = cross-sectional area of the conductor, and
- L = length of the conductor.

For electrolytes, ρ is commonly reported in Ω -cm, and r is expressed in ohms, A in cm^2 , and L in cm. In the study of the resistivity of soils and rocks, it has been found that the resistivity may be expressed more conveniently in Ω -m. To convert to Ω -m from Ω -cm, divide the resistivity in Ω -cm by 100. In oilfield practice, the resistivity in Ω -m commonly is represented by the symbol R with an appropriate subscript to define the condition to which R applies.

Fundamental Concepts

The definition of electrical formation resistivity factor is perhaps the most fundamental concept in considering electrical properties of rocks. The formation resistivity factor as defined by Archie²⁷ is

$$F_R = \frac{R_0}{R_w}, \quad (54)$$

where R_0 is the resistivity of the rock when saturated with water having a resistivity of R_w .

The second fundamental notion of electrical properties of porous rock is the resistivity index, I_R , which is defined as

$$I_R = \frac{R_t}{R_0}, \quad (55)$$

where R_t is the true resistivity of the rock system at some particular value of water saturation and R_0 is as previously defined.

Three idealized representations have been introduced in the literature from which the formation resistivity factor, F_R , and the resistivity index, I_R , have been related to the porosity, ϕ , and the rock tortuosity, τ .

From Wyllie's²⁷ analysis the relations are

$$F_R = \tau \frac{1}{\phi}$$

and

$$I_R = \tau_e \frac{1}{S_w},$$

where τ_e is the effective rock tortuosity at some water saturation.

Cornell and Katz³⁶ presented an analysis of a slightly different model. The relationships developed are as follows.

$$F_R = \sqrt{\tau} \frac{1}{\phi}$$

and

$$I_R = \sqrt{\tau_e} \frac{1}{S_w}.$$

Wyllie and Gardner³⁷ later presented an analysis based on a probability theory from which the following relationships were obtained.

$$F_R = \frac{1}{\phi^2}$$

and

$$I_R = \frac{1}{S_w^2}.$$

From the analysis of the electrical properties of the foregoing idealized pore models, general relationships between electrical properties and other physical properties of the rock may be deduced. The formation resistivity factor has been shown to be some function of the porosity and the internal geometry of the rock system. In particular, the formation resistivity factor may be expressed in the following form.

$$F_R = K\phi^{-m}, \quad (56)$$

where K is some function of the tortuosity and m is a function of the number of reductions in pore-opening sizes or closed channels. It is suggested that K should be 1 or greater. The value of m has been shown from theory to range from 1 to 2.

Both the formation resistivity factor, F_R , and the resistivity index, I_R , depend on ratios of path length or tortuosities. Therefore, to compute the formation resistivity factor or resistivity index from the relations derived from models, it is necessary to determine the electrical tortuosity. Since direct measurement of the path length is impossible, reliance has been placed primarily on empirical correlations based on laboratory measurements. Winsauer *et al.*³⁸ devised a method of determining tortuosity by transit time of ions flowing through a rock under a potential difference. The data obtained were correlated with the product $F_R\phi$. The resulting correlation of formation resistivity factor, porosity, and tortuosity is given in Eq. 57.

$$\left(\frac{L_a}{L}\right)^{1.67} = F_R\phi,$$

where L_a is the actual length of flow path, and L is the length of the sample, or

$$\tau^{1.67/2} = F_R\phi. \quad (57)$$

The deviation from the theory is believed to be an indication of the greater complexity of the actual pore system than that of the models on which the theory was based.

Archie suggested that the formation resistivity factor could be correlated with porosity and have the form

$$F_R = \phi^{-m}, \quad (58)$$

where ϕ is the fractional porosity and m is the cementation factor. Archie further reported that the cementation factor probably ranged from 1.8 to 2.0 for consolidated sandstones and, for clean unconsolidated sands, was about 1.3.

Measurement of Electrical Resistivity of Rocks

Laboratory measurements of electrical properties of rocks have been made with a variety of devices. The measurements require a knowledge of the dimensions of the rock, the fluid saturation of the rock, the resistivity of the water contained in the rock, and a suitable resistivity cell in which to test the samples. A simple cell is shown in Fig. 26.37.³⁹ A sample cut to suitable size is placed in the cell and clamped between electrodes A. Current is then passed through the sample and the potential drop observed. The resistance of the sample is computed from Ohm's law,

$$r = \frac{E}{I},$$

and R (the resistivity) is computed from

$$R = \frac{rA}{L},$$

where A is the cross-sectional area of the sample and L is the length of the sample. The saturation conditions of the test may be established at known values before measurement or determined by an extraction procedure after measurement.

Fig. 26.38—Comparison of various formation resistivity factor correlations.

Empirical Correlation of Electrical Properties

Archie, as previously mentioned, reported the results of correlating laboratory measurements of formation factor with porosity. He expressed his results in the form $F_R = \phi^{-m}$.

Winsauer *et al.*³⁸ reported a similar relationship based on correlations of data from a large number of sandstone cores. This equation, commonly referred to as the Humble relation, is

$$F_R = 0.62\phi^{-2.15}. \quad (59)$$

In discussing the theory of the formation resistivity factor, it was stated that K should be greater than 1 and that m should be 2 or less. At this time, the discrepancy between theory and experiment must be attributed to the possible effect of conducting solids.

Improved correlations should result from considering other parameters, such as permeability, as variables in the relations.

A comparison of suggested relationships between porosity and the formation resistivity factor is shown in Fig. 26.38.

Fig. 26.39—Effect of interstitial clay on formation resistivity factors.

Effect of Conductive Solids

Investigations by Wyllie⁴¹ indicate that clays contribute substantially to the conductivity of a rock when the rock is saturated with a low-conductivity water. The effect of water resistivity on the formation resistivity factor for sands containing clay minerals is shown in Fig. 26.39. The formation resistivity factor for a comparable clean (clay-free) sand is a constant. The formation resistivity factor for the clayey sand increases with decreasing water resistivity and approaches a constant value at a

Fig. 26.40—Water-saturated rock conductivity plotted against water conductivity yields these measurements: (Δ) Suite 1 No. 40; (X) Suite 1 No. 21; (●) Suite 1 No. 4; (○) Suite 2 No. 13; (□) Suite 6 No. 2.

water resistivity of about 0.1 Ω-m. Wyllie proposed that the observed effect of clay minerals was similar to having two electric circuits in parallel—the conducting clay minerals and the water-filled pores. Thus,

$$F_{Ra} = \frac{R_{0sh}}{R_w} \text{ and } \frac{1}{R_{0sh}} = \frac{1}{R_{cl}} + \frac{1}{F_R R_w}, \dots \dots (60)$$

where

F_{Ra} = apparent formation resistivity factor,

R_{0sh} = resistivity of a shaly sand when 100% saturated with water of resistivity R_w ,

R_{cl} = resistivity caused by the clay minerals,

R_w = resistivity caused by the distributed water, and

F_R = true formation resistivity factor of the rock (i.e., the constant value of formation factor approached when the rock contains low-resistivity water).

The data presented in Fig. 26.40 represent graphically the confirmation of the relationship expressed in Eq. 60. The graphs were plotted by deWitte⁴² from data presented by Hill and Milburn.⁴³ The plots are linear and are of the general form

$$\frac{1}{R_{0sh}} = m \frac{1}{R_w} + b, \dots \dots \dots (61)$$

where m is the slope of the line and b is the intercept. Comparing Eq. 60 with Eq. 61, note that $m = 1/F_R$ and $b = 1/R_{cl}$. The curve labeled Suite 1 No. 40 indicates a clean sand because the line passed through the origin, thus having a zero intercept $b = 1/R_{cl} = 0$. Then $1/R_{0sh} = m(1/R_w) = (1/F_R R_w)$, or $R_0 = F_R R_w$. The remaining samples are from shaly sands, which have a finite conductivity of the clay minerals, as indicated by the intercepts of the lines. The linearity of the plots indicates that $1/R_{cl}$ is a constant independent of R_w . This phenomenon may be explained in terms of the ions absorbed on the clay. When the clay is hydrated, the absorbed ions form an ionic conducting path, which is closely bound to the clay. The number of absorbed ions is apparently little changed by the salt concentration of the interstitial water.

Eq. 60 may be rearranged to express the apparent formation resistivity factor in terms of R_{cl} and $F_R R_w$.

$$R_{0sh} = \frac{R_{cl} R_w}{R_w + R_{cl}/F_R}$$

and

$$F_{Ra} = \frac{R_{cl}}{R_w + (R_{cl}/F_R)}$$

As $R_w \rightarrow 0$,

$$\lim F_{Ra} = \frac{R_{cl}}{R_{cl}/F_R} = F_R.$$

Therefore, F_{Ra} approaches F_R as a limit as R_w becomes small. This behavior was observed in Fig. 26.39.

Hill and Milburn⁴³ evaluated 450 samples from both sandstone and limestone formations. The formation resistivity factor was determined at a water resistivity of 0.01 Ω -m, a value at which the apparent formation resistivity factor, F_{Ra} , approaches the formation resistivity factor, F_R . They designated the formation resistivity factor as $F_{R,0.01}$. The data were fitted by the method of least squares to yield

$$F_{R,0.01} = 1.4\phi^{-1.78} \quad (62)$$

This equation conforms to the theory previously discussed. They also fitted the data with K in Eq. 56 restricted to a value of 1. This yielded $F_{R,0.01} = \phi^{-1.93}$, which corresponds closely to Archie's original expression $F = \phi^{-2}$.

In summary, Eqs. 58 (with $m=2.0$) and 59 have been used widely to represent the relation between formation resistivity factor and porosity. Both equations yield results satisfactory for most engineering purposes. However, we propose that Eq. 62 be considered as more valid because the data were taken to minimize the effect of clays. The selection of a particular relation should be based on independent observations on the formations or formations of interest in a given geologic province.

Resistivity of Partially Water-Saturated Rocks

A rock containing both water and hydrocarbon has a higher resistivity than when fully saturated with water. The resistivity of partially water-saturated rocks has been shown to be a function of the water saturation, S_w . From theoretical developments, the following generalization may be drawn.

$$I_R = K' S_w^{-n}, \quad (63)$$

where $I_R = R_t/R_0$, the resistivity index; K' is some function of tortuosity; and n is the saturation exponent.

Archie compiled and correlated experimental data from various sources from which he suggested that the data could be represented by

$$I_R = S_w^{-2}. \quad (64)$$

Wyllie confirmed the suggested relationship for clean sands but found that the presence of clays (conductive solids) altered the relationship. A comparison of Archie's relationship and that for a core containing conductive solids is shown in Fig. 26.41. The change in the relationship depends on both the amount of clays and the water resistivity. Therefore, a general correlation for sands containing conductive solids is not available, although deWitte⁴² has proposed a method of using Eq. 64 for evaluation of shaly sands.

Use of Electrical Parameters in Characterizing Porous Media

In the section on permeability, the Kozeny equation was developed as follows.

$$k = \frac{\phi}{F_s A_s^2 \tau}, \quad (65)$$

Fig. 26.41—Effect of conductive solids on the resistivity-index-vs.-saturation relationship in Stevens sandstone core.

where

- k = permeability,
- ϕ = porosity, fraction,
- F_s = shape factor,
- A_s = internal surface area/unit PV, and
- τ = Kozeny tortuosity.

τ has been shown to be a function of $F_R \phi$ —i.e., $\tau = (F_R \phi)^x$, where x ranges between 1 and 2. If the internal surface area is expressed in terms of the mean hydraulic radius, \bar{r}_H , by

$$A_s = \frac{1}{\bar{r}_H}, \quad (66)$$

the general form of the relationship may be stated as

$$k = \frac{\phi(\bar{r}_H)^2}{F_s (F_R \phi)^x}$$

or

$$\frac{(\bar{r}_H)^2}{k} = F_s \frac{(F_R)^x}{\phi}. \quad (67)$$

Eq. 67 perhaps provides an improved basis for the correlation of characteristic physical data of porous media with the electrical formation resistivity factor.

The electrical properties of porous rocks, as discussed in the foregoing sections, form the basis of quantitative evaluation of electrical-logging records. In particular, the Humble relation (Eq. 59) has been used widely by service companies in estimating porosity from measurements made with "contact" resistivity devices such as the Microlog.TM Eq. 64 forms the basis of interpretation of water saturations from deeper-penetration

resistivity devices such as the conventional resistivity curves of the standard electrical log or from the various "focused" electrical-resistivity devices.

Improvements in the statistical correlations of electrical properties of rocks will improve the results of such analyses.

Nomenclature

- A = cross-sectional area
 A_j = area of flow represented by a bundle of tubes of permeability k_j
 A_s = internal surface area/unit PV
 b = constant for a given gas in a given medium
 c = fluid compressibility
 C = flow coefficient
 d = diameter
 E = voltage drop
 f = friction factor
 F_s = shape factor
 F_R = formation resistivity factor
 F_{Ra} = apparent formation resistivity factor
 g = acceleration of gravity
 h = driving head
 h_{fo} = height above free-oil level
 h_{fw} = height above free-water level
 h_j = thickness of j th layer
 I = current
 I_R = resistivity index
 J = J function, Eq. 48
 k = permeability of the medium
 k_a = permeability to air
 k_g = permeability of the medium to a gas completely filling the pores of the medium
 k_h = thermal conductivity
 k_j = permeability of one capillary tube
 k_L = permeability of the medium to a single liquid phase completely filling the pores of the medium
 k_w = permeability to fresh water
 k_{500} = permeability to 500-grain/gal chloride solution
 K = constant of proportionality, Eq. 7
 K' = some function of the tortuosity, Eq. 63
 K_z = Kozeny's constant
 L = length of flow path or length of the sample
 L_a = actual length of the flow path
 L_j = length of j th layer
 m = slope of the curve or cementation factor
 n_j = number of tubes of radius r_j
 \bar{p} = mean flowing pressure
 Δp = pressure loss over length L
 p_b = base pressure
 p_e = pressure at the external boundary
 p_w = pressure at the wellbore
 P_c = capillary pressure
 $P_{c,L}$ = capillary pressure, laboratory conditions
 P_{cm} = capillary pressure of mercury
 $P_{c,og}$ = capillary pressure at height above free-oil surface, using oil and gas
 $P_{c,R}$ = capillary pressure, reservoir conditions
 P_{cw} = capillary pressure of water
 $P_{c,wg}$ = capillary pressure at a given height above the free-water surface determined by using water and gas
 $P_{c,wo}$ = capillary pressure at a given height above the free-water surface, using water and oil
 q_b = volume rate of flow at the base pressure
 q_o = volume rate of flow of oil
 q_p = volume rate of flow at the algebraic mean pressure $(p_e + p_w)/2$
 q_t = total flow rate
 \dot{Q} = rate of heat flow
 r = radius or resistance
 \bar{r} = mean radius
 r_e = radius at the external boundary
 r_H = hydraulic radius
 r_w = radius of the wellbore
 R_{cl} = resistivity caused by the clay minerals
 R_0 = resistivity of the rock when saturated with water having a resistivity of R_w
 R_{0sh} = resistivity of a shaly sand when 100% saturated with water of resistivity R_w
 s = distance in direction of flow, always positive
 S_g = gas saturation
 S_L = total wetting saturation
 S_o = oil saturation
 S_w = water saturation
 \bar{T}_f = average flowing temperature
 ΔT = temperature drop
 u_s = volume flux across a unit area of the porous medium in unit time along flow path s
 u_x = volume flux across a unit area of the porous medium in unit time along flow path x
 v = fluid velocity
 V_b = BV
 V_o = oil volume
 V_p = PV
 V_s = sand-grain volume
 V_w = water volume
 w = mass rate of flow
 W_{cd} = weight of dry core
 W_{cw} = weight of wet core
 W_w = weight of water
 z = vertical coordinate, considered positive downward
 θ = angle between s and the horizontal
 θ_c = angle of contact of the interface of two fluids and the capillary tube
 θ_{cwg} = water/gas contact angle
 θ_{cwo} = water/oil contact angle
 μ = fluid viscosity
 ρ = fluid density or resistivity
 ρ_b = fluid density at base pressure
 ρ_o = oil density
 σ = IFT or conductivity
 σ_m = surface tension of mercury

- σ_w = surface tension of water
 σ_{wg} = water/gas IFT
 σ_{wo} = water/oil IFT
 τ = Kozeny tortuosity
 τ_e = effective rock tortuosity
 ϕ = fractional porosity
 ϕ_e = effective porosity
 Φ = potential function

Chapter 27

Typical Core Analysis of Different Formations

R.E. Jenkins. Core Laboratories Inc.*

Introduction

The early-day analysis of cores was largely an art, a qualitative matter of odors and tastes, sucking on the rock, and visual examination. The science of core analysis has evolved from such early beginnings, using developments in instrumental methods of chemical and physical analyses as they became available. Electron microscopy, mass spectrometry, gas chromatography, high-frequency phase analysis, acoustic wave train analysis, and nuclear magnetic relaxation analysis are among the tools being used in the more sophisticated core testing today.

Many other techniques are available now to assist the geologist and petroleum engineer in the completion of wells and the evaluation and operation of oil and gas reservoirs, but core analysis still remains the basic tool for obtaining reliable information on the rock material penetrated. Study of representative core samples of an oil- or gas-bearing formation provides the only means for direct measurement of many important properties of the formation.

The minimum basic measurements made on cores generally comprise determination of porosity at no confining pressure, permeability at low confining pressure, and residual fluid saturations. Various supplementary routine tests such as chloride, oil gravity, directional permeability, grain density, and grain size frequently are made as an aid in interpretation and evaluation. These data are the subject of this chapter.

Porosity

Porosity is a measure of the void space or storage capacity of a reservoir material. Normally it is expressed as a percentage of bulk volume (%BV). Porosity may be determined by measurement of any two of the three quantities—grain volume, void volume, and bulk volume. Various generally acceptable methods and techniques for determining porosity are used by different laboratories. The void volume may be determined on a previously cleaned and dried sample by extraction or gas or air con-

tent, by saturation with a liquid, or by calculation from Boyle's law upon compression or expansion of gas in the pore spaces of the sample. The other widely used method involves the separate determination of the gas, oil, and water contents of the sample, and the summation of these three values to obtain PV.

Most of the porosity data reported in the tables here were determined by the *summation-of-fluids* method. Comparison of porosity values obtained on samples from several thousand feet of core where measurements were made by both the *summation-of-fluids* method and by a *Boyle's law* method showed agreements, in general, of 0.1 to 0.5% porosity. Extensive checks of porosity values by resaturation with brine have shown values slightly lower than by the other procedures, indicating approximately 98 to 99% resaturation.

Permeability

The permeability of a formation sample is a measure of its ability to transmit fluid. The permeability determination involves measurement of the rate of flow of a fluid of known viscosity through a shaped sample under a measured pressure differential. Air is the fluid normally used because of its convenience, availability, and relative inertness toward the core material. For many years, air-permeability measurements were corrected to an "equivalent" liquid permeability by use of the well-known Klinkenberg corrections. The permeability values reported in Tables 27.1 through 27.11 have been corrected to the "equivalent" liquid-permeability values, except as noted in the next paragraph.

In the whole-core or *full-diameter* core analysis procedures, permeability is frequently measured in two horizontal directions. One measurement is made in the direction of the major fracture planes and is reported as *k*. This value indicates the effectiveness of the fractures as flow channels. The core sample is then rotated 90° and the second measurement is made in a direction of flow perpendicular to the direction of the first measurement. This

second value is normally reported as k_{90} , and it is usually representative of the matrix permeability. Values for k_{90} are reported in the following tables for formations that are normally subjected to the whole-core or full-diameter core analysis procedures. These values are not corrected to "equivalent" liquid-permeability values.

Liquid Saturations

In the coring process, the core is exposed to the drilling fluid at a pressure greater than formation pressure. If the core contains oil or gas, some portion of this is flushed out and replaced by the drilling-fluid filtrate. As the core is brought to the surface and the external pressure is reduced, the expansion of free gas or dissolved gas expels both oil and water from the core. As a result, the pore spaces of the cores recovered at the surface contain free gas, water, and oil if oil is present in situ. The oil and water contents normally are called "*residual liquids*."

The residual oil and water contents of core samples normally are determined by retorting, vacuum distillation, or solvent extraction and distillation. The oil and water contents are converted to oil and water saturations as percentages of PV. The oil and water saturation values reported in these tables represent data obtained by the retorting or the vacuum distillation procedures.

The water content of the core as recovered is generally called "*total water*," and it may include some drilling-fluid filtrate or invasion water. The water saturation actually existing at a given interval in a reservoir may be spoken of as the *connate water* or *interstitial water*. This interstitial-water saturation value, as reported in the ta-

bles, was determined in some cases by an empirical correlation factor applied to the total water value and in some cases by the use of capillary-pressure data for the specific reservoirs.

The API oil gravity values reported normally were measured on the oil recovered in the retorting or vacuum-distillation procedures. Comparison of gravity values obtained in oil recovered from cores with values obtained on produced or drillstem test (DST) oil indicates general agreement to within $\pm 2^\circ$ API.

The liquid saturation data presented in the tables are from formations interpreted to be hydrocarbon-productive to some degree. In some cases, it was feasible to make a distinction between gas-, condensate-, and oil-productive zone characteristics. Table 27.9 shows core analysis data for zones identified as "transition" zones. These represent intervals or zones where an appreciable water cut is encountered during the life of a field. Such transition zones are present in many other areas and fields, but the available data did not permit a similar breakdown. It should be pointed out that the relative average depths reported for the gas-condensate, oil, and transition zones do not contradict the basic premises that gas overlies oil and that oil overlies water. The condensate-producing zones in the major formations in the U.S. gulf coast area, as presented in Tables 27.6 and 27.7, frequently are found at greater depths than are the oil-producing zones of the same formations. In a similar manner, the gas, oil, and transition zones shown in Table 27.9 for the extensive geologic groups and formations in the Oklahoma-Kansas area are found at different subsurface depths in different parts of the area.

Percussion Sidewall Core Data

Percussion sidewall sampling is used extensively in the U.S. gulf coast area, and in other areas where productive intervals are encountered in relatively soft formations and where this type of coring has been found satisfactory. The limited size of the individual samples has made it necessary to develop special procedures for handling and measuring the properties and fluid contents of these samples. Also, the percussion-sampling technique and the limitation of sampling to a small distance from the walls of the wellbore frequently result in questions of the degree to which sidewall core analysis data compare with data obtained on conventional wireline or diamond cores. Table 27.8 summarizes a study of core analysis results from more than 5,300 samples where approximately half were obtained by percussion-type sidewall sampling and the other half were obtained by conventional coring procedures.

Data From U.S. Areas

Data from areas in the U.S. including Alaska, are presented in Tables 27.1 through 27.12. The formation and zone

names were selected in an effort to represent generally recognized nomenclature over large areas rather than local terminology. Some important producing formations are not included because of the lack of sufficient data at this time or because of their proprietary nature.

Data From Non-U.S. Areas

The data from non-U.S. areas generally are lacking in pore liquid saturation values because of the formation evaluation practices in general use. The small quantity of data reported is a result of the problems of data being released. Data from Australia are presented in Table 27.13. Most of the Canadian data (Table 27.14) were provided by the Energy Resources Conservation Board of Alberta. The Middle East data are presented in Table 27.15. The North Sea data (Table 27.16) were published in the *European Continental Shelf Guide*.¹ Venezuela data presented in Table 27.17 were provided by Petroleum de Venezuela S.A.

^a General geologic sections taken at different points in Oklahoma-Kansas areas indicate some variations in the properties and an appreciable variation in the occurrence and relative depths of many of the more important oil- and/or gas-producing zones, formations, geologic groups, and their members. The general identification of core samples from these producing intervals reflects local conditions or activities significantly. In the development of average data values, an attempt has been made to combine data originally reported for locally named zones into more generally recognized formations or geologic groups. In some instances (i.e., Deese, Cherokee) data are reported for a major geologic group as well as for some of its individual members. The values designated by the major group name represent areas where the general characteristics permit identification as to the geologic group but not as to group member. In other areas the group members or zones are readily identifiable. The combinations of data and the use of local rather than regional geologic names in some instances are explained in the footnotes.

^b T represents transition zone or production of both water and either gas or oil.

^c Includes data reported as Dornick Hills and Dutcher.

^d Includes Bromide first and second as reported on McClain County area.

^e Data reported locally as Bromide third, Bromide upper third, and Bromide lower have been considered as part of the Tulip Creek.

^f Includes data reported as Cleveland sand, Cleveland lower, and Cleveland upper.

^g Includes the numerous zones (Deese first, second, third, fourth, fifth, Zone A, Zone B, Zone C, and Zone 1) reported locally for the Anadarko, Ardmore, and Marietta Basin areas. In northwest Oklahoma, these different zones are normally referred to as Cherokee. In other areas the zones are frequently identifiable and properties are reported as for Redfork, Bartlesville, etc.

Chapter 28

Relative Permeability

Walter Rose, Consultant *

Introduction

This chapter was written as an overview of relative permeability: the basic ideas are given and their evolution is traced. Also presented are some laboratory measurement details and comments on the use of relative permeability information in problem solving. Many unresolved issues still exist, regardless of the fact that the literature is quite rich with the descriptions of what previous workers have thought about this complex subject.

Fluid flow is the major transport process that is involved in the recovery of oil, gas, and associated formation waters from subsurface petroleum reservoirs. As a consequence, process descriptions are needed to understand, to forecast, to manage, and to control production operations. Relative permeability is the concept that is often used as a framework for describing two- and three-phase flow of immiscible fluids through porous sedimentary rocks.

The term *permeability* historically has been adopted as a measure of the porous rocks' ability to conduct fluid. If only one fluid is present in the interstices, this transport coefficient is called the *specific* permeability, but otherwise one must make reference to the *effective* permeability of each of the immiscible fluids in the connected pore space. *Relative* permeability by convention is the ratio of the effective to the specific permeability.

In transport theory one deals with *fluxes*, *forces*, and the coefficients by which these variables are interconnected. As soon as the force-flux relationships are established for particular cases, they can be written in such a way that the various permeability functions will appear explicitly. In other words, just as specific

permeability has the sense of a transport coefficient that appears in Darcy's equation for single-phase flow, effective and corresponding relative permeability functions also can be thought of analogously as important transport coefficients by which multiphase flow processes are best described.

Central to the relative permeability idea is that we are dealing with material response types of parameters that cannot be derived from theory alone. On the contrary, laboratory measurements generally also will have to be made. All measurements are to be made in accordance with how the experimental variables properly are defined and used later.

To simplify the discussion, assume that we are dealing with the steady flow of an incompressible fluid that is moving macroscopically in a horizontal direction. Then,

$$q = \frac{kA\Delta p}{\mu L}, \dots\dots\dots (1)$$

where Δp is the pressure drop that can be measured across a specimen sample of length L and cross-sectional area A , and q is the volumetric rate of discharge of the flowing fluid whose viscosity is μ . Eq. 1 serves to prescribe an experimental measurement methodology by which values for k can be determined unambiguously.

In particular, it is seen that a plot of q vs. Δp should be a straight line whose slope is proportional to the specific permeability, k , as long as certain limiting conditions prevail. These are that (1) the fluid is homogeneous; (2) the temperature is constant; (3) the transport process is free of electrokinetic effects (as occur when certain dilute electrolytes are being moved through electrically nonconducting media), and of film surface flow (as oc-

* Author of the chapter on this topic in the 1962 edition was M.R.J. Wyllie.

curs when a gas is moving at such low mean pressure that the frequency of molecular collisions at the interstitial surface boundaries becomes important); and (4) the porous rock is sufficiently rigid and inert to preclude rapid changes in the pore geometry.

Accordingly, in what follows, we adopt the idea that if Darcy's law adequately describes single-phase flow, analogs of it can be postulated just as well as useful descriptions of multiphase flow phenomena.

Historical Background

In the 1930's and 1940's, serious ideas about the meaning and measurement of relative permeability phenomena first appeared. Principal authors were Muskat, Botset, Hassler, Leverett, and perhaps a dozen more whose names punctuate the milestones described in the standard references.^{1,2} These people were connected predominantly in one way or another with the U.S. petroleum industry at a time when quantitative study of recovery of hydrocarbon fluids from subsurface sedimentary environments was in its infancy. In focusing on how reservoir fields of fluid flow would be influenced by the nature and number of the coexistent interstitial fluids, the early workers took advantage of the fact that the existing and well-developed understandings about single-phase flow in porous rocks, when generalized, seemed to provide credible descriptions of multiphase flow situations. When L.A. Richards³ published his classic 1931 paper on the flow of capillary-bound moisture in so-called unsaturated soils, Darcy's pioneering work already had stood the test of three-quarters of a century of scrutiny, use, and amplification by diverse groups of technologists that included groundwater specialists as well as petroleum, chemical, and civil engineers.

Framework Ideas

By analogy to Eq. 1, a set of separate equations can be written to describe multiphase flow phenomena under the restricted conditions that no gravity forces are affecting the steady flow of each of the incompressible immiscible fluids, or

$$q_j = (k_j A)(\Delta p_j)/(\mu_j L) = (kk_{rj} A)(\Delta p_j)/(\mu_j L), \dots (2)$$

where the subscript j refers to the j th fluid phase (oil, gas, water). Following the usual terminology, k_j is called the effective permeability, k_{rj} is called the relative permeability, and p_j denotes values of pressure locally measured in the various fluid phases that are separated by interfaces of contact.

In particular, k_j and k_{rj} are to be considered measures of the flow conductivity afforded by the porous rock when saturated with the immiscible fluid phases in some particular way. As will be seen, reference must be made to fluid saturation configurations and distributions as well as to fluid saturation levels. For example, and in analogy to the porosity concept where ϕ is given by the local ratio of pore to bulk volume, the saturation of the j th fluid, S_j , is defined as

$$S_j = \frac{V_{fj}}{V_{pt}}, \dots (3)$$

where V_{fj} is the volume of fluid j and V_{pt} is the total pore volume. In other words, the product ϕS_j can be thought of as an effective porosity of that portion of the partitioned pore space occupied by the j th fluid phase.

It follows that locally (i.e., in any representative volume element of the reservoir rock system of interest) $\Sigma S_j = 1$, even when saturation is changing with time and position. In any case, it would appear that the relative permeability, k_{rj} , has a first-order dependency on the saturation level, S_j . But this is only one of the dependencies, because usually many interstitial fluid phase distributions are possible for each level of saturation. Also, the reduced pore space occupied by each of the several pore fluid saturants is not necessarily everywhere bounded by interstitial (solid pore wall) surfaces; hence, it is possible that the influence of prevalent fluid/fluid interfacial boundaries also may have to be considered. Thus, the statement

$$0 < k_{rj} < 1 \text{ for } 0 < S_j < 1, \dots (4)$$

while always true, ignores the fact that k_{rj} may equal zero even when S_j is finite, and may be greater than unity even for values for S_j less than unity.^{4,5} Moreover, Eq. 4 is too crude to indicate explicitly that k_{rj} can have more than one value for each value of S_j (e.g., because of hysteresis).

Hysteresis

From the thermodynamic point of view, the fluid flow processes under consideration are irreversible (i.e., nonequilibrium); therefore, they are inherently path-dependent. One consequence is that the equilibrium states approached in one direction can be different from those approached in another. This phenomenon is called hysteresis, and explanations for it are not hard to find. For example, while specific permeability depends mostly on the interstitial pore geometry, effective (hence, relative) permeability depends on the fluid saturation geometry as well. Usually there will be more than one way a given fraction of the pore space can be occupied by each fluid phase of interest. The result is that relative permeability data give values that are functions of the history and sequence of the prior saturation changes as well as being merely functions of the fluid saturation levels.

As will be seen later in this chapter, little laboratory work has been published to prove that Eq. 2 truly describes multiphase flow phenomena. Nor can much reassurance be taken from the fact that the validity of Eq. 1 as a description of the characteristics of single phase flow has been confirmed experimentally for a large number of cases. This is because the unsteady states are of the greatest interest when dealing with petroleum recovery problems, but this aspect is ignored by the Darcian modeling.

In other words, Eq. 2 by itself does not make it possible to account for and to predict the saturation changes that occur as flood fronts move through reservoir space during production. And in the real processes to be modeled, the various phases may be flowing in separate directions rather than colinearly. The greatest limitation of Eq. 2, however, is that it gives no explicit prescription

of how to avoid end effects (the buildup of wetting fluid saturation levels at surfaces of capillary discontinuity such as core end-faces) in laboratory work.

Immiscible Wetting and Nonwetting Pore Fluids

Whenever wetting and nonwetting immiscible fluids compete to occupy the same pore space, it is clear that at inflow and outflow surfaces of so-called capillary discontinuity, there will tend to be a buildup of wetting fluid saturation levels during the course of multiphase flow processes. This has been understood from the earliest days.^{3,6} The central idea is that immiscible fluids that are co-existent in contiguous capillary pore space generally will be separated by curved interfaces of contact instead of by stress-free flat interfaces at contacts that occur exterior to the flow system.

In fact, the interfacial curved boundaries are a reflection of the balance between capillary and gravity forces in the static (stationary) cases, and of the viscous forces as well in the dynamic cases. This means that locally there usually will be a pressure difference between the immiscible fluids. This pressure difference, commonly called the capillary pressure, P_c , by convention is defined as the local difference between p_n and p_w (where the subscripts n and w refer to the nonwetting and the wetting fluids, respectively).

In systems at equilibrium, immiscible fluids tend to be distributed such that the free surface energy of the system is at a minimum, subject to the constraints imposed by the S_j levels and by the hysteretic path of saturation change being followed as successive equilibrium states are being established. This usually means that the wetting fluid will be found in the smaller pore spaces, and that the interfaces of contact will be concave toward the nonwetting fluid (hence, P_c will have positive values). In fact, capillary pressure, like k_j and k_{rj} , frequently is assumed to be primarily saturation-dependent, but it depends substantially on the fluid/fluid interstitial configurations at each saturation level.

The Buckley-Leverett equation⁶ takes the following special form in describing two-phase displacement processes involving one-dimensional (horizontal) flow of incompressible fluids. With density $\rho_j = \text{constant}$ and $\partial q_j / \partial x = 0$, we have

$$\begin{aligned} & \phi(\partial S_w / \partial t) + \partial \{ [(q_w + q_n) M_w] / [(M_w + M_n) A_f] \} / \partial L_h \\ & + \partial [(M_n M_w)(dP_c / dS_w)(\partial S_w / \partial L_h) / (M_w + M_n)] / \partial L_h \\ & = 0. \end{aligned} \quad (5)$$

where ϕ is the local porosity independent of time, A_f is the cross-sectional area of flow path, P_c is the capillary pressure, L_h is the horizontal distance parameter, and t is the time (both independent variables); and M_n and M_w are the mobilities of the nonwetting and wetting fluids, respectively (i.e., $M_j = k_j / \mu_j$). As can be seen from the derivations of Eq. 5 given in Refs. 1, 2, and 6, the saturation levels vary with position and time in a way that depends on the variation of P_c with S_w , on the saturation gradient, on the relative permeabilities, and on the initial and boundary conditions of the problem [as well as on certain controllable and disposable variables

such as porosity, fluid viscosities, the specific permeability, and the total flow rate given by $(q_w + q_n)$].

Indeed, the importance of having relative permeability information is to make it possible to solve reservoir engineering problems modeled by process descriptions such as given by Eq. 5. The more elaborate modeling technique involving equations with the transport and interaction coefficients described by Rose⁷ require considering more than simple relative permeability information, however. Even so, the experiments prescribed by the Buckley-Leverett⁶ and Rose⁷ equations will not be easy to perform. The laboratory difficulties obviously multiply if unsteady states are to be considered (where S_j changes with time and spatial position). This is why only state-of-the-art methodologies will be described here. Nonetheless, it is clear that future workers will continue to be challenged by the need to develop and to perfect measurement methods that are based on modeling that goes beyond the simplistic Darcian reasoning embedded in Eq. 2.

Measurement Methodologies

A number of measurement methodologies have been described in the literature; these are classified and explained to some extent as follows, along with some of the data that have been reported. Two controversial questions are (1) do the various methods yield equivalent data, and (2) if not, which are the most trustworthy ones?

Laboratory measurement techniques for relative permeability determination are of two sorts. In the so-called steady-state methods, the effective permeability as a function of saturation is calculated from the flow data that are obtained on the assumption that Eq. 2 is correct in form. The trick is to make direct measurements prescribed by the theory, of parameters such as volumetric flow rates, pressure drops, and fluid saturation levels. In one variant of the method, known as the Hassler technique,⁸ provision also is made to control and to measure the local values of capillary pressure to avoid the troublesome end effects.

The so-called unsteady-state methods are based on using integrals of Eq. 5 as the process model. The idea is to observe the consequences (i.e., the outcomes in terms of cumulative production) of controlled multiphase displacement experiments, and then to back-calculate the relative permeability values that are consistent with, and serve to explain, those outcomes. The cumulative production data also are processed to provide a basis for calculating average saturation levels to be associated with the relative permeability values.

As will be seen, the steady-state methods are more time-consuming than the unsteady-state methods; still, the data obtained by them are at least as believable as the plausible model on which they are based (Eq. 2), especially if convincing measures are taken to minimize the capillary end effects mentioned previously. On the other hand, the unsteady-state methods, comparatively speaking, supply the wanted data quickly and cheaply. This latter advantage, it may be argued, is only a partial compensation for the uncertainties in data interpretation inherent in the indirect nature of such measurements. To expose the rationale for selecting one type of procedure over another, the ideas of recent authors are reviewed below.

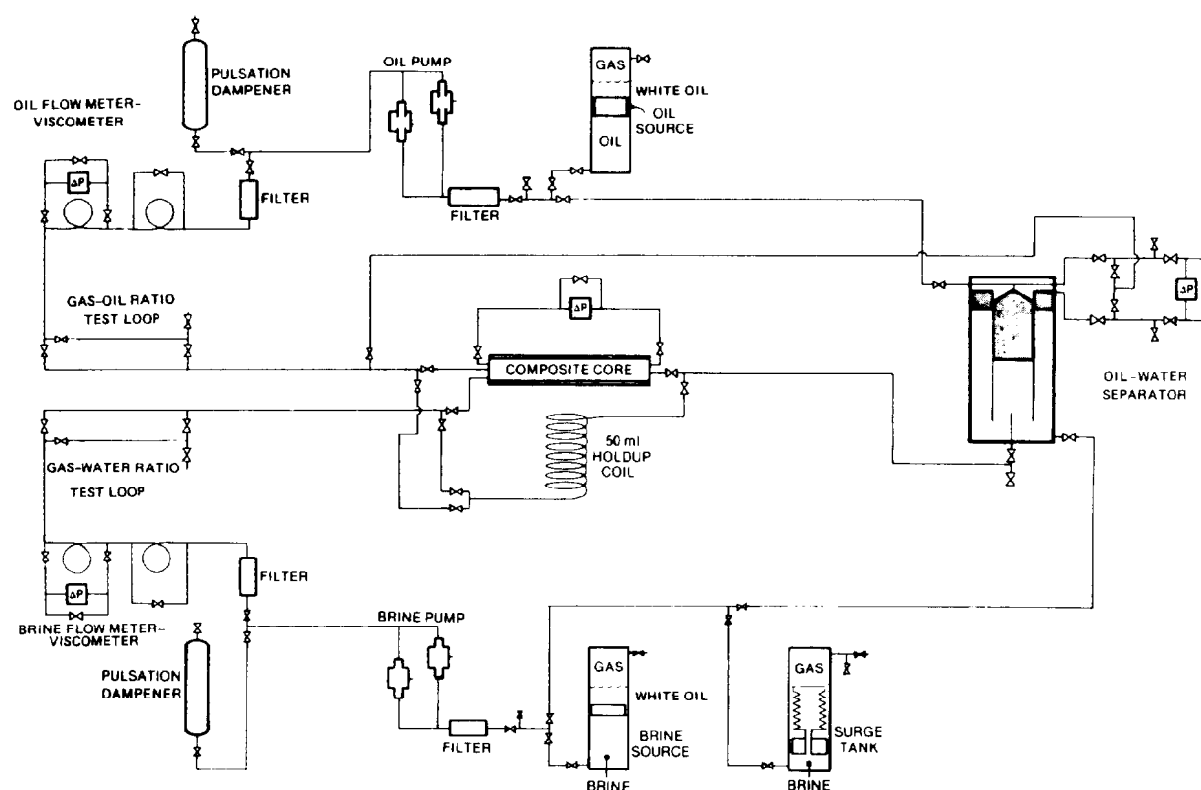

Fig. 28.1—Details of steady-state relative permeability apparatus.

Steady-State k_r Methods

Experimental Procedure. Blackwell and Braun⁹ provide a comprehensive statement of how some people think the steady-state relative permeability method should be practiced when given the understandings and instrumentation opportunities available at the start of the 1980's. Fig. 28.1 is a schematic of the laboratory system that can be used. Positive displacement or other types of constant-rate pumps, one for each fluid, discharge a fixed-ratio mixture into the core sample. Regardless of the initial saturation conditions within the core sample, the effluent fluid mixture eventually will be identical in composition to that being delivered by the pumps upstream. At this steady-state condition, effective permeabilities for the immiscible fluids can be calculated because the separate pump rates (q_o and q_w) will be known, and because an approximation of the pressure drop across the core sample can be used as the indicated driving force for each fluid.

For example, suppose that the reservoir process under consideration involves edgewater encroachment into a uniform sand that has a certain level of interstitial water saturation, with the rest of the pore space filled with an unsaturated oil. A core sample representative of the formation could be selected and, after cleaning, an appropriate initial condition with respect to water and oil saturation could be established by the so-called restored-state capillary pressure technique. Alternatively (and perhaps ideally), a "fresh" core sample could be brought into the laboratory as recovered by a pressure core barrel so that the wanted initial saturation conditions already would prevail. Or, as still another preparation

procedure, an "as-received" core could be processed so that the mud filtrate was replaced by simulated formation water that, thereafter, was displaced down to interstitial levels by flooding the sample with "live" oil. That is, in one way or another, the imbibition water/oil relative permeability data could be obtained where the experiment is started from a proper initial condition in fluid saturations and saturation distributions. And, if reservoir conditions of wettability were to be somehow preserved or restored as preparations for the experimental work are made, and if the ensuing displacement process were to be undertaken under conditions where reservoir-like overburden stress, pore fluid pressure, and/or temperature were simulated, then so much the better. However, the final saturation levels at steady state still would have to be measured. Several methods are available from which this information can be obtained.

Saturation Measurements. What the Braun and Blackwell method⁹ does is have a downstream water/oil separator where (as shown in Fig. 28.1) the bulk of each effluent phase is directed back to the inflow sides of the respective pumps, but where the differential amount between inflow and outflow of each phase is collected in a column and gravimetrically or volumetrically measured. In other schemes, X-ray absorbers or radioactive tracers can be added to one or more of the flowing fluids so that external instrument scans of the core will give the information that can be converted back to saturation levels. Even more simply, the core sample can be removed from the core holder after each steady-state condition is

Fig. 28.2—The Hassler "sandwich." C denotes the core sample of length L and B denotes the inflow and outflow capillary end barriers. NW and W designate the ports through which the nonwetting and wetting fluids are directed collinearly as shown by the arrows.

reached, and then weighed so that saturation values can be calculated from independent knowledge of fluid densities and core sample PV.

More details about the steady-state procedure under discussion are available in the references. Suffice it to say that entire curves of relative permeability vs. saturation are to be obtained, following well-defined imbibition or drainage paths, by proceeding stepwise from one steady-state condition to the next. For example, in the water influx experiment under discussion, the q_w/q_o ratio delivered by the pumps could be set at successively higher values while going from one steady state to the next until finally the high produced WOR's would confirm that a condition of residual oil saturation had been achieved.

The previous discussion provides a brief description of the sense of the steady-state relative permeability measurement scheme as used when no special effort is made to control end effects (e.g., the buildup of wetting fluid saturation levels at surfaces of capillary discontinuity such as core end-faces). Early data obtained by equivalent steady-state procedures are reported in Muskat's classic work.¹⁰ Remarkably, there does not appear to be much learned from more recently obtained data than was at least qualitatively apparent in the beginning.

For example, one conclusion that can be drawn consistently from laboratory observations is that the inequalities given previously as Eq. 4 can be written more exactly as

$$0 < k_{rj} < 1 \text{ for } S_{ij} < S_j < 1, \dots \dots \dots (6)$$

where S_{ij} is the minimum (irreducible) value of S_j when the j th fluid of interest no longer has phase continuity over sensible distances within the pore space. On the other hand, the idea that relative permeability can be greater than unity for saturations less than unity has been reported^{4,5} and explained as a reflection of the "lubrication" provided as one fluid slides by an adjacent immiscible one.

Fig. 28.3—Schematic capillary pressure curves.

On the other hand, when attention needs to be given to end effects, some workers have proposed that long cores be used so that measurements could be confined to an inner portion.¹¹ Even in such a so-called Penn State arrangement, however, the pressure-drop terms of Eq. 2 still are not measured separately for each of the immiscible fluids, and that is why it makes sense to refer back to Hassler's almost-forgotten work.

The *Hassler method* for relative permeability determination has had a curious history. The patent was granted in 1944⁸ and although cited occasionally, it has been ignored by most workers intent on developing simple state-of-the-art procedures. Scheidegger² referred to the method as superior, but difficult and time-consuming to apply, and at one point Rose¹² gave an analysis of why operational difficulties were to be expected in some applications. More recently, however, a patent has appeared that teaches how Hassler's ideas indeed might be reduced to a practical operating scheme.¹³ Whether or not these claims eventually are substantiated by the facts, it is nonetheless of interest to examine in some detail the principle of the Hassler method for relative permeability determination. Thereby, a reference frame can be established to which other steady-state relative permeability procedures can be compared.

Fig. 28.4—Schematic relative permeability curves.

Fig. 28.5—Hysteresis in waterflood vs. oilflood relative permeability curves.

Fig. 28.2 is a schematic that shows the sandwich arrangement where the wetting fluid (denoted by W) passes in series through an inflow capillary barrier as it enters the core sample, and then exits through a similar downstream barrier. The nonwetting fluid (denoted by NW) flows in parallel with the wetting fluid in the core sample but does not enter the pore space of the barriers. This exclusion is achieved by never letting the pressure in the nonwetting phase locally be so great that the barrier threshold pressure is exceeded; hence, the endflow barriers will always remain 100% saturated with the wetting fluid during the course of the test.

Fig. 28.3 is a schematic of a representative capillary pressure drainage and imbibition curve for the reservoir rock sample of interest where the relative permeability relationships are wanted. Suppose that, as an initial condition, the core (as well as the end barriers in series with it) is 100% saturated with water (say with a simulated oilfield brine). Let the threshold pressure for the core sample be P_{CA} and that for the barrier material be greater than P_{CC} . * Threshold pressure is being defined here as the lowest capillary pressure ($P_{cn} - P_{cw}$), where the nonwetting fluid will enter a wetting-fluid-saturated porous medium. Since the capillary end barriers are made of material considerably less permeable than the core sample material, $P_{CC} \gg P_{CA}$.

Hassler's way of performing the relative permeability experiment is to measure the effective permeability to each phase by using Eq. 2 at various successive capillary pressure conditions, such as $P_A, P_{B1}, P_{B2} \dots P_C, P_{D1}, P_{D2} \dots P_E$. The result is a succession of saturation states such as $S_{A1}, S_{B1}, S_{B2} \dots S_{C1}, S_{D1}, S_{D2} \dots S_E$ in the sense that from A to C a drainage curve is being traced since the wetting-phase saturation is always decreasing, while from C to E an imbibition curve is being traced since the wetting-phase saturation is always increasing. Note that at A the wetting-phase saturation, S_A , is 1.0, at C the wetting-phase saturation is close to the interstitial water level, S_{iw} , while at E the wetting-phase saturation is $(1 - S_{rn})$, where S_{rn} designates the residual (nonproducing) nonwetting fluid saturation level.

Corresponding to the saturation points where capillary pressure values have been measured and shown in Fig. 28.3 during drainage and imbibition, the associated relative permeability data to be obtained by the Hassler method are shown in Fig. 28.4 in schematic format. It is instructive to draw some comparisons between these presentations. Capillary pressure as well as relative permeability functions are saturation-dependent. They both appear as parameters in the Buckley-Leverett description of multiphase flow and displacement processes (Eq. 5). Both functions are a direct reflection of the network structure of the pore space (size, shape, orientation, mode of branching, tortuosity, etc.). It is for these reasons that early workers were quick to search for the direct dependency between capillary pressure and relative permeability phenomena¹⁴ and that Hassler, with such great insight, was provoked to emphasize the interconnections that still earlier had been recognized by Leverett¹⁵ and Richards.³

* P_{CC} is the highest value of capillary pressure to be used in the experiment to obtain the lowest value of S_w .

The process under discussion is complicated and not easy to describe without many details. Since these are fully covered in the original references,^{1,2,7} it is enough to end the discussion here with the observation that there are at least two ways, in principle, to practice the Hassler method. One is to impose fixed boundary conditions in pressure upstream as well as downstream, and then to observe flow rates needed for the calculations of permeability data.⁸ The other¹³ is to have constant flow rate as the upstream boundary condition while keeping constant pressure as the downstream boundary condition. What is gained thereby is circumvention of the practical difficulties of avoiding end effects encountered when the boundary conditions are set in terms of upstream and downstream pressure only.

Unsteady-State k_r Method

Compared to the unsteady-state methods to be described now, the steady-state methods are quite straightforward and involve few uncertainties. The following analyses will reveal why this is so.

Experimental Procedure. In so-called unsteady-state procedures, effluent production from a core sample during the course of an imposed displacement process is recorded, and relative permeability functions are generated on the basis of a mathematical modeling of the process that is supposed to be consistent with what is being observed. In practice, the mathematical model usually selected is a simplified form of an integral of the Buckley-Leverett Eq. 5. By linearizing the equation by dropping the capillary pressure (end effect) terms, back-calculating the relative permeability functions appears to be possible.

Since the aim is to get more resolution for calculation of intermediate values of relative permeability and for calculation of the associated saturation values, one needs to spread out the effluent production data. The whole enterprise is compromised, however, when a very *unfavorable mobility ratio* is chosen as the way to prolong the transient period before total breakthrough of the displacing phase. The reader is referred to one analysis of this situation⁷ for further information.

Methods of Calculation

Institut Français du Pétrole Method. The reader also is referred to the definitive paper by authors at the Institut Français du Pétrole¹⁶ for full details about how to practice the unsteady-state method for relative permeability determination. Constant-flow-rate and constant-pressure schemes are described, precautions are enumerated, and calculation schemes are given. Fig. 28.5 is taken from another paper¹⁷ that shows how representative data and the associated relative permeability curves might look in a representative case.

Automated Centrifuge Technique. To finish with the discussion of the variants of the unsteady-state methodologies, it will be useful to cite the work of O'Meara and Lease,¹⁸ who gave three-phase data obtained with an automated centrifuge technique. By spinning core samples in a centrifugal field of known strength and observing effluent volumes as a function of

Fig. 28.6—Three-phase saturation trajectory and oil isoperms ranging from 1×10^{-7} to 2×10^{-3} .

time, a back-calculation of relative permeability can be made (which, again, will be at most of qualitative value because of the limiting assumptions that have been used in the mathematical modeling).

Claims made for the centrifuge technique are (1) it does not suffer from viscous fingering distortions, as in the case of the conventional unsteady-state procedures, and (2) it is faster than the competing steady-state procedures. However, the capillary end-effect problem still has to be faced. Another disadvantage is that in any given run, the information obtained applies only to the relative permeability of the invading phase. Since the conventional unsteady-state procedures give relative permeabilities for the displaced (as well as the displacing) fluids, and since larger samples can be processed than is possible in the centrifuge, the conventional approaches are the ones that are considered to be state-of-the-art. In fact, the appeal that the centrifuge technique holds for experimenters is related to its suitability for automation, and to the fact that it is already generating three-phase data. Fig. 28.6, for example, is a display of some of the data that have been reported.

Critique of Methods

To summarize what has been published about relative permeability measurement methodologies, the critique originally given by Scheidegger,² and more recently affirmed,¹⁸ is accepted enthusiastically here. The consensus seems to be that the steady-state methods, Hassler's in particular, give the most believable results since they are based on a plausible (however naive) definition of relative permeability (i.e., as embedded in Eq. 2). Unsteady-state methods, while quicker and easier to apply from the laboratory operational point of view, nonetheless are beset with enormous interpretation difficulties. This is mostly because they involve drawing inferences (by way of back-calculations) from a rough-integral form of the Buckley-Leverett Eq. 5. As noted previously, Eq. 5 is at most an imperfect model of the flow process under study.⁷

Fig. 28.7—Gas relative permeability vs. total wetting-liquid saturation.

Fig. 28.8—Matching Corey *et al.* Berea sandstone data.

Other k_r Methods

Still other methods to arrive at relative permeability information remain to be cited for completeness. For example, there are the so-called stationary fluid methods¹⁹ and the calculation methods based on capillary pressure and endpoint displacement data associated with Corey *et al.*²⁰ and Stone.²¹ Figs. 28.7 and 28.8 display some of the results given by these investigators.

In the stationary fluid methods, the effective permeability of one phase is measured by flowing that fluid at such a low pressure gradient that the contiguous immiscible fluid is left (it is hoped) unaffected. Clearly, the method can be trusted most when the stationary fluid has a saturation level close to its minimum (irreducible) value (i.e., $S_j \rightarrow S_{ij}$ for the stationary fluid). Otherwise, it may be concluded that the data generated by applying the method will be distorted by the ever-present end effects. On the other hand, the method is easy to apply operationally, and the data generated giving k_o at S_{iw} (irreducible water saturation) and k_w at S_{io} (irreducible oil saturation) are needed along with other parameters when calculated values of relative permeability are to be made by the popular Corey *et al.* and Stone methodologies. In any case, values for k_o at S_{iw} give an indication of the initial productivity of oil wells from horizons where there is only initial oil plus interstitial water saturation. Similarly, values for k_w at S_{io} can be used to indicate the level of the effective water/brine permeabilities when residual oil saturation conditions are reached at the end of a waterflood recovery process.

To understand better the rationale for using relative permeability calculation schemes, reference can be made to the early papers where they were first advocated.^{14,22} All along, the idea underlying them has been that petrophysical properties (e.g., relative permeability and capillary pressure relationships, specific surface area,

electrical resistivity parameters, etc.) depend in one way or another on the nature of the pore structure, and on how it will be partitioned in representative cases between the intertwining filaments of the adjacent immiscible fluid phases. Of the pore textural properties enumerated previously, relative permeability turns out to be the most difficult one to measure in the laboratory. This has been the origin of the thought (and hope) that an economy could be expected if relative permeability information somehow could be extracted (by way of calculations) from the more easily obtainable data. Wyllie,²³ a foremost advocate of these ways of thinking, is the authority to be consulted when more information is needed.

Eqs. 7a and 7b are the ones given by Corey *et al.*²⁰ for calculating k_{ro} under three-phase saturation conditions, and Eq. 8 is the one proposed by Stone.²¹ For $S_L > S_{Lr}$,

$$k_{ro} = (1 - S_g - S_w)^3 (1 - S_g + S_w - 2S_{Lr}) / (1 - S_{Lr})^4, \quad \dots \dots \dots (7a)$$

and for $S_L \leq S_{Lr}$

$$k_{ro} = (1 - S_g - S_w) / (1 - S_{Lr})^4. \quad \dots \dots \dots (7b)$$

Also,

$$k_{ro} = (k_{row} + k_{rw})(k_{rog} + k_{rg}) - (k_{rw} + k_{rg}), \quad \dots \dots \dots (8)$$

where

S_L = total liquid saturation, fraction,

S_{Lr} = residual liquid saturation left in pore space, fraction,

k_{row} = relative permeability to oil in a gas-free system, and

k_{rog} = relative permeability to oil in a water-free system.

Fig. 28.9—Gas/oil relative permeability in poorly consolidated sandstone.

The recommendation for using Eqs. 7 and 8 to obtain calculated values for the difficult-to-measure k_{ro} under three-phase saturation conditions is that one only needs to enter more easily obtained two-phase data. Inspection will show that while such equations give plausible results (e.g., compatible with the indications of Eq. 6), the results are no more trustworthy than the modeling assumptions when measured relative permeability values are needed but are otherwise unavailable.

Comments. A conclusion to be drawn from this analysis is that if there is any merit to taking short-cuts, it is only when the benefits outweigh the risks. While many (perhaps most) of the readers of this chapter will never have to go to the laboratory to make relative permeability measurements, it is important for them to realize that someone, some day, has to make such measurements before any of the calculation schemes can be used with confidence. In other words, computer guesswork in general will be no substitute for laboratory work. This is because direct observations always will be needed before reliable predictions can be made for processes that inherently depend on material response parameters such as relative permeability.

Recent Literature

More than 30 years have elapsed between an early and a later time when the author of this chapter was provoked to write papers on the then-current problems of relative permeability measurement.^{24,25} It is as though some of the problems have continued to be unsolved and/or unsolvable, while other vexing ones have emerged to take the place of any of the earlier ones that somehow were resolved. In the meantime, work continues on many fronts such as those critiqued in this paper. Note that all the papers now to be referenced have appeared after

Fig. 28.10—Unsteady-state, three-phase relative mobility (relative permeability to oil, Berea sandstone).

Fig. 28.11—Relative permeability to gas in three-phase flow as a function of gas saturation.

Fig. 28.12—Relative permeability to oil and water showing the effect of displacement (Curve 1) vs. carbonated water displacement (Curve 2).

Fig. 28.14—Imbibition relative permeabilities for two wetting conditions, Torpedo sandstone.

Fig. 28.13—A comparison of restored-state and native-state water/gas relative permeability data.

Wyllie wrote the original chapter on "Relative Permeability" in the first edition of this handbook (in 1962) referencing the literature through the 1950's.²³

Critique of Recent Work

Loomis and Crowell²⁶ present an early but extensive comparison of data obtained by various methods, and as calculated by various mathematical modeling schemes. The high degree of conformity reported makes suspect the objectivity of the work. On the other hand, the authors were quick to point out that wettability was an uncontrolled laboratory variable in their work. This disquieting contention was matched by the surprising result reported without explanation by other workers at the same time, namely that hysteresis effects were different for unconsolidated vs. consolidated core samples.²⁷ Fig. 28.9 shows the trends observed.

The paper of Sarem²⁸ was one of several describing three-phase measurements by an unsteady-state method. One observation (see Fig. 28.10) of this work had to do with the important role played by the initial saturation conditions. At about the same time, Saref and Fatt²⁹ reported success in the development of a nuclear magnetic resonance technique for measurements of fluid saturation levels. These workers, moreover, confirmed the long-held view that relative permeability to gas in three-phase systems depended mostly on the total liquid saturation. This calculation is supported by the data shown in Fig. 28.11.

Two papers appeared in the early 1970's^{30,31} indicating that relative permeability to oil is greatly increased if CO₂ is present (see Fig. 28.12). At this same point in time, Lefebvre du Prey³² was dealing with the question of interfacial tension effects on relative

Fig. 28.15—Gas/oil relative permeability calculated from production data from experiments.

permeability while Schneider and Owens³³ and Owens and Archer³⁴ were concluding that because of wettability effects, experimenters were advised to make use of so-called native-state cores. The work of Bardon and Longeron³⁵ also dealt with this subject. And somewhat later Sigmund and MacCaffery³⁶ were trying to sort out the influence of reservoir rock heterogeneity on relative permeability characteristics. Some of the data presented by these authors are shown in Figs. 28.13, 28.14, and 28.15.

In the 1980's, numerous relative permeability papers continue to appear as though a renaissance interest in the old subject is developing. A noteworthy one was by Hagoort,³⁷ who used a centrifuge technique to show the high efficiency of the gravity drainage recovery process in water-wet cores. Bogdanov and Markhasin³⁸ introduced the less familiar subject that speculated that viscosity changes (because of molecular-surface interactions with the rock matrix) could distort relative permeability data. At the same time, Ashford,³⁹ in a very comprehensive paper, was reopening the dubious issue of how relative permeability and capillary pressure data can be linked directly. (As implied above, it is nice to have a conceptual theory available to explain relative permeability effects, but to expect that calculations avoid the need for careful experimental work is a kind of wishful thinking that can be justified only when there is a great urgency to have qualitative inputs for reservoir process simulations). Fig. 28.16 is representative of the fits reported by Ashford between calculated and measured values.

Delshad *et al.*⁴⁰ currently have addressed the interesting question of whether the transport of low-tension micellar fluids will significantly change classical relative permeability trends. They show that the residual (end-point) saturations decrease and relative permeabilities increase as interfacial tension decreases. The predicted nearly 45° relative permeability curves are shown for one case in Fig. 28.17. Yokoyama⁴¹ has been dealing

Fig. 28.16—Relative permeability relations for imbibition and drainage experiments, with values calculated by Naar *et al.* method.

Fig. 28.17—Imbibition relative permeability curves for microemulsion and decane vs. oil saturation in Berea sandstone.

Fig. 28.18—Drainage k_{ro} and k_{rg} curves.

with the equally complex problem of accounting for transverse and longitudinal capillary imbibition during displacements in stratified media.

In another direction, Carlson⁴² extends Land's⁴³ earlier prescriptions for calculating flow from independent measurements of rock properties. Chierici⁴⁴ does the same thing, on the basis of the "bundle of capillary tubes" model described earlier by Brooks and Corey.⁴⁵ Some of these data are shown in Fig. 28.18.

Finally, Lin and Slattery⁴⁶ and Mohanty and Salter⁴⁷ carry pore structure (network) modeling as a basis for arriving at calculated relative permeabilities to still higher plateaus of sophistication. Extensive bibliographies are provided by these latter authors. Some of their results are given in Figs. 28.19 and 28.20.

For example, Fig. 28.20 indicates that (1) relative permeabilities to the nonwetting phase k_{rn} during secondary imbibition (SI) and imbibition (IM) are essentially the same but lower than the values that refer to the primary drainage (PD) conditions, and (2) relative permeabilities to the wetting phase k_{rw} during primary drainage is lower than that in either secondary drainage or imbibition. In other words, those authors⁴⁷ conclude that "the ratio of conductivity or nooks and crannies to that of a full throat feature influences the wetting fluid permeabilities only at low saturation."

Other recent papers are those of Salter and Mohanty,⁴⁸ who made observations to justify a modeling of multiphase flow that postulates flowing, dendritic, and isolated configurations for each phase, and of Maini and Batycky,⁴⁹ who claim (see Fig. 28.21) that temperature influences both the endpoint saturation and the shape of the relative permeability curves. A different view about the importance of temperature effects had been expressed earlier by Sufi *et al.*⁵⁰

Fig. 28.19—Comparison of drainage relative permeabilities from randomized network model with experimental data for 100 to 200 mesh sand.

The paper of O'Meara and Lease¹⁸ has been cited previously in connection with the unsteady-state determination of three-phase relative permeabilities using the centrifuge technique. It, along with the Maini and Batycky paper,⁴⁹ are just two of nine other papers on relative permeability presented at the 1983 Society of Petroleum Engineers Annual Technical Conference and Exhibition in San Francisco, Oct. 5-8. Listing them by topic is one way to expose the depth and breadth of current interests in the subject. Thus, Kortekass⁵¹ describes displacement in cross-bedded reservoirs. Meads and Bassiouni⁵² speak of combining production history and petrophysical correlations to enhance the representativeness of relative permeability data. Miller and Ramey⁵³ deal further with temperature effects for oil/water systems. Mohanty and Salter⁵⁴ extend their work on oil mobilization, transverse dispersion, and wettability effects. Fulcher *et al.*⁵⁵ and Harbert⁵⁶ deal further with low interfacial systems. Heiba *et al.*⁵⁷ address the wettability questions. And in companion papers, Heaviside *et al.*⁵⁸ cover the experimental and theoretical aspects of relative permeability phenomena. Such are the extensive details currently being discussed.

Ramifications Needing Attention

In summary, the reader who has studied the representative papers cited here, and the even larger number that are scattered in the literature at large, will conclude that this chapter is not the final one to be written on what amounts to be a very complex subject. Some of the ramifications that appear to need further attention include studies of the following effects: (1) phase changes such as gas evolution during multiphase flow, (2) non-collinear flow in a gravity force field between immisci-

ble fluids of differing densities, and counterflow imbibition, (3) reservoir rock anisotropy and heterogeneity by which sample size and sampling frequency requirements are to be determined, (4) "fines" movements, (5) overburden stress simulation and related stress-relaxation and creep compaction phenomena, (6) viscous drag at interstitial interfaces between contiguous immiscible fluids, (7) chemical precipitation and dissolution phenomena, (8) chemical reactions, (9) high Reynolds-number conditions (nonlinear laminar and turbulent flow regimes) (10) Klinkenberg gas-slippage effects, (11) concentration and/or thermal gradients being superimposed on fields of flow primarily caused by mechanical energy gradients, (12) non-Newtonian rheology, (13) systems characterized by more than one local pore space type, (14) fluid/solid interactions, for example, as related to the mineralogy of interstitial clays, (15) viscous fingering, and (16) hysteresis related to wettability changes.

While theoretical considerations may permit a qualitative prediction of the nature of some of these effects, in the final analysis, any truly quantitative assessments should be based on directly undertaken experimental work, if possible. This is not to say that in every case the laboratory data obtained on small hand specimens will reveal everything that needs to be known about large composite petroleum reservoirs, but rather that observations generally are more trustworthy indicators than are blind guesses.

Conclusions

Several questions come to mind whenever the subject of relative permeability is raised: how is it to be defined? where can the information be obtained? why is it needed and by whom? What are the proper (fruitful) ways to use it? Only partial answers to some of these questions have been given in this chapter. This is because the subject is too vast to be dealt with fully in limited space and because the details not covered are probably too specialized for the average reader, whose concern is only with the ordinary applications.

Here we have asserted that definitions of permeability (specific, effective, relative) are embedded in the differential equations that describe the transport equations governing fluid flow in petroleum reservoirs. Eqs. 1 and 5 are examples that apply to special situations (steady single-phase flow and unsteady multiphase flow of immiscible fluids, respectively). Obviously, the differential equations of transport will have other forms for more general cases of fluid flow, such as those observed when there is coupling with chemical diffusion and/or heat transfer processes. This is to say that there may be different kinds of relative permeability to deal with according to the nature of the process under consideration. In all cases, however, one must start by constructing the defining equations to be compatible with the underlying principles of nonequilibrium thermodynamics.

Relative permeability information can be obtained in two major ways. The preferred method is to have an experiment performed on a representative sample of the reservoir rock according to the procedure prescribed by the appropriate integral form of the defining differential equation. Eqs. 1 and 2 are examples of integrals that involve measurable terms (such as volumetric flow rates

Fig. 28.20—Relative permeability curves.

Fig. 28.21—High-temperature relative permeability curves for oil and water.

and pressures, p_i , at bounding sample surfaces). Since the parent differential equations themselves have terms that cannot be directly measured in the laboratory (such as velocity and mechanical energy gradients), integral forms that apply to the particular initial and boundary conditions of the problem must be derived and used for each specific case.

In these connections, it will be revealing (and disturbing) to mention that the degree of equivalence of relative permeability functions obtained by different methods (e.g., the steady- vs. the unsteady-state schemes mentioned previously) so far has not been established fully. Eq. 2 prescribes how the steady-state results are to be obtained, while integrals of Eq. 5 prescribe how the unsteady-state results are to be obtained. Until the definitive laboratory work is done and the comparisons are reported in the literature, users of relative permeability information today will continue to be left in the dark as to which procedure can be used with the most confidence when applications are being made.

As for ordinary applications, relative permeability information is used by petroleum reservoir engineers when interpretations and assessments are being made about the outcomes of observed and probable petroleum recovery processes. These applications are referenced in other chapters in this handbook (e.g., on reservoir simulation, well testing analysis, etc.), and will not be discussed further here. Suffice it to say that the same governing transport equations and their integrals by which relative permeability is defined, necessarily are used again in the ensuing analyses of reservoir performance; hence, relative permeability will be needed as input data whenever analytical studies are undertaken. Among other things, this means that using drainage relative permeability data to describe an imbibition process (such as waterflooding) should be avoided.

A second way to obtain relative permeability information is to develop suitable models of the processes under consideration for use as calculation algorithms. Eqs. 7 and 8 are examples that in use require laboratory data more easily obtained than the relative permeability functions themselves. For example, to calculate three-phase oil relative permeability as a function of oil saturation (where $S_o = 1 - S_w - S_g$) by Eq. 7, all that is needed is prior knowledge of the interstitial water saturation. Naturally, such calculation schemes cannot be used blindly except for cases where it has been independently validated that calculated and experimental values are equivalent. In other words, even the most carefully constructed calculation scheme does not circumvent the need to have experimental measurement methods also developed and available.

However, calculation schemes usually involve analytical functions that can be entered directly into the computer software used for such things as qualitative economic forecasting. Similarly, the related way to obtain relative permeability information, namely by inferring it from the values that force history matches of observed field data, also has a utility when qualitative assessments are being made using reservoir simulators.

The points being made here are both subtle and self-evident. The aim has been simply to convey a certain set of useful ideas to users of relative permeability information such as (1) that relative permeability methodologies

are still in the developmental state even after more than a half century of well-intentioned labor by hundreds of workers and (2) that users of relative permeability information must put the burden of proof on those that supply it, to demonstrate that credible schemes have been used.

Acknowledgment

Any author who has been writing narrowly on a specialized subject like relative permeability for more than a third of a century (specifically from 1948¹⁹ to 1984²⁵) has to be deeply indebted to all those inspiring workers who have managed to keep the issues alive and in focus over such a long period. A few of them, but not all, are named in the abbreviated references that appear here. Likewise, any teacher for a similarly long period must be deeply indebted to the generations of inquisitive students who were willing to ask the provocative questions before they graduated and left to disappear into oblivion. What a lucky thing it was to have had so many companions on what otherwise would have been a dreary Orwellian journey.

Nomenclature

A	= cross-sectional area
A_f	= cross-sectional area of flow path
k	= specific permeability
k_j	= effective permeability, Fluid j (gas, oil, or water)
k_{rj}	= relative permeability, Fluid j (gas, oil, or water)
k_{rog}	= relative permeability to oil in water-free system
k_{row}	= relative permeability to oil in gas-free system
k_{rw}	= relative permeability of wetting fluid
K_{me}	= microemulsion dispersion coefficient
L	= length
L_h	= horizontal distance
M_n	= mobility of nonwetting phase
M_w	= mobility of wetting phase
p_j	= pressure, Fluid j
Δp	= pressure drop
P_c	= capillary pressure
q	= volumetric flow rate
S_{gr}	= residual gas saturation
S_{ij}	= irreducible (minimum) value of S_j
S_{iw}	= irreducible (interstitial) water saturation
S_j	= fractional saturation of j th fluid
S_L	= total liquid saturation
S_{Lr}	= residual liquid saturation
S_{Lw}	= wetting liquid saturation
S_{rn}	= residual (nonproduced) nonwetting fluid saturation
S_w	= water saturation
S_{wr}	= residual water saturation
t	= time
V_{fj}	= volume of Fluid j
V_{pt}	= total PV
Δp	= pressure drop
μ	= fluid viscosity

σ = interfacial tension

ϕ = porosity

Subscripts

g = gas

j = j th fluid (gas, oil, or water)

n = nonwetting

o = oil

w = water or wetting

Chapter 29

Petroleum Reservoir Traps

Raymond T. Skirvin, J.R. Butler and Co
Brian E. Ausburn, J.R. Butler and Co.*

Introduction

A reservoir trap is a combination of physical conditions that will cause hydrocarbon liquids and/or gases and water to accumulate in porous and permeable rock and prevent them from escaping either laterally or vertically because of differences in specific gravity, pressure, fluid/gas characteristics, and/or lithology. It has the capability of collecting, holding, and yielding hydrocarbon fluids and water.

The portion of the trap that contains oil and/or gas accumulations is the petroleum reservoir. It generally occupies a limited portion of the trap capacity, the remainder being occupied by formation waters that underlie and are interspersed within the petroleum accumulation.

Traps are formed by an infinite variety of structural and stratigraphic conditions of rock formations combined with pressure differentials among the various fluids within the reservoir rock. A trap consists of an impervious cover or roof rock overlying a porous and permeable rock. Reservoir pressure gradients and fluid flow within the reservoir rock can create traps that do not have structural closure. The boundary between oil and water or between gas and water need not be flat or level when these pressure gradients are present. Generally, however, traps do have structural closure, and as viewed from below, the impervious cover is concave, preventing the oil and gas, if present, from escaping vertically or laterally. The water underlying the oil and gas exerts a buoyant force on the oil/water boundary or contact, lifting and holding the oil and gas to the crest of the structure or area of minimum hydrostatic pressure.

Trap Classification

Classification of traps logically falls into three broad general groups: (1) structural, (2) stratigraphic, and (3) combination. More detailed classifications have been

made by geologists attempting to include all factors and conditions that account for petroleum reservoirs. Many reservoirs have unique features that cause the oil to accumulate at a given location. The purpose of this chapter is to illustrate the more common geological conditions that cause traps and to point out a few of the infinite variety of minor variations that help create and hold petroleum accumulations in place.

Structural Traps

Structure implies some form of rock deformation, commonly expressed as a positive uplift, which may result in four-way dip closure. With the proper stratigraphy, structural traps may be present. Domes, anticlines, and folds are common structures. Fault-related features also may be classified as structural traps if closure is present. Structural traps are the easiest to locate by surface and subsurface geological and geophysical studies. They are the most numerous among traps and have received a greater amount of attention in the search for oil than all other types of traps. In new areas of exploration the prime search is for potential reservoir rock, source beds for hydrocarbons, and structural deformation. This structural deformation provides opportunities for several types of structural traps.

Domes, Anticlines, and Folds. Domes, anticlines, and folds in general must have structural closure to become effective traps. The reservoir rock must dip away in all directions from the crest of the structure. If there is not dip in all directions away from the crest but hydrocarbons are present, there are other contributing physical factors that helped complete the trap.

Domes, anticlines, and folds caused by structural deformation of sedimentary rocks generally create many potential traps because the deformation extends vertically through potential reservoirs. Thus a single well can reveal many possible pay zones when drilled on the crest of a domal structure.

*Fred L. Oliver wrote the original chapter on this topic in the 1962 edition.

Fig. 29.1—Example of anticlinal folds creating structural traps; Kettleman Hills field.

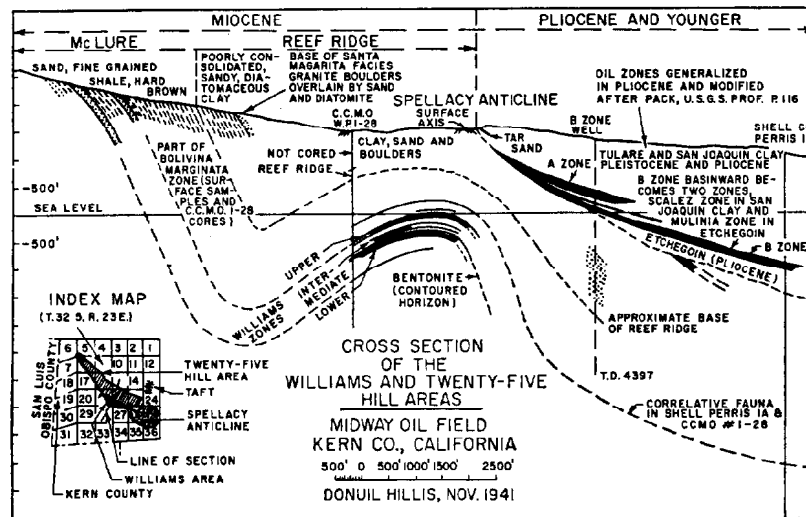

Fig. 29.2—Example of anticlinal folds creating structural and stratigraphic traps; Midway oilfield.

Fig. 29.3—Example of anticlinal folds creating many separate reservoirs; Santa Fe Springs field.

Figs. 29.1, 29.2, and 29.3 are cross sections of Kettleman Hills, Midway, and Santa Fe Springs fields, CA.¹ These are examples of single folds creating many separate accumulations. The separation between the various reservoirs is demonstrated in each case by different oil/water and gas/oil contacts in most reservoirs. The Midway field also illustrates stratigraphic traps formed on the flanks of the anticlinal fold.

Folds, anticlines, and domes are the easiest to interpret in subsurface studies. They vary in size from a few acres to several thousand acres. Folds and anticlines were created by compressional or tensional forces in the earth's crust or by differential compaction of the sediments. Asymmetrical anticlines, overturned anticlines, thrust faulting, and fracturing generally indicate areas of compression. Symmetrical folds and anticlines, low-angle normal faulting, monoclines, homoclines, and low-relief domal structures generally indicate areas of tensional forces or compaction.

Mountainous areas usually result from compressional forces. Torsion and shearing help cause local complex structures but are generally forces resulting from the more regional compressional forces of the earth's crust.

Stable areas or areas of subsidence are the counterpart to mountain-building compressional areas. They are areas where structures are caused by differential

Fig. 29.4—Examples of fault traps: normal or gravity faults.

downwarping, as in the midcontinent area of the U.S. and areas where structures are created by the lengthening of the earth's crust, such as the gulf coast of Texas and Louisiana. This lengthening causes regional horizontal tensional forces that create simple and more predictable local structures. The many prolific structural and stratigraphic oil trends that parallel the U.S. gulf coast today are the result of regional downwarping and tensional forces.

Fault Traps. Fault traps are classified as structural traps where closure is effected in one or more directions by faulting or where faulting has caused definite changes in the reservoir configuration (such as along strike-slip faults). Many structures are faulted without being limited by the faults or without changing the reservoir configuration. Fault traps can occur in both the up- and downthrown blocks. Closure against the fault can result from faults striking across regional dip or across anticlines or domes. Horsts and grabens and other closed fault blocks can result in traps with relatively no structural closure.

Normal or gravity faults (Fig. 29.4) occur as a result of tensional or gravitational forces. The angle of the fault plane with the horizontal generally ranges between 25 and 60°. Normal faults involve horizontal lengthening of the earth's crust and are recognized in the subsurface by loss of stratigraphic section in wells drilled through the fault plane. Geophysically, they are recognized by interruptions in the continuity of reflective interfaces.

Two common types of normal fault-related traps are: (1) fault closures and (2) rollover fault closures. Any structural nose cut at right angles by a fault results in a fault closure. The direction of throw on the fault is not important but the closure created by the fault is. For example, a south-plunging structural nose cut at right angles by a fault will result in a potential trap. The fault throw may be in either direction. A trap will result if the fault acts as a seal or if the potential reservoir is thrown against a shale or other impermeable member on the opposite side of the fault.

Gravity-type faulting commonly occurs in areas of tension and over the crests of domes and anticlines because of the stresses involved. Fault traps are common in such an environment, and hydrocarbon accumulations may occur on either the up- or downthrown blocks, in horsts, and/or in grabens.

Rollover fault closures are common in sedimentary basins receiving great quantities of sediments. Closure is created on the downthrown block by contemporaneous sedimentation and fault movement. Through this interaction, more deposition takes place next to the active fault plane, resulting in a "downbending" of the deposits into

Fig. 29.5—Examples of fault traps: reverse or thrust faults.

the fault. This "downbending" creates a reversal in dip and this results in closure. This type of trap is extremely common in the Cenozoic formations of the U.S. gulf coast.

Reverse or thrust faults (Fig. 29.5) result from compressional forces and involve horizontal shortening of the earth's crust. The angle of the fault plane with a horizontal plane can vary from a few degrees to 90° and can be recognized in the subsurface by repetition of stratigraphic section in wells drilled through the fault plane. Structural traps of this nature are common on both the east and west coasts of North America. The occurrence of a trap against a fault depends on the fault plane sealing the porous reservoir rock and preventing migration across or along the fault plane.

Fractured formations usually are caused by local deformation, faulting and folding, reduction in overburden permitting expansion of the underlying rock, and differential compaction. Brittle rocks are more commonly affected because of their inelasticity. In many cases minor joints, fractures, and fissures are modified by solution and combine with primary and secondary porosity to give a greater effective reservoir porosity and permeability. Fractures in reservoirs increase the wellbore radius and permit extremely tight and impermeable areas to bleed into the fractures over a wide area and thus be connected with channels leading to the wellbore.

Production is sometimes obtained from igneous and metamorphosed rock as a result of fracturing. The fractures provide the reservoir space as well as the permeability to permit oil and gas migration, accumulation, and production from the reservoir.

For a trap to occur in a fractured formation, it must be overlain by a more pliable or less brittle rock that has not been fractured by the deformation. Otherwise, migration would occur up through the fractures and there would be no trap.

Where faulting caused the fracturing, production is limited to a narrow band along the fault. When folding or other deformation has caused the fracturing, the reservoir can become very complex in shape and unpredictable in production performance. Generally, the areas of greatest deformation have the greater number of fractures, which results in better well performance and recovery of more oil or gas.

Stratigraphic Traps

Traps created by changes in stratigraphy have the same physical requirements as structural traps. There is an up-dip limitation or termination of the reservoir rock, creating an area of minimum hydrodynamic potential or concave closure. In case of structural limitations, this is

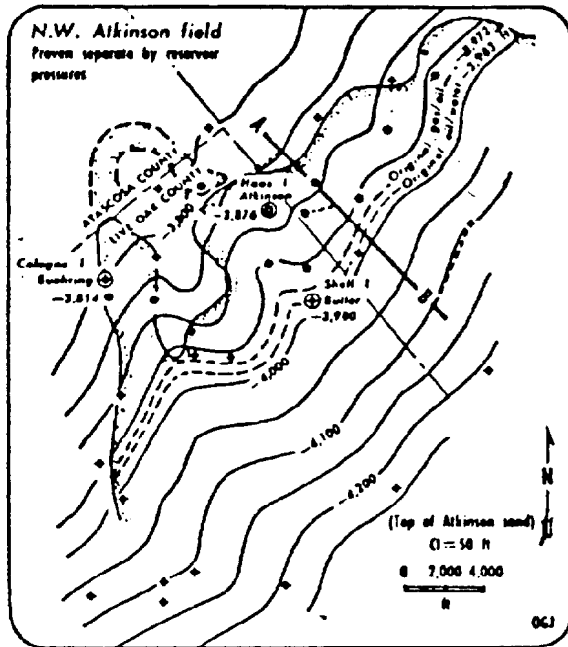

Fig. 29.6—Structural/stratigraphic interpretation; Northwest Atkinson field, TX.

obtained by faulting or a turnover of the reservoir rock. In stratigraphic traps, this limitation is accomplished by changes in porosity and permeability, which result from nondeposition, erosion and overlap, facies, and lithological changes caused by depositional variations, truncation, and differential compaction.

Stratigraphic traps can be classified as primary or secondary. Primary traps are those formed during sedimentary deposition: lenses, facies changes, shoestring sands, offshore sandbars, reefs, and detrital limestone or dolomite reservoirs can be classified as primary. Secondary traps are those resulting from later causes such as solution, cementation, erosion, fracturing, and chemical alteration or replacement.

Primary Stratigraphic Traps. These traps result from deposition of clastic or chemical materials. Shoestring sands, lenses, sand patches, bars, channel fillings, facies changes, strand-line (shoreline) deposits, coquinas, and weathered or reworked igneous materials are classified as clastic sedimentary deposits and can result in stratigraphic traps. Fig. 29.6 is a structural/stratigraphic interpretation of the northwest Atkinson field in Live Oak County, TX.² An ancient sand-filled stream channel meander has cut into older south-dipping shales and created a perfect stratigraphic trap. Fig. 29.7 is a cross section³ across the Yoakum Channel in Lavaca County, TX. This is an example of a channel filled with shale. The shale plug served as the seal for reservoirs within a west-plunging structural nose. Hydrocarbons are trapped in the truncated updip portions of the reservoirs.

Organic reefs or bioherms and biostromes are the primary chemical stratigraphic traps; they are built by organisms and are foreign bodies to the surrounding deposits. A cross section of Scurry field in Scurry County, TX (Fig. 29.8) gives an example of a primary chemical stratigraphic trap.⁴ The Strawn and Cisco-Canyon series are limestone reefs that have had younger sediments deposited on the flanks and eventually over the crest of the reef deposits. The shale serves as the seal. Differential compaction of the thicker shales on the

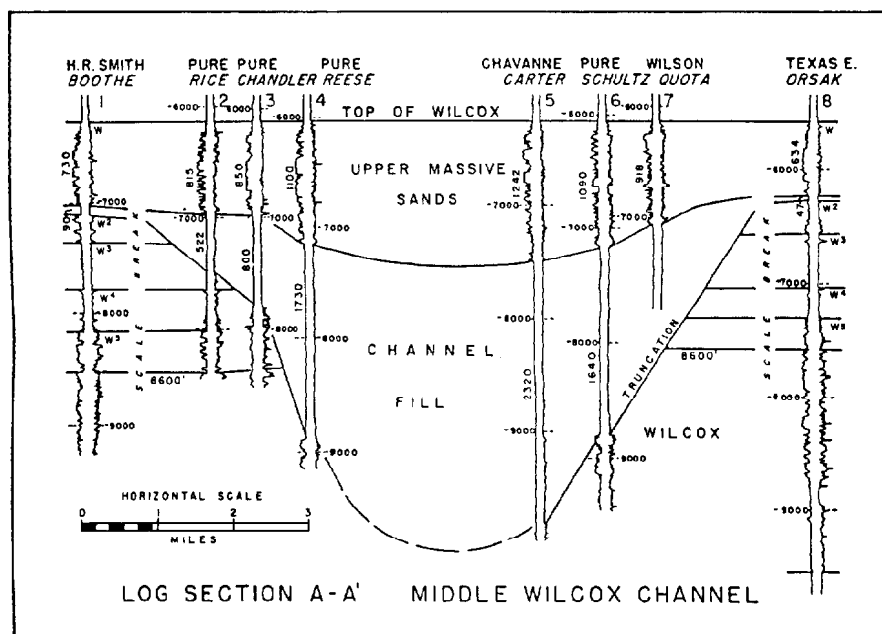

Fig. 29.7—Cross section showing stratigraphic position of upper Wilcox Yoakum channel.

Fig. 29.8—Example of a stratigraphic reef field; structure and cross section of Scurry field.

flanks of the reef as compared with the thinner shale at the crest has created structural closure in younger overlying formations. Hydrocarbon accumulations have occurred in the Cisco and Fuller formations as a result of this differential compaction. Additional traps in other reservoirs are the result of updip permeability and porosity barriers and are either primary or secondary stratigraphic traps.

Secondary Stratigraphic Traps. Traps of this type were formed after the deposition of the reservoir rock by erosion and/or alteration of a portion of the reservoir rock through solution or chemical replacement.

Secondary stratigraphic traps actually should fall into the combination-trap classification because most are associated with or are the result of structural relief during some stage of development of porosity and permeability or limitation of the reservoir rock. However, many of the so-called typical "stratigraphic traps" fall into this category, and it is felt that it would be impossible to change the historical usage of this term. Therefore, secondary stratigraphic traps are defined for this discussion as those traps created after deposition and having limitations caused by lithology changes.

Erosion creates a major part of these through truncation of the reservoir rock. On-lap deposition (when the water is encroaching landward), off-lap deposition (when the water is regressing), and the chemical alteration of limestone result in many secondary stratigraphic traps.

The East Texas field (Figs. 29.9 and 29.10) is perhaps the most famous field in this classification. It is a truncation of the Woodbine formation as it approaches the regional Sabine uplift.⁵ A certain amount of leaching of the cementing material by waters over the unconformity

has resulted in increased porosity and permeability in the field as compared with similar Woodbine sands in the deeper portions of the East Texas basin.

Combination Traps

Combination traps are structural closures or deformations in which the reservoir rock covers only part of the structure. Both structural and stratigraphic changes are essential to the creation of this type of trap. Traps of this nature are dependent on stratigraphic changes to limit permeability and structure to create closure and complete the trap. Updip shale-outs, strand-lines, and facies changes on anticlines, domes, or other structural features causing dip of the reservoir rock create many combination traps. Unconformities, overlap of porous rocks, and truncation are equally important in forming combination traps. Faulting is also a controlling factor in many of these traps. Asphalt seals and other secondary plugging agents may assist in creating traps.

Salt Domes. These structures are of enough importance to justify a separate classification. However, sometimes they are difficult to identify, and many of the traps result from both stratigraphic variations and structural deformation.

Intrusion of rocks into overlying sediments may result in many different types of traps. Salt intrusions are more commonly associated with petroleum traps, although some igneous intrusions have also resulted in the formation of petroleum traps.

Salt domes are classified as piercement, intermediate, and deep-seated domes. Salt plugs or masses have moved up from greater depths through overlying sediments, forming traps in the sediments that have not been penetrated by the salt. Most salt intrusions took

Fig. 29.9—Example of a secondary stratigraphic trap: structure and cross section of East Texas field.

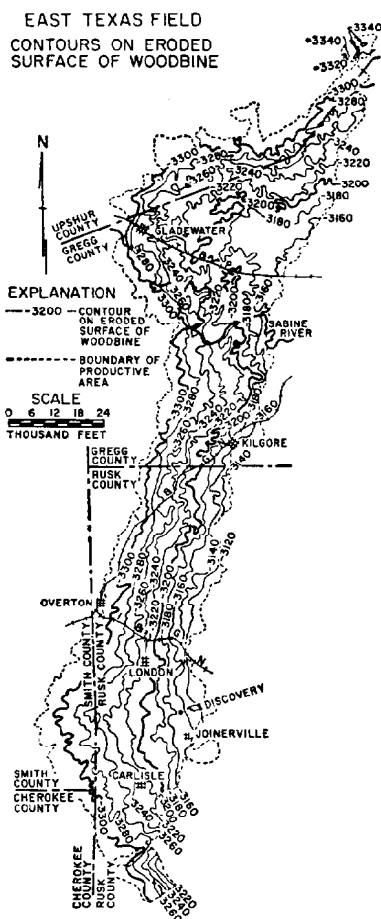

Fig. 29.10—Example of a secondary stratigraphic trap: structure and cross section of East Texas field.

considerable geologic time to reach their current position in the crust of the earth. Some are still growing, and apparently all have grown intermittently, allowing sands to be deposited over the crest of the structure at certain times and limiting deposition to the flanks of the structure at other times. The movement of the salt mass up through the surrounding rock creates many complex structures and sedimentary variations. Radial and peripheral faulting provide the avenue for the salt pushing up through overlying sediments. At times, the overlying formations were competent enough to stop or delay the growth of the salt plug. At other times, the salt

apparently grew steadily and contemporaneously with the deposition. Many times the salt masses of some domes must have reached the surface or near surface, where groundwaters could act on the intrusive salt mass. Some of the domes are very near the surface of the ground. Some have reached the surface and are currently extruding salt. In areas of very low rainfall, such as southwest Iran, salt has reached a height of 5,000 ft above the surrounding terrain.

Deep-seated salt domes are normally those at considerable depths where the salt may not have been penetrated by drilling. These can be identified by the overlying characteristic structure or by geophysical data, which help prove salt is present at depths of 12,000 ft or more and can be assumed to have caused the overlying complex structure. Intermediate domes can be defined arbitrarily as those where the salt is deeper than 2,500 ft but has been penetrated by drilling at depths less than 12,000 ft.

Traps occur on the flanks of salt domes where sands have been faulted and deformed or terminate against the salt mass and where facies changes have resulted because of the associated uplift. These conditions are illustrated in Fig. 29.11.⁶ Traps occur in the caprock, which consists of calcite, anhydrite, and limestone. Caprock is the insoluble residue on top of the plug that results from the dissolution of the salt from the crest of the plug. Porosity and permeability in the caprock result from fracturing, solution, chemical alteration, or any combination of these and are generally restricted to the calcite or limestone portions of the caprock.

Traps also overlie the salt mass and may result entirely from structural closure, faulting, differential compaction, or stratigraphic variations combined with the deformation, as indicated in Fig. 29.12.⁷

Characteristics of Reservoir Rocks

Classification of reservoirs* can be made on the basis of the texture, composition, and origin of the containing rock or the geometric configuration of the reservoir trap. Classification of reservoirs on the basis of rock texture and composition can assist in the prediction of reservoir performance. Variations in the mineralogy of reservoir rocks can be as important in reservoir performance as structural configuration or areal extent of the reservoir rock.

Sedimentary reservoir rocks can be divided into two groups: chemical and detrital. Sedimentary rocks are created by the weathering, disintegration, erosion, reworking, and deposition of material from older rocks.

*For more detailed coverage of this subject, refer to Refs. 8 and 9.

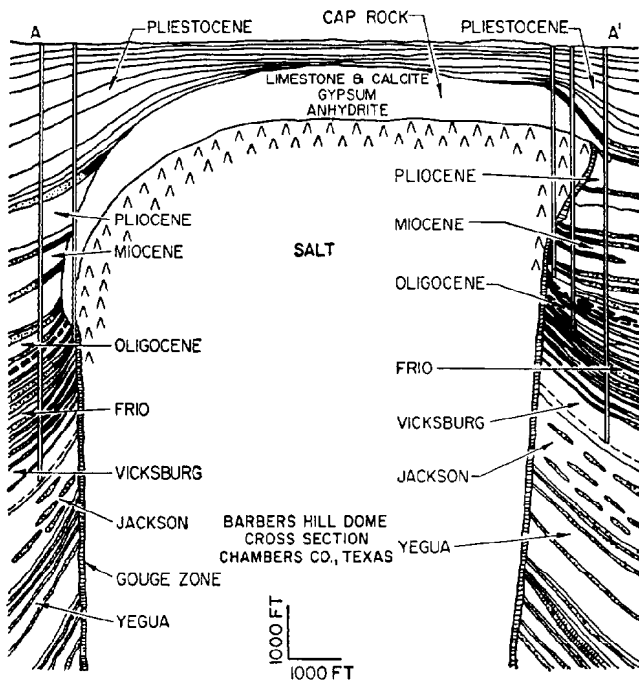

Fig. 29.11—Example of piercement-type dome showing termination of sands on the flanks of the salt plug and the resultant reservoir traps.

Clastic or detrital rocks are created from fragments transported by wind or water and allowed to settle out of suspension when the weight of the fragments is sufficient to exceed the carrying capacity of the transporting agent (wind or water). Chemical rocks are the result of precipitation of materials out of aqueous solution by organic growth and deposition or evaporation of seawater in closed basins, which precipitates salt and other evaporites. A list of reservoir rocks is given in Table 29.1.

Detrital Reservoirs

Clastic or Detrital Granular Reservoirs. These reservoirs can be classified according to rock types, depend-

ing on variations in source rock, transport distance, and depositional environment.

Quartzose-Type. Quartzose-type sediments occur in periods of geologic quiescence, with relatively flat coastal plains bordered by shallow seas. Weathering and chemical decay are at a maximum and erosion is at a minimum. Only stable minerals remain, and these are well sorted and generally uniform in texture and composition. Blanket sands and shales over extensive areas are general factors and the sandstones demonstrate high vertical as well as horizontal permeability. Waterdrive reservoir mechanisms can be expected and high recoveries by primary methods of production are the general rule because of the homogeneity of the reservoir rock. The coastal plains, embayments, and continental shelf along the Gulf of Mexico from Texas to Florida are typical of the physical requirements for this type of deposition.

Graywacke Sediments. These sediments occur in periods of moderate geologic disturbances. The coastal region is moderately uplifted and the depositional basins are somewhat deeper with a shorter continental shelf. More rapid erosion and shorter distances of transportation prevent the complete weathering and chemical decay of the sediments, and some of the more unstable minerals are able to remain. The land and adjacent basin areas are unstable, and minor isostatic adjustments occur from time to time, causing abrupt changes in the sediments being deposited. This causes poor sorting, lenticularity, irregular porosity and permeability variations, and heterogeneous deposition. Vertical permeability is poor, limiting water drive and gravity drainage. Production is normally gas-depletion drive, and the opportunities for secondary recovery operations are excellent. The New England coast is typical of the environment necessary for these types of deposits.

Arkose Sediments. Arkose sediments result from deposition during periods of intense orogenic movements. Certain land areas are sharply elevated above other land areas and/or the shoreline. Faulting and major isostatic adjustments occur frequently. The con-

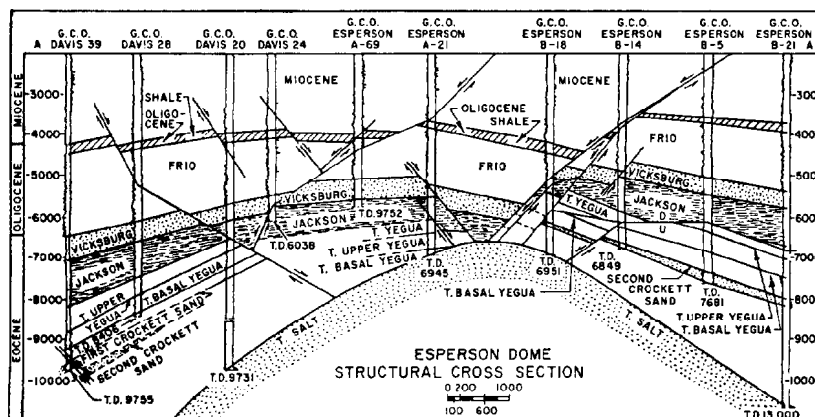

Fig. 29.12—Example of traps caused by a combination of structural and stratigraphic variations and of the complex faulting occurring above an intrusive salt mass.

TABLE 29.1—RESERVOIR ROCKS

Clastic and Detrital Porosity

1. Sand, conglomeratic sand, and gravel (clean, argillaceous, silty, lignitic, etc.)
2. Porous calcareous sandstone and siliceous sandstone (incomplete cementation)
3. Arkosic (feldspathic) sand, arkose, arkosic conglomerate (granite wash)
4. Detrital limestone and dolomite, oolitic and pisolitic limestone, coquina, and shell breccia

Fractured Porosity

1. Fractured sandstone and conglomerate
2. Fractured limestone, shale, and chert

Crystalline Porosity

1. Crystalline limestone and dolomite
2. Sugary dolomite "saccharoidal" porosity

Solution Porosity

1. Crystalline limestone and dolomite
2. Cavernous limestone and dolomite
3. Porous caprock
4. Honeycombed anhydrite
5. Oolitic limestone

tinental shelf is extremely narrow or nonexistent. Maximum erosion and the short distance of transportation virtually eliminate chemical decay and weathering. Sediments are deposited and covered over by younger sediments before any appreciable sorting and weathering can take place. Unstable minerals are present in the thick heterogeneous deposits. Highly porous stratigraphic traps are developed by lensing, pinchouts, and unconformities. Depletion-drive reservoirs are the general rule and recoveries are usually low. Much of the California coast is typical of the depositional environment for the deposition of arkosic sediments.

Chemical Reservoirs

Limestones and Dolomites. Limestones and dolomites also are deposited in quiescent geologic environments. Deposition of limy deposits is occurring along the west coast of Florida and some of the Bahama Islands while clastic sediments are being deposited in other nearby local areas.

Carbonate Reservoirs. Carbonate reservoirs include reefs, clastic limestones, chemical limestones, and dolomite. Porosity may be intercrystalline, intergranular, oolitic or oolitic, vuggy fractured, fossiliferous, cavernous, or saccharoidal. Production characteristics are highly variable in carbonate reservoirs, depending almost entirely on the type of porosity and fracturing developed and the resultant permeability.

Other types of reservoirs are given in Table 29.2.

Glossary of Terms

Bioherm: A moundlike, domelike, lenslike, or reeflike mass of rock built by sedentary organisms (such as corals, algae, foraminifers, mollusks, and gastropods), composed almost exclusively of their calcareous remains and enclosed or surrounded by rock of different lithology.

Biotrom: A distinctly bedded and widely extensive or broadly lenticular, blanketlike mass of rock built by and composed mainly of the remains of sedentary organisms and not swelling into a

TABLE 29.2—TYPES OF RESERVOIRS

Shale Reservoirs

Sometimes present in brittle, siliceous fractured shales

Anhydrite Evaporites

Develop porosity from leaching by circulating waters

Igneous or Metamorphic Rock

1. Very uncommon
2. Sometimes contain oil when secondary porosity is developed by fracturing or weathering
3. Best-known igneous reservoirs are the serpentine plugs of Bastrop and Caldwell counties, Texas

moundlike or lenslike form. As an organic layer, such as a bed of shells, crinoids, or corals or a modern reef in the course of formation.

Breccia: A coarse-grained clastic rock composed of angular broken fragments held together by a mineral cement or in a fine-grained matrix.

Closure: In a subsurface fold, dome, or other structural trap, the vertical distance between the structure's highest point and its lowest closed structure contour. Four-way dip is determined by in-line and cross-line right angle control demonstrating dip in four directions away from the crest of the closure.

Coquina: A detrital limestone composed wholly or chiefly of mechanically sorted fossil debris that experienced abrasion and transport before reaching the deposition site, and weakly to moderately cemented but not completely endurated.

Detrital: Pertaining to or formed from detritus of rocks, minerals, and sediments. The term may indicate a source outside or inside the depositional basin.

Facies: The aspect, appearance, and characteristics of a rock unit, usually reflecting the conditions of its origin; especially as differentiating the unit from adjacent or associated units.

Graben: An elongate, relatively depressed crustal unit or block that is bounded by faults on its long sides.

Horst: An elongate, relatively uplifted crustal unit or block that is bounded by faults on its long sides.

Minimum hydrodynamic potential: As used here, a geologic position or condition due to impermeability in the reservoir rock where the dynamic action of fluid movement is abated.

Minor isostatic adjustment: The minor adjustment of the lithosphere of the earth to maintain equilibrium among units of varying mass and density; excess mass above is balanced by a deficit of density below and vice versa.

Normal fault: A fault in which the hanging wall appears to have moved downward relative to the foot wall. The angle of the fault is usually 45° to 90°. A low-angle normal fault is a normal fault with the angle of the fault less than 45°.

Off-lap deposition: The progressive offshore regression of the updip terminations of the sedimentary units within a conformable sequence of rocks in which each successively younger unit leaves exposed a portion of the older unit on which it lies. The successive contraction in the lateral extent of strata (as seen in an upward sequence) resulting from their being deposited in a shrinking sea or on the margin of a rising land mass.

On-lap deposition: The regular and progressive pinching out toward the margins or shores of a depositional basin of the sedimentary units within a conformable sequence of rocks in which the boundary of each unit is transgressed by the next overlying unit and each unit, in turn, terminates farther from the point of reference.

Oolicast: One of the small, subspherical openings found in an oolitic rock, produced by the selective solution of ooliths without destruction of the matrix.

Oolicastic porosity: The porosity produced in an oolitic rock by removal of the ooids and formation of oolcasts.

Oolith: One of the small round or oval accretionary bodies in a sedimentary rock resembling the roe of fish, usually formed of calcium carbonate and having a diameter of 0.25 to 2 mm.

Pisolith: One of the small, round or ellipsoidal accretionary bodies in a sedimentary rock, resembling a pea in size and shape, and constituting one of the grains that make up a pisolite. It is often formed of calcium carbonate and some are thought to have been produced by a biochemical algae-encrustation process. A pisolith is larger and less regular in form than an oolith.

Pisolitic: Pertaining to pisolite or to the texture of a rock made up of pisoliths or pealike grains.

Pisolitic limestone: A limestone with pisolitic texture.

Saccharoidal: Said of a granular or crystalline texture resembling sugar.

Shell breccia: A breccia composed of angular broken shell fragments.

Shoestring sands: A shoestring of sand or sandstone usually buried in the midst of mud or shale as in a buried sandbar or channel fill.

Strand line: The ephemeral line or level at which a body of standing water meets the land; the shoreline, especially a former shoreline now elevated above the present water level.

Strike-slip fault: A fault on which the movement is parallel to the fault's strike.

Torsion: The state of stress produced by two force couples of opposite movement acting in different but parallel planes about a common axis. Torsion faults are wrench faults or lateral faults in which the fault surface is more or less vertical.

Truncation: An act or instance of cutting or breaking off the top or end of a geologic structure or land form, as by erosion.

Unconformity: A substantial break or gap in the geologic record where a rock unit is overlain by another that is not next in stratigraphic succession, such as interruption in the continuity of a depositional sequence of sedimentary rocks or a break between eroded igneous rocks and younger sedimentary strata. It results from a change that caused deposition to cease for a considerable span of time, and it normally implies uplift and erosion with loss of the previously formed record.

Chapter 30

Bottomhole Pressures

G.J. Plisga, Sohio Alaska Petroleum Co.*

Introduction

The practice of using bottomhole pressure (BHP) to improve oil production and to solve petroleum engineering problems started in about 1930. Pressures in oil wells were first calculated from fluid levels and later by injecting gas into the tubing until the pressure became constant. The earliest BHP measurements were made with pressure bombs and with maximum-indicating or maximum-recording pressure gauges that did not have the accuracy, reliability, or durability now demanded. These early pressure measurements were occasional, or spot tests rather than systematic diagnostic engineering measurements.

BHP Instruments

The development of precision recording pressure gauges small enough in diameter to be run through tubing made it feasible to make BHP measurements in sufficient number to develop the science that now makes them indispensable to petroleum engineering. BHP now is determined with continuously recording pressure gauges, which are either self-contained or surface-recording.

Self-Contained Gauges

Mechanical self-contained pressure gauges are used universally. The pressure element and recording section are encased and sealed against external pressure except for an opening to communicate the pressure to the element. The entire instrument is run to the depth at which the pressure is to be measured, allowed to stabilize thermally, and then returned to the surface and the pressure determined from the chart. Modern pressure measurement systems incorporate force summing devices that convert energy into physical displacement or deformation. These force summing devices can take many forms, three of which are shown in Fig. 30.1. Although there

are numerous mechanical self-contained pressure devices available (Table 30.1) only the most commonly used continuously recording BHP gauges are discussed fully. Regardless of the type of force summing device incorporated into the BHP gauge, whether physical displacement (piston elements) or deformation (bellows/bourdon tubes), the generated force is coupled to a recording device.

The Amerada pressure gauge has a helical bourdon tube as a pressure element that is of sufficient length to rotate the stylus the full inside circumference of the cylindrical chart holder without multiplication of movement. A clock moves the chart longitudinally. The gauge is made in both 1 1/4- and 1-in. diameters with a length of approximately 74 in. A vapor-pressure-type recording thermometer can be run in combination with this to obtain continuously recorded temperatures and allow correction of pressure measurements. This will also ensure that thermal stabilization has occurred.

The Humble gauge pressure element has a piston, which moves through a stuffing box against a helical spring in tension. Attached to the inner end of the piston is a stylus that records longitudinally on a chart in a cylindrical holder, which is rotated by a clock. The instrument is made in two sizes, with 1 1/4- and 15/16-in. OD's, and is approximately 60 in. long. Thermometer elements are available for both sizes.

Other recording gauges have been described in the literature, two of which were continuously recording, but they are no longer available on the market. The Gulf BHP gauge has a pressure element consisting of a long metallic bellows restrained by a double helical spring in tension. The recording mechanism is a cylindrical chart holder rotated by a clock. The USBM BHP gauge pressure element is a multiple-bellows type with a movement of about 0.6 in., which is multiplied through a rack and gears to about 5 1/2 in. of stylus movement. The stylus records longitudinally on a cylindrical chart that is

*The original chapter on this topic in the 1962 edition was written by C.V. Millikan.

rotated by a helical spring but controlled by a watch movement.

BHP gauges, although rugged and capable of service in severe conditions, must be considered precision instruments. Proper attention to adjustment, calibration, and operation is required to obtain consistently reliable and accurate pressure measurements. A comparison of the commonly used mechanical continuously recording BHP gauges is shown in Table 30.1.

Charts

Charts used in a BHP gauge are paper or metal. Paper charts have an abrasive coating and are marked by a brass or gold stylus. Metal charts, which are made of brass, copper, or aluminum, are generally preferred because they are not affected by humidity. Plain metal charts require a sharp pointed stylus. Coated metal charts are generally preferred because they produce less stylus friction. Black-coated charts are marked with a steel or jewel stylus, which burnishes the coated surface. White-coated charts are used with a brass or gold stylus. A finer line can be made on the black chart, but it is more difficult to read. A brass or gold stylus used with white-coated charts, paper, or metal, must be sharpened very frequently.

A small magnifying lens and steel scale with 0.01-in. divisions are most frequently used for reading charts with static pressure—i.e., where only one or two

pressures readings are made on a chart. When a number of readings are to be made from a chart, it is advantageous to use one of the several available chart scanners. Some engineers have used microscopic comparators to read pressure deflection to 0.0001 in., but the inherent errors of a pressure element even under most careful handling are usually greater than the added accuracy of such precise measurement of the chart. New electronic chart scanners have improved the readability and accuracy of mechanical BHP gauges.

Calibration

Self-contained pressure gauges, like all pressure gauges used for precision work, must be calibrated on a dead-weight tester at regular intervals. To obtain maximum accuracy, the pressure gauge is calibrated before a survey at the anticipated bottomhole temperature, (BHT), the survey conducted, and then the chart read using the presurvey calibration lines. New pressure elements should be calibrated frequently until they have become seasoned in service and their ability to retain calibration has been established. Before calibration, pressure equal to the maximum range of the element should be applied and released several times. The number of calibration points should be more on a new element, and two or more curves should be run as a check. The element should also be calibrated at the reservoir temperature at which the pressures are to be determined, or a temperature-correction factor should be determined to correct pressures measured at other than calibration temperature (Fig. 30.2). During calibration, the gauge should be tapped lightly to relieve residual friction in the moving parts of the element. Under normal operating conditions, pressure determination in a well should have an accuracy within a range of 0.2% of the maximum range of the element. The pressure element range should be selected to operate in the upper two-thirds range when at bottomhole conditions. Greater accuracy can be obtained by greater attention to details of calibration and the use of instruments that are well-seasoned by service. Pressure increase inside the gauge caused by an increase in temperature is considered only when extra effort is made to obtain precision pressures.

Temperature Effect

Temperature effect is an inherent property of metals and is present in all gauges, although for some alloys it is very small. Except for such alloys, temperature change

Fig. 30.2—Temperature effect on pressure gauges.

must be considered in pressure measurements. The preferred method is to calibrate the pressure element at the temperature of the reservoir in which pressures are to be measured. The calibration curve for most pressure elements is practically a straight line; therefore, a temperature-correction coefficient may be determined for a given pressure element and used to correct for temperatures other than the calibration temperature as follows. For a given pressure, preferably about three-fourths of the maximum for the element, determine the pressure deflection and the temperature. For the same pressure, determine the deflection at a higher temperature, preferably 100°F higher.

Then¹

$$C_T = \frac{d_2 - d_1}{d_1(T_2 - T_1)}, \dots\dots\dots (1)$$

where

- C_T = temperature coefficient,
- T_1 = lower temperature,
- T_2 = higher temperature,
- d_1 = deflection at T_1 for given pressure, and
- d_2 = deflection at T_2 for same pressure.

The corrected deflection can be calculated as

$$d_c = \frac{d_o}{1 + C_T(T_o - T_c)}, \dots\dots\dots (2)$$

where

- d_c = deflection at calibration temperature,
- d_o = observed deflection,
- T_c = calibration temperature, and
- T_o = observed temperature.

Fig. 30.3—Hysteresis.

If it is more convenient, pressure readings may be substituted for deflections in Eq. 2. Gauges with a steel pressure element usually have a temperature coefficient of about 0.0002 in./°F.

When the pressure gauge is run to the depth of the pressure determination, it should remain long enough to stabilize thermally, usually 15 to 20 minutes. If the instrument cannot remain long enough to reach temperature equilibrium, a maximum-indicating thermometer run in a closed container as part of the gauge will give a satisfactory reading for temperature correction.

Many BHP gauge elements are made of an alloy with a very low temperature coefficient such as Ni-Span C®, and a temperature correction may be neglected up to 200°F except where extra precautions are taken to obtain very precise pressure measurements. For temperatures above 200°F, most elements require a varying correction that can be determined only by actual calibration.

Hysteresis

Hysteresis is a characteristic of metals under strain that must be recognized in pressure gauges. Because of hysteresis, the calibration of a gauge made with increasing pressures will differ slightly from a calibration made with decreasing pressures (Fig. 30.3). If only static pressures are to be determined, a calibration at increasing pressure is satisfactory. When a flowing pressure starting from a static condition is to be determined, hysteresis may be of sufficient magnitude to take into account. To determine the hysteresis effect, the pressure element should be pressurized somewhat higher than the highest anticipated well pressure and released several times before running the calibration, first with increasing pressures, then with decreasing pressures. Flexing the element several times will substantially reduce the hysteretic effect and should be done each time just before the gauge is run into a well.²

Operating Equipment

The BHP gauge, a self-contained instrument, is run on a wireline and depth is measured by the line running in contact with a calibrated measuring wheel, which operates a counter. The most frequently used calibration of the measuring wheel is 2 ft/rev. When the contact of the line is tangent to the measuring wheel, the wheel

TABLE 30.2—WIRELINE TENSILE STRENGTHS AND WEIGHTS

	Tensile Strength (psi)	Nominal Tensile Strength (lbf)			
		Diameter Line (in.)			
		0.066	0.072	0.082	0.092
Plow steel	232,000	794	945	1,225	1,542
Stainless steel	170,000	582	692	898	1,130
Monel	150,000	513	611	792	997
Nominal Weight per 1,000 ft of Line (lbm)					
Plow steel		11.4	14.0	18.0	22.6
Stainless steel		11.8	14.1	18.3	23.0
Monel		13.1	15.6	20.2	25.4

diameter in inches is $24/\pi$. When the contact is an arc of the wheel, the wheel diameter is $D=(24/\pi)-d$, where d is the diameter of the wireline. This applies if the greatest distance of the chord of the contact arc from the periphery of the wheel is greater than the diameter of the wireline. The measuring wheel diameter should be checked at reasonable intervals to maintain accuracy of depth measurements. A decrease in the diameter of the wireline caused by wear or by permanent stretch resulting from a hard pull will also cause errors in depth measurements.

The most common wirelines have diameters of 0.066, 0.072, 0.082, or 0.092 in. In areas having noncorrosive well fluids, plow steel lines are most satisfactory, but for corrosive conditions, stainless steel and Monel® lines are used. Both plow steel and stainless steel are subject to hydrogen embrittlement, but are satisfactory for short runs such as static-pressure tests, except under severe conditions. For an operation that requires the line to be in the hole under corrosive conditions for several hours, a Monel line should be used. Nominal tensile strengths of wire lines and their weights are given in Table 30.2.

Equipment for operating a wireline varies greatly. The most frequently used unit is a trailer-mounted reel driven by a 2- to 4-hp air-cooled gasoline engine. Power is transmitted to the reel by V-belt, through a disk clutch, or by hydraulic drive. On smaller equipment, an idler pulley permits the V-belt to serve as a clutch also. Braking may be by friction disk, brakeband, or hydraulic

pump. When the equipment is used for a continuous program it may be mounted in a pickup truck, with housing to protect against the weather.

Pressure Bombs

Pressure bombs were used to some extent before recording pressure gauges small enough in diameter for oilwell use became available. They were usually made from tubing approximately 1½ in. in diameter with a small needle valve in the top and a ball and seat in the bottom to hold maximum pressure in the well. When the bomb was recovered, the pressure was determined by attaching a pressure gauge to the valve. The bomb had to be long enough to leave a volume of gas (or air) in the top to reduce the error of filling the bourdon tube of the pressure gauge. There was also substantial correction for temperature unless the bomb was raised to BHT before the pressure was read. An ordinary commercial maximum-indicating pressure gauge enclosed in a pressure-tight container was used occasionally, and in some cases a recording mechanism and clock were added. Such instruments were 3 in. or larger in diameter, which limited their use to wells without tubing.

Surface Recording Gauges

Surface recording pressure gauges can be used either permanently installed or wireline retrievable. All surface recording pressure gauges must be run on a single-

Fig. 30.4—E-Core transformer

conductor armored cable that carries a direct current from the surface to the transducer in the bottomhole instrument. Oscillating current returns through the same circuit from the transducer to surface instruments that determine and record its frequency. A transducer is any device that converts energy from one form to another. There is a large variety of transducers that allow nonelectrical variations to be converted into changes in resistance, current, voltage, capacitance, etc. Some examples are the strain gauge, thermistor, and the microphone. Readings are made at selected intervals of 1 second to 30 minutes or more. The frequency recorded in cycles per second is translated to pounds per square inch from a calibration curve. Table 30.3 shows a comparison of commonly used surface recording pressure gauges.

A permanently installed surface recording pressure gauge requires a gauge carrier or receiver and either a single conductor line or small diameter tubing (0.092 in.) strapped to the production tubing. The pressure gauge can be run with the tubing or by wireline retrievable, which sits in a gas lift mandrel or some other device to complete the circuit. The surface instruments may be connected permanently, or one set can be used to monitor BHP in several wells.

Modern precision pressure-measuring systems incorporate force summing devices that convert gas or liquid entry into physical displacement or deformation. The following sections discuss various concepts of pressure transducer technology shown in Table 30.4.³

Pressure Transducer Technology

Capacitive Transducer

In a capacitive transducer, a diaphragm is spaced evenly between capacitor plates. BHP causes displacement of the diaphragm and a change in capacitance. The advantages of a capacitive transducer are excellent frequency response, low hysteresis, good linearity, and excellent stability and repeatability. Disadvantages are high sensitivity to temperature variations and vibration.

Fig. 30.5—Piezoelectric transducer.

Variable Inductance Transducer

In the variable inductance transducer, a flux linkage bar is mechanically linked to a spiral bourdon tube, diaphragm, or bellows (Fig. 30.1). The flux linkage bar is in the magnetic path of an E-core transformer (Fig. 30.4). Displacement of the flux linkage bar by pressure changes the E-core flux density resulting in a transformer output proportional to the pressure applied. The advantages are medium-level output and rugged construction. Disadvantages are a requirement for AC excitation, poor linearity, and susceptibility to stray magnetic fields.

Piezoelectric Transducer

The piezoelectric effect is the property exhibited by certain crystals of generating voltage when subjected to pressure (Fig. 30.5). When a strain is applied to an asymmetrical crystalline material such as barium, titanite, quartz, or rochell salt, an electrical charge is generated. When a piezoelectric crystal is connected to a diaphragm, bellows, or bourdon tube, the generated charge can be made proportional to the applied pressure. Advantages are very high frequency response (250 kHz), small size, rugged construction, and ability to accept large overpressures without damage. Disadvantages are temperature sensitivity, inability to make static measurements, and special electronics required.

Potentiometric Transducer

This transducer is constructed by coupling the wiper of a multiturn potentiometer to an amplifying mechanical linkage to a diaphragm, bellows, or bourdon tube. Advantages are low-cost, high-level output and simple electronic circuits. Disadvantages are limited life, poor resolution, large hysteresis, and low frequency response.

Vibrating Wire Transducer

A thin wire is connected in tension to a diaphragm, bellows, or bourdon tube and is caused to vibrate under the influence of a magnetic field (Fig. 30.6). The wire's frequency of vibration is directly related to its tension.

Fig. 30.6—Vibrating wire transducer.

Advantages are very high accuracy, low hysteresis, and excellent long-term stability. Disadvantages are sensitivity to shock and vibration, temperature sensitivity, and additional electronics.

Strain Gauge Transducers

A strain gauge transducer is a strain-sensitive resistor mounted to a diaphragm, bellows, or bourdon tube. When pressure is applied, the resistor changes its physical length thereby causing change in resistance. This effect is expressed by

$$F_g = \frac{\Delta r/r}{\Delta L/L}, \dots \dots \dots (3)$$

where

- F_g = gauge factor,
- Δr = change in resistance,
- r = unstrained resistance,
- ΔL = change in length, and
- L = unstrained length.

There are four basic types of strain gauge transducers; unbonded wire, bonded foil, thin film, and semiconductor. A rule that applies to strain gauge transducers is the larger the gauge factor, the higher the output of the device. For unbonded wire, the gauge factor is four. Bonded foil and thin film (Fig. 30.7) have factors of two. For semiconductor transducers, the factor ranges from 80 to 150.

Vibrating Crystal Transducer

In vibrating crystal transducers, a crystal is forced by external electronic circuits to oscillate at its resonate frequency when external stress is applied to the crystal by mechanical linkage to the diaphragm, bellows, or bourdon tube. The resonate frequency of the crystal shifts in proportion to the stress. In at least one transducer of this type, the pressure is applied directly to the crystal itself. The vibrating crystal is usually manufactured out of quartz because of its excellent elastic properties, long-

Fig. 30.7—Thin film strain gauge transducer.

Fig. 30.8—Cross-sections showing different modes of motion of quartz crystals.

term stability characteristics, and ease of vibrational excitement. Fig. 30.8 shows various modes of motion of quartz crystal. Advantages are excellent accuracy, resolution, and long-term stability. Disadvantages are sensitivity to temperature and extremely high costs.

New technology is constantly evolving a new generation of surface recording pressure gauges that are more and more advantageous to the petroleum engineer and petroleum engineering problems.

Calculated BHP

BHP calculated from surface pressure and fluid level, although less accurate than measured pressure, is sufficient for many practical uses. In an open hole or open tubing, the fluid level can be determined by a float run on a measuring line.

In pumping wells, the fluid level can be determined by sound reflection. There are four types of commercial instruments available. These are the depthograph, echometer, sonoloy, and acoustical well sounder. Each of these instruments records sound reflection initiated by firing a blank shotgun shell or pistol cartridge or venting pressure into a chamber attached to the casing head. A sound reflection is received and recorded from each tubing collar. By counting the collar reflections and knowing the tubing tally, the depth to the fluid can be calculated. In deep wells, attenuation of the collar reflection makes accurate counting difficult. In some oil wells,

usually those having considerable gas, a foaming condition makes the fluid level difficult to identify or may indicate a fluid level much higher than actual. A foaming condition is usually indicated when the fluid level changes several feet on tests made at short intervals of time. Fluid level can also be calculated from the time interval for the reflection to be received from the fluid level, but the variation in the speed of sound through gases of different compositions and the effect of temperature make the procedures more laborious and usually less accurate than the simpler method of counting collar reflections.

In calculating the pressure caused by the column of fluid, allowances should be made for gas in solution in the oil, which will reduce its specific gravity below that measured in the stock tank. This can reduce the gradient 5 psi/100 ft or more where much gas is in solution under high pressure. For wells producing water, it is customary to calculate the fluid head on a basis of a column of oil and water in the same ratio as normal production for the well, but this calculation is less reliable for low-capacity wells with high casinghead pressure and for pumping wells in which the pump is several hundred feet above the producing formation. If the surface pressure is low, the pressure caused by the weight of a column of gas may be too small to warrant consideration, but under high pressure it should be calculated and added to the hydrostatic head by the same equation used for calculating BHP in a gas well, where D is the depth of the fluid level.

Producing BHP of a pumping well that is sufficiently accurate for practical use may be calculated by shutting in the casing head until the gas pressure depresses the fluid level to the inlet of the pump, at which time fluid delivery is stopped. The casinghead pressure at that time, plus the head of the column of gas from the casing head to the pump inlet, plus the head of the column of liquid from the pump inlet to the producing formation is the producing BHP. A check of the determination should be made by releasing and controlling the pressure a few pounds less than the maximum pressure read and determining the rate of production under such conditions.

The BHP in a gas well can be calculated with an equation developed by Pierce and Rawlins⁴:

$$p_{ws} = (p_{wh})^{e^{0.0000347\gamma_g D}}, \quad \dots \dots \dots (4)$$

where

- p_{ws} = static BHP, psia,
- p_{wh} = wellhead pressure, psia,
- e = base, natural logarithms,
- γ_g = specific gravity of gas (air=1), and
- D = depth of well, ft.

This equation is based on an average temperature of the column of gas of 60°F. While the temperature gradient in a producing well is rarely a straight line, the average temperature at a depth below seasonal effect (20 to 30 ft) and at a depth of the pressure is sufficiently accurate for practical purposes. The equation can then be written⁵:

$$p_{ws} = (p_{wh})^{e^{\gamma_g D/(53.34T)}}$$

or

$$\log p_{ws} = \log p_{wh} + \frac{\gamma_g D}{122.82 \bar{T}}, \quad \dots \dots \dots (5)$$

where \bar{T} is the average temperature in the borehole, °F+460.

Deviation of a gas from Boyle's law will affect the calculated BHP enough to be considered only in high pressure deep wells. USBM Monograph 7 presents the following equation.⁵

$$\frac{p_{ws}}{1 + p_{ws}z} = \left(\frac{p_{wh}}{1 + p_{wh}z} \right)^{e^{\gamma_g D/(53.34T)}} \quad \dots \dots \dots (6)$$

where z is the deviation coefficient, deviation per psi expressed as a decimal.

Application of BHP

The importance of pressure analysis in projecting and enhancing the performance of producing oil and gas wells emphasizes the need for precision pressure measurement systems. Today's petroleum engineer must have sufficient information about the reservoir to adequately analyze current performance and predict and optimize future performance. More specifically, such pressures are a basic part of reservoir calculations, rate of equalization of pressures, interference tests for well spacing or rate of development, formation damage during completion, rework or workover operations, and indication of deposition of salts, sediments, or other restrictions at the wellbore. Other applications are design of downhole equipment for artificial lifting, efficiency of operation of such equipment, and evaluation of drillstem test (DST) information.

Static Pressure

Static pressure is the most frequent BHP measurement. Most such measurements are made as a pressure survey of a pool where the pressures in all wells are determined in a short period of time either by cooperation of the operators or by order of a conservation commission, usually as a result of a recommendation by the operators. Pressures are taken under reasonably uniform conditions after the wells have been shut in a specified length of time such as 24 or 48 hours, or longer, if the pressure buildup is at a slow rate. The pressures should be measured at or adjusted to a common data plane. In many pools, the pressures will not reach equilibrium in the specified shut-in time. However, if the pressures are determined for several surveys under the same conditions, the indicated rate of decline of the reservoir pressure should be reasonably accurate. Tests in representative wells which have been shut in long enough to reach pressure equilibrium will show the relation of the measured pressure to the actual reservoir pressure. Pressures in inactive wells may be used to confirm the actual pressure and the rate of decline.

Average Reservoir Pressure

The average reservoir pressure for a pool may be determined by arithmetically averaging the pressures of all

wells. For some pools it is preferable to determine a weighted average by weighting each pressure by the productive thickness of the reservoir at that point. When for any reason the pressure cannot be determined in substantially all wells or where wells are irregularly spaced, a better average reservoir pressure is determined by recording the pressures, either actual or weighted, on a map of the area and drawing isobars from which the average pressure weighted for an area is determined by planimeter, grid system, or other means.

Static Pressure from Partial Buildup

Many low-permeability reservoirs require excessive shut-in time to reach static or equilibrium pressure. Several methods have been proposed for calculating the reservoir pressure from partial buildup of pressure. Muskat⁶ proposed plotting $\log(p_{ws} - p_t)$ vs. time, where p_{ws} is an estimated static BHP and p_t is the measured pressure at different times, p_{t_1} , p_{t_2} , p_{t_3} , etc. When plotted on semilog cross-sectional paper with pressure on the log scale, the selected p_{ws} is the static pressure when the plot is a straight line.

Arps and Smith⁷ proposed plotting increments of pressure increase for uniform time periods against measured pressure on rectangular cross-sectional paper, and extrapolating the curve to intersect the zero line of the incremental-pressure scale, which gives the static pressure. Both the Arps and Smith and the Muskat methods are more commonly used in cases of rapid pressure buildup.

Miller *et al.*⁸ presented an equation to calculate the static pressure from a partial buildup curve:

$$p_{ws} = p^* + \frac{(p_{sd} - \Delta\bar{p})q\mu B}{0.00708 kh}, \quad \dots \quad (7)$$

where

- p_{ws} = static BHP, psi
- p^* = last pressure on buildup curve, psi
- $p_{sd} = \log_e(r_d/r_w)$ for constant pressure at radius of drainage, or
 $= \log_e(r_d/r_w) - 0.75$ when no influx across external boundary,
- q = production rate at shut-in, B/D,
- μ = reservoir fluid viscosity, cp,
- B = formation volume factor for total fluid produced, RB/STB
- k = permeability of reservoir, md,
- h = effective thickness of reservoir, ft,
- $\Delta\bar{p}$ = dimensionless pressure variable from curves (see Fig. 30.9),
- $\Delta p = p_{wf} - p_{ws}$,
- p_{wf} = BHP during buildup, psi,
- p_{ws} = BHP at time of shut-in, psi, and
- t = time after well was shut in, hours.

The value of p^* is determined by plotting the buildup pressure vs. the time on semilog paper, with time on the log scale. When afterflow is completed following shut-in, the points should fall on a straight line and p^* is the

Fig. 30.9—Curves from which $\Delta\bar{p}$ is determined in the Miller *et al.* equation for calculating static pressure from buildup pressure curve. Solid lines assume influx at r_d and dotted line indicates direction of curves when no influx at r_d .

highest measured pressure lying on the straight line. This is the same straight line by which the slope, m , is determined in the equation for permeability from buildup pressures by the same authors and is discussed further under that topic.

The straight line by which the slope m is determined comes from the middle time region of a Horner plot. Afterflow causes lack of development of the middle time region (with long periods of afterflow), early onset of boundary effects, and development of several false straight lines that could be mistaken for the middle time region. This makes the middle time region difficult for the buildup test analyst to recognize. Recognition of the middle time region is essential for successful buildup curve analysis based on Horner plot method. The line must be identified to estimate reservoir permeability, to calculate skin factor, and to estimate static drainage area pressure.

A log-log graph of the pressure change, $p_{ws} - p_{wf}$ (Δp), in a buildup test vs. shut-in time t presents a good estimation of where the straight line portion, or middle time region, begins (Fig. 30.10).⁹ A log-log graph of pressure change $p_{ws} - p_{wf}$ vs. Δt ¹⁶ is an even more diagnostic indicator of the end of afterflow distortion. Fig. 30.11 shows a semilog plot of theoretical buildup test data. The use of type curves has greatly improved identification of the straight line portion of the buildup curve after wellbore storage effects have ended.

Horner¹⁰ plotted buildup pressure vs. $(t + \Delta t)/\Delta t$ on semilog paper with $(t + \Delta t)/\Delta t$ on the log scale where t = total producing time since well completion, hours, and Δt = time since the well was closed in, hours. Extrapolation of the curve to a value of $(t + \Delta t)/\Delta t = 1$ is the approximate static pressure.

Fig. 30.10—Log-log vs. semilog plots.

The value of t is determined by dividing the cumulative production of the well by the rate of production per hour at the time the well is shut in. The uncertainty of the value of t increases with the age of the well. Experience indicates that using the time of the flow period before the well is shut in for the buildup test is often more reliable than using the total time since completion provided fully stabilized conditions exist both when the well is opened and when it is shut in.

Thomas,¹¹ with Horner's basic equation, preferred using the reciprocal of $(t + \Delta t)/\Delta t$ and therefore plotted pressure vs. $\Delta t/(t + \Delta t)$ on semilog paper with $\Delta t/(t + \Delta t)$ on the log scale, and extrapolated the curve to a value of $\Delta t/(t + \Delta t) = 1$, which gives the approximate reservoir pressure.

Hurst¹² plotted the buildup pressure vs. the shut-in time in minutes on semilog paper with time on the log scale. A straight line is drawn through the points and extrapolated to an intercept time value of 1. The slope is the value of pressure change in one log cycle. Expressing his equation in English units, the static pressure is calculated:

$$p_{ws} = b + m \log 625 m, \quad (8)$$

where

p_{ws} = static BHP, psi,

m = slope of buildup curve, and

b = intercept of curve with time value of 1 minute.

Correct identification of the straight-line portion of the buildup curve is necessary for the interpretation of pressure buildup data. The straight-line portion of the

Fig. 30.11—Plot of typical buildup with afterflow.

curve is frequently masked by one or more factors, such as skin effect, afterflow, and the early onset of boundary effects. Chap. 35, "Well Performance Equations," addresses these problems.

The capacity of a well to produce can be estimated from the BHP drawdown on a flow test. For gas wells, the open-flow capacity is calculated by the procedure proposed in Ref. 5 except that both the static pressure and the flowing pressure are measured with a BHP gauge. Open-flow capacity of oil wells having large capacity and high pressure is rarely of value, and little work has been reported on such determinations. Theoretically, so long as single-phase flow maintains, the rate of flow should increase in proportion to the drawdown pressure. But, because of gas coming out of solution below the bubblepoint, turbulence in the flow, and borehole restrictions, the flow conditions change and the proportionality does not hold. Engineers who have investigated the problem usually consider that little increase will be obtained after the drawdown pressure is one-half the static pressure. For low-pressure wells, the rate of production will usually continue to increase until the flowing pressure is equal to or close to atmospheric pressure.

Productivity Index

PI is defined as the barrels of oil produced per day per pound decline in BHP. To determine the PI, a well is shut in until static or reservoir pressure is reached. The well then is opened and produced until the BHP and rate of production are stabilized. Since a stabilized pressure at surface does not necessarily indicate a stabilized BHP, the BHP should be recorded continuously from the time the well is opened. The PI is then

$$J = \frac{q_o}{p_{ws} - p_{wf}}, \quad (9)$$

where

J = PI, B/D-psi,

q_o = rate of oil production, B/D,

p_{ws} = static BHP, psi, and

p_{wf} = flowing BHP, psi.

Fig. 30.12—Flow-test data on a well having a negligible transient or stabilization period.

Specific PI is defined as barrels of oil produced per day per pound decline in BHP per foot of effective reservoir thickness, and is expressed as

$$J_s = \frac{q_o}{(p_{ws} - p_{wf})h}, \quad (10)$$

where J_s is the specific PI and h is the effective reservoir thickness, ft.

On a flow test the time required for a well to reach a stabilized BHP and rate of production, that is, the transient period, may require several hours or even days and occasionally several weeks. The duration of the transient period and the rate of the pressure decline and the PI decline during the transient period will indicate the quality of the reservoir. A short transient period indicates a high-quality reservoir, and a long transient indicates a low-quality reservoir which will have a comparatively low recovery of the amount of oil calculated to be in place. Reservoir quality is not related to the numerical value of the PI. The nature of the transient period is most conveniently expressed by plotting the productivity index by hours on log-log paper.

Typical well test data are presented in Figs. 30.12 through 30.15. The negligible transient period of the test shown in Fig. 30.12 indicates a high-quality reservoir from which relatively high recovery may be expected. The short transient period in the flow test in Fig. 30.13 indicates a comparatively high recovery of the original oil in place. In Fig. 30.14, the transient period is quite long but the continuous flattening of the slope of the PI curve indicates eventual stabilization. Fig. 30.15 is the flow test of a well in which the continuous decline in pressure, production, and PI shows that the flow will not stabilize and therefore the ultimate recovery will be lower than that reasonably expected from a consideration of the producing formation and its apparent productivity.

Flow tests and PI tests are conducted by other procedures. Some prefer to run the test at two or more different rates of flow. There is usually some difference in the PI at different rates, sometimes more than can be accounted for by inherent limitation of accuracy of pressure measurement and production gauging. Changing GOR or WOR will affect the relative permeability

and therefore the PI. Calculating a PI based on total fluid mass instead of liquid production has given more consistent results in some pools.

Permeability

Permeability of the reservoir rock can be calculated from the PI. Wycoff *et al.*¹³ used

$$k = \frac{q\mu B \log(r_d/r_w)}{0.003076 h(p_{ws} - p_{wf})} \\ = 325 J_s \mu B \log \frac{r_d}{r_w}, \quad (11)$$

where

- k = permeability, md,
- r_d = radius of drainage area, ft,
- r_w = wellbore radius, ft,
- q = production rate, B/D,
- μ = viscosity of produced fluid, cp,
- B = formation volume factor, RB/STB,
- h = effective reservoir thickness, ft,
- p_{ws} = static BHP,
- p_{wf} = flowing BHP, and
- J_s = specific PI.

Permeability can be calculated from the buildup curve obtained when a producing well is shut in following a flow test. Muskat discussed this in 1937 and presented an equation in 1949.¹⁴ The equation in commonly used units is

$$k = \frac{40.37 md^2 \mu B \log(r_d/r_w)}{h\gamma}, \quad (12)$$

where m = slope of $\log(p_{ws} - p_{wf})$ vs. t , d = diameter of flow pipe, in., t = time, hours, since well was closed in, and other parameters are as previously defined.

The equation has limitations, but it may be helpful in cases of severe reservoir damage such as interpretation of DST buildup curves where recovery is low.

Fig. 30.13—Flow-test data on a well having a short transient period.

Miller *et al.*⁸ calculated permeability from a BHP buildup curve with the equation

$$k_o = \frac{162.5 q_o \mu_o B_o}{hm}, \quad (13)$$

where

- k_o = effective oil permeability, md,
- k = permeability, md,
- q_o = oil production rate, B/D,
- μ_o = viscosity of reservoir oil, cp,
- B_o = formation volume factor of oil, RB/STB,
- h = effective reservoir thickness, ft, and
- m = slope of buildup curve.

The slope m can be determined most conveniently by plotting BHP against time in hours on semilog paper, with time on the log scale. The initial part of the curve is affected by the afterflow into the wellbore, and the last part of the buildup curve may be too flat and therefore unreliable because of interference of drainage areas or limited reservoir. The calculation is simplified by extrapolating the buildup curve to encompass one complete cycle of the log scale. The slope is then the difference in the pressure reading at the beginning and at the end of the cycle.

The part of the curve representing the slope of the buildup curve is usually evident, but occasionally interferences and irregularities in the reservoir make the slope uncertain. We consider that if the value

$$m = \frac{0.0002637kt}{\phi c_L r_d^2 \mu}, \quad (14)$$

where

- k = permeability, md,
- t = time, hours, from closed in to end of straight-line portion,
- ϕ = porosity, fractional,
- c_L = liquid compressibility, psi⁻¹,
- μ = viscosity, cp,
- r_d = drainage radius, ft,

falls to the range 10^{-1} to 10^{-2} , the slope m is proper and the calculated value of k is valid. This tacitly assumes that the values of the other factors are known and that the conditions exist for which the equation was derived. A valid calculation of permeability from buildup curves requires stabilized conditions of pressure and rate of production at the time the well is closed in.

These equations for calculating permeability are based on liquid single-phase flow. When a small amount of free gas is produced with the liquid, adjustment by the relative permeability will give an acceptable answer. When gas only is produced from the reservoir, the equations for permeability are as follows.

Radial flow equation:

$$k = \frac{q_g \mu_g T_R z \log(r_d/r_w)}{0.00306h(p_{ws}^2 - p_{wf}^2)}, \quad (15)$$

Pressure buildup¹⁵:

$$k = \frac{1,637 q_g \mu_g T_R z}{hm_g}, \quad (16)$$

where

- k = permeability, md,
- q_g = rate of production, Mcf/D at 14.7 psi and 60°F,
- μ_g = viscosity of reservoir gas, cp,
- T_R = reservoir temperature, °F + 460,
- z = gas deviation factor, reservoir conditions,
- h = effective reservoir thickness, ft,
- p_{ws} = static BHP, psia,
- p_{wf} = flowing BHP, psia,
- r_d = drainage radius,
- r_w = wellbore radius, and,
- m_g = slope of pressure buildup curve, p_w^2 vs. $\log t$, where t = time after shut-in, hours,
- p_w = BHP at t .

Fig. 30.14—Flow-test data on a well having a long but finite transient period.

Fig. 30.15—Flow-test data on a well having a very long transient period.

Permeability Damage

The permeability of the reservoir adjacent to the borehole is frequently reduced by the invasion of drilling mud, water blocking by invasion of filtrate water from drilling fluid or other source, swelling of clay particles, or deposition of salts or wax. Blinding or partial clogging of screens or perforations will give a similar effect. A substantial restriction of flow can be observed on the BHP chart by the straight-line buildup until near the maximum pressure instead of the normal exponential shaped curve. On the other hand, permeability adjacent to the borehole may be increased as a result of acidizing, fracturing, or shooting.

The amount of damage or improvement to the permeability adjacent to the borehole is determined by comparing the permeability calculated from flow test with the permeability calculated from the buildup and is expressed as the productivity ratio:

$$F_P = \frac{k_j}{k_b} \quad \dots \dots \dots (17)$$

where

- F_P = productivity ratio,
- k_j = permeability calculated from productivity index, and
- k_b = permeability calculated from buildup pressure.

Substituting the equated expressions of k_j and k_b and simplifying:

$$F_P = \frac{2m \log(r_d/r_w)}{p_{ws} - p_{wf}} \quad \dots \dots \dots (18)$$

A fractional F_P indicates restricted flow at the borehole and an F_P greater than unity indicates better permeability at the borehole, usually the result of stimulation.

Dolan *et al.*¹⁶ presented an empirical equation to determine "damage factor" that does not involve the use of the amount of production. It is of particular value for interpretation of drillstem test charts that have an acceptable buildup but negligible fluid recovery. His equation expressed as productivity ratio is

$$F_P = \frac{\Delta p}{0.183(p_{ws} - p_{wf})} \quad \dots \dots \dots (19)$$

where

F_P = productivity ratio,
 p_{ws} = static BHP,
 p_{wf} = flowing BHP, and
 Δp = slope of plot of p vs. $\log(t + \Delta t / \Delta t)$,

where

t = time well was open, minutes,
 Δt = time after well was shut in, minutes, and
 p = pressure at $t + \Delta t$.

Hurst¹² has developed equations for calculating restrictions to flow through the reservoir adjacent to the borehole, which they have called "skin effect." Expressed in oilfield units, these equations are

for oil:

$$p_s = m \left[\frac{(p_t - p_{wf})}{m} - \log \left(\frac{q_o B_o}{10.4 m h \phi c_o r_w^2} \right) \right] \dots \dots \dots (20)$$

and for gas:

$$p_s = m_g \left[\frac{(p_t - p_{wf})}{m_g} - \log \left(\frac{q_g z T_R}{2.063 \phi h m_g c_g \bar{p} r_w^2} \right) \right], \dots \dots \dots (21)$$

where

p_s = pressure loss due to skin effect, psi,
 p_{ws} = static BHP, psi,
 p_{wf} = flowing BHP, psi,
 p_t = well pressure 1 hour after shut-in, psi,
 q_o = production rate for oil, B/D,
 q_g = production rates for gas, Mcf/D at 14.7 psia and 60°F,
 B_o = formation volume factor of oil, RB/STB,
 z = compressibility factor (gas deviation factor),
 h = effective reservoir thickness, ft,
 T_R = reservoir temperature, °F + 460,
 ϕ = porosity reservoir rock, fraction,
 c_o = compressibility of reservoir oil, psi⁻¹,
 r_w = borehole radius, ft,
 m = slope, p_t vs. $\log t$, and
 m_g = slope p_t^2 vs. $\log t$, where p_t is the well pressure at time t and t is time after well shut-in, hours.

Positive values of p_s indicate damage and negative values of p_s indicate improvement of permeability adjacent to the wellbore in terms of pressure loss due to skin effect.

It is usually difficult to delineate specific heterogeneities from well test results only because different heterogeneities may cause the same or similar well test response. A higher degree of confidence is achieved when the interpretation of test results is confirmed by geological and geophysical evidence of heterogeneities.

Linear discontinuities, faults, and barriers affect a pressure buildup behavior and are manifested by a second straight line, the slope of which is double the initial straight line. For a well near a linear fault, drawdown testing can be used to estimate reservoir permeability and skin factor in the usual fashion, as long as wellbore storage effects do not mask the initial straight-line section. If the well is very close to the fault, the initial straight-line section may end so quickly that it will be masked by wellbore storage.

As the drawdown proceeds and the pressure at the producing well falls below the initial semilog straight line, the following equation indicates that p_{wf} vs. $\log t$ plot will have a second straight line portion with a slope double that of the initial straight line.

$$p_{wf} = 2(m \log t + p_{thr}) + p_i + m \left[0.86859s + \log \left(\frac{4L^2}{r_w^2} \right) \right], \dots \dots \dots (22)$$

where

$$m = \frac{-162.5 q_o \mu_o B_o}{kh},$$

p_{thr} = pressure on straight-line portion of semilog plot one hour after beginning a transient test, psi,

p_i = initial reservoir pressure, psi,

s = skin effect, and

L = distance to a linear discontinuity, ft.

However, the simple occurrence of a doubling slope in a transient test does not guarantee the existence of a linear boundary near the well.

To estimate the distance to a linear discontinuity, we use the intersection time, t_x , of the two straight line segments of the drawdown curve. The following equation applies for drawdown testing.¹⁷

$$L = 0.01217 \sqrt{\frac{k_o t_x}{\phi c_t \mu_o}}, \dots \dots \dots (23)$$

where c_t is compressibility of the total system, psi⁻¹. The effects of reservoir heterogeneities and method of determining them are discussed in Chap. 26.

Lifting Equipment

BHP measurements are valuable to the engineer for determining the size and type of artificial lift to install and to monitor the efficiency of such equipment.

The efficiency of a gas lift depends, among other factors, on the pressure at the depth of gas injection. From

the flowing pressure or PI, the pressure can be calculated for a given rate of production and after a gas lift is in operation. Knowing the PI, the producing efficiency can be calculated from the rate of production. The change in pressure gradient in a well being gas lifted will determine the point at which gas is entering the flow string, which is of interest where multiple flow or unloading valves are installed.

The PI is used to determine the amount of fluid available to be pumped from a well and therefore the size of the pump that should be run and the depth at which it should be set. After a well has been on the pump for some time and declined in production, the question frequently arises as to whether the productivity of the well has declined or the pumping equipment has decreased in efficiency. The correct condition can be determined by measuring the static and producing pressures, either with a bottomhole gauge or from fluid-level calculation by sound reflections as described previously. If fluid-level determinations are known to be unreliable for a given pool or are proved uncertain in a given well because of fluctuating fluid-level by several determinations, a BHP gauge should be run. Many operators have successfully run a pressure gauge in the annulus between the tubing and casing. During such runs the wireline will sometimes wrap around the tubing or the gauge will wedge between the tubing and casing. It can usually be released by starting the pumping equipment, but sometimes it is necessary to move in a pulling unit to lift the tubing to free the gauge. Many operators use an eccentric tubing head to position the tubing against one side of the casing instead of its normal central position and thus minimize chances of the gauge's becoming hung up in the annulus. The BHP gauge can be run on the rods in most wells by attaching it, preferably rigidly, to the standing valve. A pressure gauge under these conditions is subject to severe vibrations resulting from both the vibration of the pumping equipment and a "water-hammer" effect from the liquid at the pump level.

Drillstem Tests

The most common use of BHP gauges in a drilling well is in evaluating DST's. Pressure gauges were first used to determine that the valve functioned properly and was open during the test. Subsequently the pressure information has become important. The detailed pressure information obtained on a DST can be used to determine the productivity of the formation by calculating the PI from the amount of fluid recovered during the test and the static and drawdown pressures. A more recent use has been to confirm indicated productivity from the buildup after the valve is closed. It is not unusual to have a very poor recovery of fluid and obtain a good buildup curve such as can be obtained only when the producing capacity is much better than indicated by the quantity of fluid recovered. The permeability can be calculated from the buildup curve. While subject to a high probable error because of the short time of the test and usually high reservoir damage adjacent to the borehole, it is sufficient to indicate whether further testing may be warranted.

Mud Weight

The pressure at the depth of a DST, before seating the packer and also after the test is completed and the packer

unseated, permits calculating the average weight of mud in the hole and is used to verify mud weight as measured by routine tests.

Nomenclature

- b = intercept of curve with time value of 1 minute
- B = formation volume factor for total fluid produced
- B_o = formation volume factor of oil
- c_L = liquid compressibility
- c_o = compressibility of reservoir oil
- c_t = compressibility of the total system
- C_g = gas compressibility
- C_T = temperature coefficient
- d = diameter of flow pipe
- d_c = deflection of calibration temperature
- d_o = observed deflection
- d_1 = deflection at T_1 for given pressure
- d_2 = deflection at T_2 for same pressure
- D = depth of well
- e = base, natural logarithms
- F_g = gauge factor
- F_p = productivity ratio
- h = effective reservoir thickness
- J = PI
- J_s = specific PI
- k = permeability of reservoir
- k_b = permeability calculated from buildup pressure
- k_j = permeability calculated from productivity index
- k_o = effective permeability of oil
- L = distance to a linear discontinuity and unstrained length
- ΔL = change in length
- m = slope of buildup curve, p_t vs. $\log t$ or slope of $\log(p_{ws} - p_{wf})$ vs. t
- m_g = slope of pressure buildup curve, p_w^2 vs. $\log t$
- p = pressure at $t + \Delta t$
- Δp = slope of plot of p vs. $\log t + \Delta t / \Delta t$ or $\Delta p = p_{wf} - p_{ws}$
- $\tilde{\Delta p}$ = dimensionless factor from curves (see Fig. 30.9)
- p^* = last pressure on buildup curve
- p_i = initial reservoir pressure
- p_s = pressure loss due to skin effect
- $p_{sd} = \log e \, r_d / r_w$ for constant pressure at radius of drainage or $\log e \, (r_d / r_w) - 0.75$ when no influx across external boundary
- p_t = well pressure 1 hour after shut-in
- p_w = BHP at t
- p_{wf} = flowing BHP
- p_{wh} = wellhead pressure
- p_{ws} = static BHP
- p_{1hr} = pressure on straight-line portion of semilog plot one hour after beginning a transient test

q = production rate at shut-in
 q_g = rate of production
 q_o = rate of oil production
 r = unstrained resistance
 Δr = change in resistance
 r_d = drainage radius
 r_w = wellbore radius
 s = skin effect
 t = time
 t = time from closed in to end of straight-line portion of buildup curve
 Δt = time after well was shut in
 t_x = intersection time of the two straight line segments of the drawdown curve
 \bar{T} = average temperature in the borehole
 T_c = calibration temperature
 T_o = observed temperature
 T_R = reservoir temperature
 T_1 = lower temperature
 T_2 = higher temperature
 z = compressibility factor (gas deviation factor)
 γ_g = specific gravity of gas (air=1)
 μ = viscosity of produced fluid
 μ_g = viscosity of reservoir gas
 μ_o = viscosity of reservoir oil
 ϕ = porosity reservoir rock

$$m = \frac{kt}{\phi c_L r_d^2 \mu} \quad (14)$$

$$k = \frac{254.359 q_g \mu_g T_R z \log \left(\frac{r_d}{r_w} \right)}{h(p_{ws}^2 - p_{wf}^2)} \quad (15)$$

$$k = \frac{127.2 q_g \mu_g T_R z}{hm_g} \quad (16)$$

$$p_s = m \left[\frac{p_t - p_{wf}}{m} - \log \left(\frac{0.412 q_o B_o}{\phi m h c_o r_w^2} \right) \right] \quad (20)$$

$$p_s = m_g \left[\frac{p_t - p_{wf}}{m_g} - \log \left(\frac{142.817 q_g z T_R}{\phi h m_g c_g r_w^2 \bar{p}} \right) \right] \quad (21)$$

$$L = \sqrt{\frac{kt_x}{1.781 \phi c_L \mu_o}} \quad (23)$$

Key Equations in SI Metric Units

$$p_{ws} = p_{wh} \exp(1.139 \times 10^{-4} \gamma_g D) \quad (4)$$

$$\log p_{ws} = \log p_{wh} + \frac{\gamma_g D}{67.37 T} \quad (5)$$

$$\frac{p_{ws}}{1 + p_{ws} z} = \frac{p_{wh}}{1 + p_{wh} z} \exp \left(\frac{\gamma_g D}{29.26 T} \right) \quad (6)$$

$$p_{ws} = p^* + \frac{(p_{sd} - \Delta \bar{p}) q \mu B}{2 \pi h k} \quad (7)$$

$$k = \frac{q \mu B \log \left(\frac{r_d}{r_w} \right)}{2 \pi h (p_{ws} - p_{wf})} = \frac{J_s \mu B \log \left(\frac{r_d}{r_w} \right)}{2 \pi} \quad (11)$$

$$k = \frac{44,330 \text{ m}^2 \mu B \log \left(\frac{r_d}{r_w} \right)}{h \gamma} \quad (12)$$

$$k_o = \frac{q_o \mu_o B_o}{5.4575 h m} \quad (13)$$

Chapter 31

Temperature in Wells

G.J. Plisga, Sohio Alaska Petroleum Co.*

Introduction

Frequently, when working with a wildcat or deepening old production into zones that are relatively unknown, it becomes necessary to know the underground temperatures expected at a predetermined depth. In the 1920's, API Research Project 25 investigated the relationship between geothermal gradients and the geologic structures of oil fields.¹ Initially, interest in subsurface temperatures in oil fields focused on high temperature in deep wells, which caused cement to take initial set before it was placed behind the casing. More recently, cements with low hydration heat have been developed to protect permafrost intervals in northern frontier areas. Temperature surveys in wells were used to determine the top of the column of cement behind the casing.² With continual development of temperature devices, the reliability, accuracy, and speed of response have opened new horizons to temperature logging. Temperature logs are used currently to identify fluid entry into the wellbore, fluid migration behind the casing, tubing/casing leaks, and the extent of hydraulic fracturing and to monitor injectivity profiles.

Thermometers

Self-Contained Recording Thermometers

Self-contained recording thermometers, as used in the oil fields, use the same mechanism to record as the bottomhole pressure (BHP) gauge, with a thermometer element substituted for a pressure element. Temperature elements are made for some of the commercially available BHP gauges.

Humble Gauge Temperature Element. The temperature element for the Humble gauge is a container filled with mercury. With an increase in temperature, the mercury expands into a small-diameter cylinder at the end of

a piston, which extends through a packing gland against a tense helical spring. A stylus arm attached to the end of the piston extends into the cylindrical chart holder of the recording mechanism. The temperature range may be changed by varying the diameter of the cylinder and piston. To prevent the well pressure from affecting the temperature element, the mercury container is enclosed within an outer tube, which is filled with mercury to reduce thermal lag. With reasonable care in calibration and operation, temperature readings are accurate to 2°F and differential temperatures of 0.5°F can be read.

Amerada Gauge Temperature Element. The temperature element for an Amerada gauge is a pressure element with a bulb attached to the pressure end of the helical Bourdon tube, but thermally insulated from the gauge to reduce thermal lag. The bulb contains a liquid that has a substantial vapor pressure in the temperature range of interest. For various temperature ranges, different liquids and different ranges of helical Bourdon tubes are selected, preferably in such a combination that the maximum temperature range is near the critical temperature of the liquid, which gives maximum deflection per degree change in temperature. Ranges of approximately 120 and 200°F are used most frequently, with the minimum or maximum temperature as requested on the order. For maximum chart readability, the span between the minimum and maximum should be no greater than 200°F. Thermometers with a range of 120 to 200°F, as ordinarily calibrated, have a sensitivity of about 0.5°F and temperature changes of 0.1°F can be detected. The absolute accuracy of the Amerada temperature gauges is $\pm 2^\circ\text{F}$. The time required for thermal equilibrium is 20 minutes, but some 70% of the change in temperature will be recorded in 30 to 45 seconds when the instrument is immersed in liquid. A faster-responding gauge design, which increases the

*Author of the original chapter on this topic in the 1962 edition was C.V. Millikan.

temperature sensing area and reduces the heated mass, reaches thermal equilibrium in 8 to 10 minutes. The response of a liquid-vapor element is not a straight line, and therefore the accuracy and sensitivity of the element depend on the temperature to be measured.

Time Response. The time response of a thermometer to a change in temperature is directly related to the rate of movement through fluid, or flow of fluid past the thermometer. When a long section of hole is to be surveyed for a possible anomaly, the thermometer can be run at 50 to 100 ft/min followed by a second run at 2 to 5 ft/min through intervals of interest indicated on the first run.

Thermometers in Gas. The thermal conductivity of a gas is much lower than that of liquid. Therefore, a thermometer in gas has greater thermal lag for a given change in temperature. However, in most wells in which a thermometer is run through gas, any anomaly present is caused by expansion of gas, and the change in temperature is much greater than normally found when the anomaly is caused by migration of liquids. Because of the greater change in temperature, the presence of an anomaly is recorded as quickly in gas as in liquid. If a wellbore contains gas through the interval of interest and no gas expansion is present, such as a survey to determine migration of fluid behind the pipe, it is preferable to fill the well with liquid. If this is not feasible, then the thermometer must be run much slower (one-fifth to one-tenth) than the normal rate in liquid.

Electrical Surface-Recording Thermometers

Electrical surface-recording thermometers have a thermocouple, resistance wire, or thermistor as a temperature element. As normally calibrated for oil well use, electrical surface-recording thermometers have a sensitivity of 0.5°F and a thermal lag of only a few seconds. They are run on armored, insulated cables and the measuring wheel is geared to drive a chart recorder, camera, or computer to record temperature against depth.

Differential thermometers have been developed that record very small changes in temperature, 0.1°F or less, and are useful for identifying an anomaly in a long section when surveying at logging speeds of 100 to 150 ft/min. Once an anomaly is recorded, the thermometer can be run at slower speeds to completely define the anomaly. The differential thermometer is usually run in conjunction with an electrical thermometer to allow the absolute temperature to be measured in conjunction with the differential temperature.

By using electrical surface-recording thermometers, any temperature change noted can be checked by a rerun without returning the instrument to the surface. Very small anomalies under static conditions may be disturbed by the movement of the instrument, and therefore when a check of such condition is run, it should be delayed long enough to reestablish temperature equilibrium in the hole.

Advantages and Disadvantages

Self-contained thermometers and electrical surface-recording thermometers each have advantages and disad-

vantages. Self-contained thermometers have the advantages of portability and low investment. Disadvantages are much greater thermal lag and the necessity of returning the instrument to surface and reading the charts before the results are known. Electrical surface-recording thermometers have the advantage of quick response to temperature change, which permits running faster, plotting temperature against depth as the survey progresses, and checking any temperature anomaly without having to recover the instrument from the well. Disadvantages include a much greater investment, larger and heavier equipment, and delicate instrumentation.

Thermometry

Introduction

Two types of temperature surveys are used in the oil fields. One determines the true temperature at the depth of interest, and the second determines the depth or interval of a change in temperature. Usually, true temperature is measured with a maximum-recording thermometer. However, the use of electrical surface-recording thermometers is becoming more widespread for measuring true temperatures. Determination of a change in temperature requires a continuous record some distance above and below (as well as through) the interval of interest. In this case, the use of a differential thermometer will show the existence of a change in temperature rather than the true temperature or the actual magnitude of the change.

Actual Temperature

The geothermal gradient is very different in the various sedimentary basins, but within a given basin the change is gradual from one part to another.^{3,4} In most oil-producing areas, the gradient is usually within the range of 1 to 2°F increase for each 100 ft of depth. Temperatures just below the seasonal effect, ordinarily 30 ft below the surface, are about 1.5°F higher than the isotherms of the average annual temperature, as shown by climatological data of the U.S. Weather Bureau (Fig. 31.1). An exception to this is in northern latitudes where continuous permafrost exists. A geothermal gradient determined from such surface temperatures and the temperature of the producing formation is sufficiently accurate for most practical uses (Fig. 31.2). The rate of temperature increase in some areas is greater with depth, especially below 10,000 ft, and marked increases have been reported below 18,000 ft. When a precise geothermal gradient is to be determined, the hole selected must not have been disturbed for several months. In any event, the survey must be conducted while the well is in operation, since the passage of the thermometer will alter the static gradient.

The thermal conductivity of geological strata varies. The average heat conductivity of common sediments is given approximately by the figures in Table 31.1.⁴

When fluid movement continues in a borehole for periods of time, such as in drilling operations or a producing well, the temperature effect will be different on each formation. Any effect on a given formation will depend on its thermal conductivity, the difference in temperature between the moving fluid and the formation, and the length of time such movement continues. When fluid movement is stopped, temperature equalization

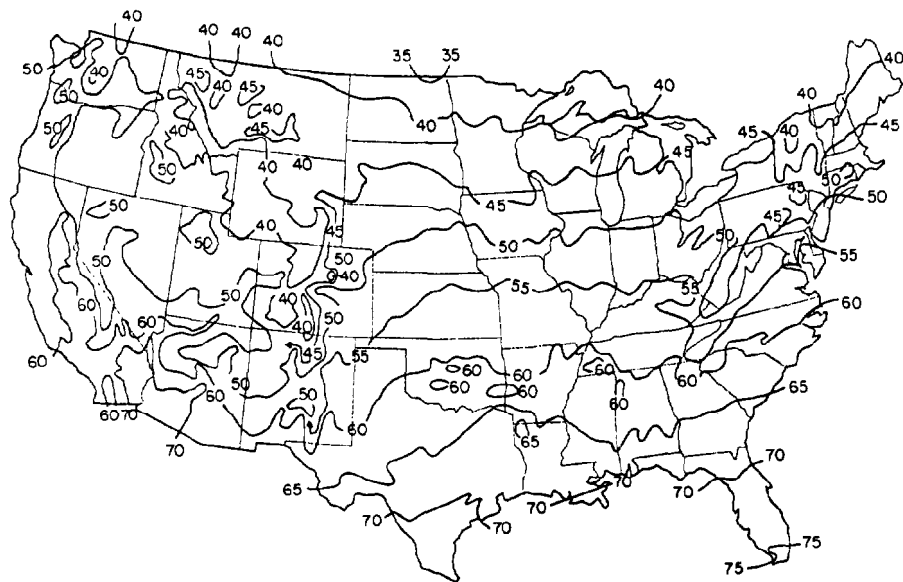

Fig. 31.1—Average annual temperature, °F, for the period 1899 to 1938. Isolines are drawn through points of approximate equal values.

begins, but considerable time, usually several months, is required to approach temperature equilibrium. In temperature surveys of wells, such temperature irregularities can be confused with an anomaly caused by some operating condition. Normally, however, the irregularities in the gradient resulting from normal operating conditions are small and the abnormal condition being investigated, such as a hole in the casing, fluid migration behind the pipe, or cement top, is of such size

or character that there is no uncertainty as to cause.

The actual temperature at depth is very important in many problems in drilling, production, and reservoir work. Drilling mud is often adversely affected by high temperature. The type of cement and additives are determined by the temperature at the casing seat or zone of interest. In oil reservoirs, the amount of gas in solution, the bubblepoint, and the viscosity are all related to the temperature, as is the amount of condensate formed and

Shale	12

the amount that remains as a liquid wetting the reservoir rock. The volume of gas per unit of reservoir rock and the supercompressibility of the gas are also related to the actual temperature.

Temperature Surveys

A temperature survey of a well is made either by running the thermometer continuously at a slow speed or by stopping it for a short time at regular intervals. For a survey through a long interval of hole, a continuous run is often preferred, while for a short interval numerous stops of 1 to 2 minutes are made. Temperature readings should be taken through the interval of interest, while running the thermometer in and while pulling up. Both runs should be at the same speed or at the same stops to determine more accurately the depth of any anomaly. On runs made very slowly, 2 to 5 ft/min, the actual thermal lag may be too small to warrant surveying the opposite direction. When a survey is started at a given rate, that rate should not be changed during the survey. To do so will cause a change in gradient or anomaly on the chart that may mask an actual anomaly or change in gradient in the well. Since the temperature chart is not available until the survey is completed and the thermometer is removed from the well, thorough notes that record time and depth of the instrument are required to correlate temperature and depth.

The location of a temperature change on a temperature survey is, in most cases, much more significant than the actual temperature or the amount of change in temperature. Normally, the temperature gradient in a well is reasonably uniform, and any deviation is indicative of an abnormal condition at that depth. The deviation may be an irregularity or anomaly in an otherwise uniform gradient, or it may be merely a change in the gradient. The primary causes of temperature change in a wellbore are expansion of gas, hydration of cement, and migration of fluid. Expansion of liquids in producing wells and heat of solution and chemical reaction are often present, especially in drilling wells, but the net effect on the temperature in the borehole is normally too small to be recognized. Gas expansion will cause an anomaly on the gradient, and migration of fluid will cause a change in gradient.

Gas expanding as it enters the borehole from the reservoir formation is much cooler than the adjacent formations, and therefore the particular intervals from which the gas is flowing can be identified by a temperature survey (Fig. 31.3A). A typical temperature survey conducted in a well producing minimal or no gas can be identified by a temperature survey (Fig. 31.3B). Greater detail will be recorded if the thermometer is run across the open hole or perforated sections while the well is pro-

Fig. 31.3—(a) Example gradient gas flow. (b) Example gradient fluid flow.

ducing. When the tubing tail is below the producing interval, any gas produced that travels downward to the bottom of the tubing, then up the tubing past the thermometer, mixed with any other fluid that may be flowing into the wellbore, will mask anomalies that exist at the producing interval. With this type of completion, the tubing must be shut in and the annulus allowed to produce with the thermometer being run in the tubing. If a packer is set or, for other reasons, the well cannot be produced through the annulus, the survey can be run after the well is shut in. A temperature survey on a shut-in well relies on gas cooling by expansion to lower the temperature of that part of the formation producing gas below that of the formation not producing gas. Some time is required for the temperature to equalize, and a temperature survey run long enough after shut-in to complete afterflow will record lower temperatures in the principal intervals of gas production. A sequence of runs through the interval will permit a more reliable interpretation.

The lowest interval producing gas can be identified from a temperature survey by the cooling effect through the intervals producing the free gas and the return to the normal gradient below. Water-producing intervals can be determined only if enough free gas is produced with the oil to give a change in gradient at the lowest interval producing oil.

A hole in the casing through which fluid is moving can usually be found by running a temperature survey. In addition to the depth of the hole in the casing, the depth of the formation, which is the source of the migrating fluid, and the depth of the formation into which the fluid is moving must be determined when a hole is known or suspected to exist.

A permeability or injectivity profile of a water-injection well can be determined from a temperature survey. A typical temperature survey of a water-injection well with a homogeneous formation shows a cooling across the injection interval (Fig. 31.4). Two procedures are used to obtain injection-well temperature surveys. After injecting water for a period of time, injection is discontinued and, after a few hours, the survey is run. A more reliable answer would be expected from a series of

Fig. 31.4—Water-injection gradient.

Fig. 31.5—Fluid channel gradient.

surveys at intervals of a few hours. Continued injection for many months can cool the entire formation and make it difficult to identify the relative injection capacity of the different parts. Under some conditions, another method that may give more detail is to discontinue injection for a day or more, then run a survey while injecting water at a very low rate, such as 1 to 5 bbl/hr. Because of the residual variations of temperature from normal water-injection operations, a survey before injection is recommended for comparison.

If water were channeling from below, the temperature survey would show a warmer anomaly at the base of the producing interval (Fig. 31.5). Fig. 31.6 shows ideal-temperature curves for various conditions of migration of fluid through a hole in the casing. Certain assumptions were made in drawing these ideal curves. Where gas is migrating, some expansion and, therefore, cooling is presumed as the gas leaves the formation. Also, it is assumed there will be a drop in pressure and, therefore, expansion and cooling at the depth of the hole in the casing. If there is no expansion at either point, the curves for gas would have the same appearance as the curves for

liquid. In cases where both formations are either above or below the casing hole, the movement of fluid from the hole to the farthest formation will mask any gradient between the hole and the nearest formation.

There are times when the volume of migrating fluids is not sufficient to affect the temperature. Gas leaking through a small hole in the casing will cause a very sharp temperature drop, but the volume may be too small to affect the gradient. Migration of fluids behind the casing will create a lower rate of temperature change than the normal gradient. If the flow is upward the gradient temperature will be higher than the normal gradient, and for downward flow the gradient temperature will be lower.

Preparation of the well is essential for a successful and reliable interpretation of the survey results. Usually the maximum anomaly is of the order of 2°F, and under less than optimal conditions the anomaly may be so small or so masked that a reliable interpretation is impossible. In these instances, the use of an electrical surface-recording differential thermometer may be the only method of obtaining a successful survey.

Fig. 31.6—Ideal-temperature curves of fluid migrating through casing hole.

Casing-leak and channeling-of-fluid temperature surveys are run with the well shut in. The shut-in time must be long enough for the entire wellbore to approach an even temperature gradient. A minimum of 24 hours should be allowed. However, the shut-in time required should be determined from past experience, type of problem to be identified, and location. Gas production and water production intervals are located with the well flowing at the maximum practical rate. If the survey cannot be run while flowing the well, the time interval between shutting in the well and running the survey may be critical. All afterflow must have ceased, but not so long as to allow the temperature to approach the normal gradient, which would mask any anomaly.

A temperature anomaly can be created by injection of fluid, usually oil or water, when normal conditions will not give a temperature change. Examples of this are identifying a channel below the producing interval and locating a packer or tubing leak by pumping cool fluids.

Drilling Wells

In drilling deep wells or wells that encounter high temperatures, especially in excess of 250°F, a representative bottomhole temperature (BHT) is required for selection of a proper mud program, cement, and additives to ensure proper cementing of the casing. In development drilling, temperature data from neighboring wells can be used in estimating the BHT of a new well. In exploration drilling, an estimation of the BHT may be all that is available. Unless offset data are available a

geothermal gradient must be assumed that will permit estimation of the BHT.

A technique exists for determining static BHT's by plotting on semilog paper T_{ws} vs. $(t_k + \Delta t)/\Delta t$ where

T_{ws} = bottomhole shut-in temperature measured at Δt , °F,

t_k = circulation time, hours, and

Δt = time after circulation ceases or shut-in time, hours.

The data required for this graph usually are obtained on successive openhole logging runs and allow an approximation of static BHT.⁵ Although this Horner-type analysis is not mathematically correct, when assuming short circulating times the technique provides reliable estimates of static temperature. This technique is most applicable in regions of high geothermal gradient, where log-recorded temperatures can be significantly lower than the static temperature.

The hydration of cement is an exothermic reaction, and sufficient heat is generated that the presence of cement behind a string of casing can be determined by a temperature survey for up to several days after cementing. The character of the anomaly at the top of cement in a particular field is fairly uniform but varies greatly in different fluids. The anomaly may be a large, sharp increase (Fig. 31.7A) in some cases 35 to 45°F, or it may be a very slight increase in gradient (Fig. 31.7B).

Fig. 31.7A—Effect of cement behind casing on temperature gradient.

Fig. 31.7B—Effect of cement behind casing on temperature gradient.

The principal influence on the survey is the time elapsed between placement of the cement and running the survey. Other influential conditions include fineness of cement, chemical composition, rate of hydration, mass of cement in place, and the thermal conductivity of the adjacent formation. The maximum temperature usually occurs 4 to 9 hours after cementing, but reliable data can be determined in most areas after 48 hours. Any temperature change is affected more by the rate of hydration than by the total amount of heat liberated. Although hydration continues indefinitely, the rate decreases rapidly from the peak. A washed-out section of hole may be responsible for a large, sharp increase in temperature and can indicate a false cement top. A small temperature change or slight change in gradient could be caused by a small annular area or dilution of the cement with drilling mud. These factors, which influence the size of the temperature anomaly at the top of the cement in a given well, vary widely in their effect. However, even under an unfavorable combination enough heat is generated to permit a determination of the cement top.

A new cased-hole logging method exists for detecting vertical flow outside the casing resulting from faulty cement. The radial differential temperature (RDT) log measures variations in temperature in the plane of the casing radius on the inside of the casing.⁶ Normally, two sensors are used, placed 180° apart; one sensor may be used at the wall of the casing and the other sensor in the body of the tool. An anchor spring at the top of the logging tools prevents the entire tool from turning as the sensors rotate. A motor rotates the tool at a speed of one revolution every 4 minutes. The RDT logging tools are designed to allow attachment of a perforating gun, which can be adjusted to perforate into the suspected channel or abnormality located by logging.

If a channel is suspected in a perforated well, the well should be produced long enough to ensure that channel fluid is being produced before running the RDT log. The RDT sonde is placed at depths in the well where the channel is suspected. The arms are extended and the instrument revolves once or twice. Before moving to another depth the arms are retracted. As many measurements as required to delineate the channel can be made on one run. In some cases better results are obtained by injecting fluids at the surface to cool the channel.

Temperature surveys can be used to locate depth of lost circulation in an area where formations above the depth of drilling are known to have taken fluid. The

temperature survey will show a sharp increase in temperature immediately below the point of loss of fluid. The temperature break will be even greater if slow losses are occurring while running the survey. At times when the hole is considered dangerous, the survey can be run through open-ended drillpipe over the suspected interval.

Summary

Wellbore temperature surveys are an inexpensive method to determine problem well conditions. The data obtained from a temperature survey are often the only data available and usually are accurate and reliable. When an anomaly occurs, one of these conditions must exist: (1) expansion of gas, (2) migration of fluid, or (3) some type of chemical reaction. With the exception of measuring the actual temperature at a point in a wellbore, temperature surveying is highly qualitative. In the majority of surveys, consistency of procedures, past experience, and the engineer's ingenuity allow reliable information to be collected and unique analyses to be performed. Since no quantitative relationship between temperature and depth exists that covers all areas and sedimentary basins, an assumed gradient of 1 to 2°F/100 ft depth is appropriate.

Chapter 32

Potential Tests of Oil Wells

J.D. Kimmel, Oilcovery Inc.*

Richard N. Dalati, Cockrell Oil Corp.

A potential test is a simple production test under stabilized flowing conditions to determine the ability of a well to produce. Potential or production tests are used to determine the rate of production through a given size of choke. This production rate and GOR then are used to determine if the well is capable of producing the assigned daily allowable production rates.

Production-rate tests are conducted on a well so that its producing capabilities can be determined and a record of its producing abilities maintained. The results of these tests are used in diagnosing and evaluating a producing well. Their importance cannot be overemphasized since they are used in every phase of reservoir and equipment analysis in which a knowledge of the productivity of the reservoir is essential. The test results aid in determining the parameters shown in Table 32.1.

Production tests usually are considered part of routine field operations. Because they are performed on every type of producing well, a standard method of procedure that would cover every well cannot be set forth in detail. In many cases, the method or procedure for obtaining the results desired is left to the engineer's initiative and judgment and, in many cases, ingenuity.

In every production test an initial understanding of the equipment employed and the method of completion, and a general knowledge of the producing reservoir and the results of previous tests on the well or on comparable wells will greatly simplify the testing procedure and aid in obtaining the desired results.

Potential or production rate tests generally are required periodically by most state regulatory bodies in the U.S., such as the Texas Railroad Commission and the Louisiana Dept. of Conservation. The state regulatory bodies, authorized by the various states to control the production of oil and gas, set up a daily allowable or maximum rate at which each individual well may be produced. The well and reservoir conditions are considered

in setting up this maximum producing rate. Usually one other condition is involved in setting the producing allowable: *the produced or refined oil and gas storage or market capacity*. These regulatory bodies meet periodically and set a maximum number of producing days for a given period. The allowable is specified in two ways: the maximum amount of oil that can be produced each day and the maximum number of days each set period (usually 1 month) that this maximum daily allowable may be produced.

It is a responsibility of the engineer or person in charge to set up and supervise the proper testing of all producing wells. When the production is controlled by state regulatory bodies, it is also the responsibility of the engineer or person in charge to find out the requirements set up by these regulatory bodies as to the proper method for testing and reporting the tests on producing wells.

The importance of testing and information required to be supplied to the state regulatory agencies cannot be overlooked. Form W-2 of the Texas Railroad Commission's Oil and Gas Div. is an example of the information required (see Fig. 32.1).

As a general rule in Texas and Louisiana, the daily allowable is determined by the producing horizon of the well, but there are exceptions to this rule. The reservoir characteristics, previous reservoir performances, and completion procedures are considered before a definite allowable is set for the well. The general case in Texas is covered by a depth allowable set up in 1947. These allowables are set up for wells completed in proven areas and known reservoirs.

Texas Allowable Rule

The Texas Allowable Rules of 1947 and 1965 were based on producing depth and well spacing. These are normally referred to as "yardsticks." In 1966, another yardstick was established for offshore only (Table 32.2).

*This author also wrote the original chapter on this topic in the 1962 edition.

TABLE 32.1—DETERMINATIONS FROM TEST RESULTS

1. Optimal or maximum efficient production rates.
2. Correlation and identification of producing horizons.
3. Results of recovery methods.
4. Estimates of oil and gas reserves; for example, gauged rate production decline vs. time.
5. Decline trends and performance productions in the ability of the reservoir to produce.
6. Qualitative determinations of gas and/or liquid contacts.
7. Determinations relative to artificially imposed harmful wellbore or reservoir conditions such as gas or water coning, sanding or bridging action, and paraffin depositions.
8. Analyses and comparisons of well-completion practices and equipment.
9. Performance of and comparison between subsurface well equipment and installation principles.
10. Analyses and comparisons of artificial lifting practices and equipment.
11. Determining the necessity of and evaluating the results of remedial measures.

The allowable given a well completed in a new field or new reservoir is called the "Discovery Allowable." It is usually set up on a producing-depth basis. This allowable is for a certain period of time or until a certain number of wells are completed into the reservoir. For example, in Texas the onshore discovery allowable is for a 24-month period or until the 11th well is completed into the reservoir. The offshore discovery allowable is for an 18-month period or until the sixth well is completed into the reservoir. The discovery allowable in Texas is set up as in Table 32.3.

The allowables set up by the state regulatory bodies are not necessarily the proper rate to produce the wells. The producer should work very closely with the reservoir engineers and geologists to see that the test data, along with all other information available, are used to determine the most efficient producing rate of the well or reservoir.

When several companies produce from the same reservoir, it is common procedure to combine their knowledge and arrive at a maximum efficient producing rate (MER).

It is permissible for a company to request a change of allowables to conform more closely to the MER as determined by the company's engineers. Before any change in the allowables is made by the regulatory bodies, a meeting or hearing of all the companies involved in producing from the reservoir is proposed. At this time all the information available is evaluated to determine if a new and different allowable is warranted. This new allowable (to conform more to the MER) usually involves a reduction in the normal allowable set up by the regulatory body.

Productivity Index (PI)

It is desirable to be able to assign to a producing well a quantity that indicates the well's ability to produce. It was once a common occurrence "to open the well up" and measure the amount of production under wide-open flow. Today it is realized that wide-open flow of an oil or gas well can be very harmful to future well conditions.

Oil Well Potential Test, Completion or Recompletion Report, and Log

1. FIELD NAME (See also REC Records or Wellbore) 2. LEASE NAME 3. OPERATOR'S NAME (Establish as shown on Form P-3 Organization Report) 4. ADDRESS 5. If Operator has changed within last 90 days name former operator 6. Location (Section, Block and Survey) 7. REC District No. 8. REC Lease No. 9. REC Well No. 10. Location of well site 11. Purpose of filing 12. If wellbore or recompletion, give former field (with recompletion) or gas ID or oil lease no. 13. If wellbore or recompletion, give former field (with recompletion) or gas ID or oil lease no. 14. Completion or recompletion date 15. Type of electric or other log run

SECTION I: POTENTIAL TEST DATA IMPORTANT: Test should be for 24 hours unless otherwise specified in field rules.

16. Date of test 17. Production started (Pumping Gas, Lifting, Pumping) 18. Test rate 19. Production during test 20. Calculated 24 hour rate 21. Was well shut during test? 22. Oil produced prior to test (See P-3 Recombination well) 23. Injection Gas-Oil Ratio

INSTRUCTIONS: File as original and one copy of the completed Form W-2 to the appropriate REC District Office within 30 days after completing a well and within 10 days after a potential test. If an operator does not properly report the results of a potential test within the 10-day period, the effective date of the allowable assigned to the well will not extend back more than 10 days before the W-2 was received in the District Office (Statute Rules 16 and 31). To report a completion or recompletion, fill in both sides of this form. To report a retest, fill in only the front side.

WELL TESTER'S CERTIFICATION
I declare under penalties prescribed in Sec. 91.143 Texas Natural Resources Code that I conducted or supervised this test by observation of (a) meter readings on (b) the top and bottom gauges of each tank into which production was run during the test. I further certify that the pressure test data shown above is true, correct, and complete to the best of my knowledge.

Signature: Well Tester Date of Completion REC Representative

OPERATOR'S CERTIFICATION
I declare under penalties prescribed in Sec. 91.143 Texas Natural Resources Code that I am authorized to make this report. That this report was prepared by me or under my supervision and direction, and that data and facts stated herein are true, correct, and complete to the best of my knowledge.

Typed or printed name of operator's representative Title of Person Telephone Area Code Number Date Signature

SECTION II: DATA ON WELL COMPLETION AND LOG (Not Required on Retest)

24. Type of Completion 25. Permit to Drill 26. Number of Interventions to Drill this well since first or last 27. Number of producing wells on this lease in this field (including this well) 28. Total number of acres in this lease 29. Lease Plug Back (Lifting, Pumping, or Drilling) 30. Interventions to produce well (Name, Lease, or Permit) 31. Location of well relative to nearest lease boundaries of lease on which this well is located 32. Elevation (OF, BBL, BT, CA, FT) 33. Well directional survey made other than on completion (Factor W-12) 34. Top of Pay 35. Total Depth 36. P in Layer 37. Surface casing (Determined by) 38. Is well multiple completion? 39. If multiple completion, list all intervals (completion or layer) 40. Is well recompletion? 41. Name of drilling contractor 42. Is recompleting Affiliates also used? 43. Casing Record (Report All Stringers Set in Well) 44. Tubing Record 45. Producing Interval (this completion) Indicate depth of perforation or open hole 46. Formation Record (List Depths of Principal Geological Formations and Formation Types)

*1965 yardstick effective if field discovered after Jan. 1, 1965.

**1966 offshore yardstick effective Jan. 1, 1966.

Wide-open flow may cause water or gas coning, influx of sand into the wellbore, collapse of tubing or casing, and/or many other harmful results.

The ability of a well to produce usually is determined by use of the PI. The use of the PI was first mentioned by Moore in 1930.¹ In a 1936 paper M.L. Harder states that the relative ability of a well to produce shows the PI to be superior.²

API states in *Recommended Practice for Determining Productivity Indices*³ that the PI is calculated from the observed production rates and subsurface pressure measurements obtained. Special applications and modifications by the user to conform to individual requirements and conditions are normally used. The following discussion of PI is not meant to cover all applications but only to show how the PI may be used.

By definition, the PI is equal to the barrels per day of stock-tank oil production per pound force of pressure differential between the wellbore opposite the producing horizon and the static reservoir pressure, which is the average pressure of the well drainage area. Therefore, the PI is, in barrels of oil produced per day per psi decrease in reservoir pressure, the difference between the average pressure in the drainage area of the well and the flowing bottomhole pressure (BHP) of the well. According to the accepted concepts of flow, the rate of flow in a system containing a single fluid under steady-state conditions should be directly proportional to the pressure drop. Using this concept, the PI would be the slope of the line resulting from plotting the rate of flow against pressure drop. On such a plot the wide-open flow quantity or well potential would be measured at the maximum pressure drop available. Such a case is referred to as the “ideal PI.” Observed values of production rates vs. pressure differentials do not give straight lines. PI data on nonflowing wells are usually more linear than the data

on flowing wells. Experience has shown that the line will be curved. This is because PI is defined to occur under steady or pseudosteady-state flow conditions. The curvature results because μB is not constant if the flow is single phase and/or gas evolution or water coning exists around the wellbore — i.e., relative permeability effects. PI is higher than theoretical when calculated erroneously before pseudosteady-state flow exists. PI is meaningless unless the radius of wellbore damage is fixed — i.e., pseudosteady-state flow is established. The flow of compressible fluids (oil and water) into a wellbore after the drainage area has been established is, strictly speaking, described by a pseudosteady-state flow equation.

TABLE 32.3—DISCOVERY ALLOWABLES

Interval of Depth (ft)	Daily Well Allowable (bbl)
0 to 1,000	20
1,000 to 2,000	40
2,000 to 3,000	60
3,000 to 4,000	80
4,000 to 5,000	100
5,000 to 6,000	120
6,000 to 7,000	140
7,000 to 8,000	160
8,000 to 9,000	180
9,000 to 10,000	200
10,000 to 10,500	210
10,500 to 11,000	225
11,000 to 11,500	255
11,500 to 12,000	290
12,000 to 12,500	330
12,500 to 13,000	375
13,000 to 13,500	425
13,500 to 14,000	480
14,000 to 14,500	540

However, some people in the oil industry describe the flow by a Darcy-type equation, which is referred to as steady-state flow. The difference in the flow rates determined from the two equations is very small. We discuss PI by use of both the steady-state and pseudosteady-state flow equations.

Steady-State Flow

For a radial system under steady-state flow, the equation giving the flow rate is

$$q_o = \frac{7.08 \times 10^{-3} kh(p_e - p_{wf})}{\mu_o B_o [\ln(r_e/r_w) + s]}, \dots\dots\dots (1)$$

where

- q_o = oil production rate, STB/D,
- k = permeability of formation, md,
- h = thickness of formation, ft,
- p_e = pressure at the effective drainage radius r_e
normally approximated by \bar{p}_R ,
- \bar{p}_R = average reservoir pressure in drainage area, psi,
- p_{wf} = flowing BHP, psi,
- μ_o = oil viscosity, cp,
- B_o = oil formation volume factor, RB/STB,
- r_e = effective drainage radius, ft,
- r_w = wellbore radius, ft, and
- s = skin effect (zone of reduced or improved permeability), dimensionless

The term equivalent to the PI is

$$J = \frac{q_o}{\Delta p} = \frac{7.08 \times 10^{-3} kh}{\mu_o B_o [\ln(r_e/r_w) + s]}, \dots\dots\dots (2)$$

Fig. 32.2—PI—permeability correlation.

where J is the PI, STB/D-psi, and Δp is the pressure difference between p_e and p_{wf} , psi.

In analyzing the PI, it can be seen that it is a function of the formation characteristics, k and h , the fluid characteristics, μ_o and B_o , and the system characteristics, h , r_e , r_w , and s .

Specific PI

The term "specific PI" is frequently used and usually means the PI per foot of pay. When the term "specific" is used, it is necessary to state why. The productivity could just as well have been made specific to any other variable in Eq. 2.

Well systems do not operate at any time under steady-state conditions, but they do under pseudosteady-state conditions. Oil, water, and gas are compressible fluids; therefore, only pseudosteady-state occurs. Thus, we cannot expect Eq. 2 to yield exact correlation. The primary correlation sought has been with permeability so that the PI could be predicted from core analysis. An example of an early correlation is given by Fig. 32.2.⁴

Oil flowing into a wellbore will practically always seem to enter the wellbore from a formation of lower permeability than the homogeneous fluid value determined in the laboratory. In many cases the relative permeability to oil at interstitial water saturation is one. What actually happens is that the permeability measured in the laboratory is too high because the confining pressure is lower than in the reservoir.

Muskat⁵ states that the PI should not be used to predict production of high differential pressures by simply multiplying the PI by the pressure drop of interest. He states that it is doubtful that calculated potential tests would agree with actual tests. The relative comparison should reflect the comparative production capacity with fair approximation. The PI times reservoir pressure equals the open flow potential.

Muskat also states that the productivity index is an excellent tool to determine well problems such as:

1. Comparison before and after well treatments to evaluate these treatments. J should increase.
2. Stable GOR, R , with a declining J indicates plugging of wellbore.
3. R increasing markedly without decline in J indicates entry of extraneous gas. This would be the same if R changes with various production rates and J stays constant.
4. Rapid increase in water production should bring a decline in J if water is entering through typical strata within oil pay. If J is maintained, this should indicate the water is not coming through the oil-producing strata.
5. Decline of J should take place during normal reservoir depletion and parallel the normal growth of GOR or water/oil ratio (WOR). If not, plugging of the wellbore should be considered.

These are guidelines for further investigation.

Theoretical PI

Muskat and Evinger⁶ first showed that a theoretical PI could be worked out using the steady-state formula as developed for a radial system flowing oil and gas. By

such a system it can be shown that the J for a given well system can be expressed in terms of three parameters: (1) the producing GOR, (2) the pressure gradient in the well system, and (3) the absolute reservoir pressure.

It can be shown that for the steady-state flow of oil and gas in a radial system, the following equation expresses the rate of oil flow.

$$q_o = \frac{7.08 \times 10^{-3} kh}{\ln r_e/r_w + s} \int_{p_{wf}}^{\bar{p}_R} \frac{k_o/k}{\mu_o B_o} dp, \dots\dots\dots (3)$$

where k_o is effective permeability to oil.

The integral

$$\int_{p_{wf}}^{\bar{p}_R} \frac{k_o/k}{\mu_o B_o} dp$$

can be evaluated using Fig. 32.3.

The PI is, therefore,

$$J = \frac{q_o}{p_e - p_{wf}} = \frac{7.08 \times 10^{-3} kh A_c}{(p_e - p_{wf})[\ln(r_e/r_w) + s]}, \dots\dots\dots (4)$$

where A_c is the area under the curve.

By using Fig. 32.3 and the definition of the PI, it can be seen that J will not double if $(p_e - p_{wf})$ is doubled because the area under the curve will not double. Also p_e is determined by reservoir conditions and cannot be varied. Note that for a definite value of $(p_e - p_{wf})$ taken at a high absolute pressure, J will be greater than for the same $(p_e - p_{wf})$ taken at a lower pressure because the area under the curve will be greater.

It is not readily apparent, but can be shown, that J depends on the producing GOR, R . A simple explanation is that an increase in R means that the oil saturation is less, thus k_o is smaller. In Fig. 32.3, the curves labeled R_1 , R_2 , and R_3 are for different GOR's with $R_1 > R_2 > R_3$.

Pseudosteady-State Flow

The steady-state equation is used frequently; however, this would only apply if the pressure at the outer radius stayed constant, which would only happen if a complete pressure maintenance program were maintained. If the well has a closed boundary or is operating with an established drainage radius, then pseudosteady-state flow occurs. The pseudosteady-state equation is

$$q_o = \frac{7.08 \times 10^{-3} kh (\bar{p}_R - p_{wf})}{\mu_o B_o [\ln(r_e/r_w) - 0.75 + s]} \dots\dots\dots (5)$$

for a circular drainage area and

$$q_o = \frac{7.08 \times 10^{-3} kh (\bar{p}_R - p_{wf})}{\mu_o B_o (\ln x - 0.75 + s)} \dots\dots\dots (6)$$

Fig. 32.3—Plot for determining PI for different GOR's.

for a non-circular drainage area.⁷

From Eq. 6 the actual PI is

$$J = \frac{7.08 \times 10^{-3} kh}{\mu_o B_o (\ln x - 0.75 + s)},$$

where x is a factor for noncircular drainage area and well location.

Most reservoir engineering flow equations assume radial geometry. This assumes the drainage area of the well is circular and the well is located in the center. Experience has shown that in many cases the drainage area of the well is rectangular, triangular, or other shapes. As stated previously, the PI, J , is a function of the system characteristics, which can be applied to the productivity index. Shape functions can be determined by reservoir limit tests.⁸

Van Everdingen originally defined the skin effects as the additional resistance concentrated around the wellbore that result from the drilling and completion techniques employed.⁹ This skin effect detracts considerably from a well's capacity to produce. More recently the skin effect is also used to indicate improved permeability around the wellbore that results from acidizing and/or fracturing. The skin effect can be defined as

$$s = \ln \frac{r_s}{r_w} \left(\frac{k - k_s}{k_s} \right), \dots\dots\dots (7)$$

where

- r_s = radius of area around the wellbore affected by skin effect, ft,
- k = formation permeability, md, and
- k_s = permeability of area around the wellbore affected by skin effect, md.

The skin effect, s , normally is determined from pressure transient analysis. The reader is referred to Chap. 35, Well Performance Equations, for a detailed treatment of skin effect.

The aim of the production engineer is to make the PI, J , as high as possible; the equation for J indicates this may be done by several ways that include¹⁰:

1. Remove the skin effect through acid treatment or the use of various completion or drilling fluids, depending on the formation.
2. Increase the effective permeability by fracturing or propping.
3. Reduce the viscosity by formation heating.
4. Reduce formation volume factor, B_o , by production techniques and surface separation system.
5. Increase the well penetration, h , by completing across the entire producing formation. Care should be taken not to complete across a zone of excessive gas or water production.
6. Reduce the ratio r_e/r_w . Since it appears as a logarithmic term, this has little influence. Underreaming is seldom considered as a means of well stimulation.

The above equations should indicate that the most important step in determining and analyzing the performance of any well, especially flowing wells, is to determine the well production rate for any given flowing BHP.

It is now readily apparent that to compare a PI of a well it is necessary to know what is being compared, which includes the permeability, sand thickness, well radius, drainage radius, fluid characteristics, and flow relations. A comparison should also be made on reservoir pressure and pressure drawdown for a similar GOR.

The standard procedure for conducting PI tests mainly consists of following the directions that have been set forth in the procedures for conducting static and flowing reservoir pressures and gauged-rate production tests. The most popular wireline pressure gauge is the Amerada recording pressure gauge.

In some cases, the use of artificial-lift equipment prevents the passage of subsurface gauges; therefore, other means must be found for determining these pressures. It is possible with the use of sounding devices—i.e., Ecometer or Sonolog—to determine the liquid level. Knowing the liquid level, the static or flowing pressures can be approximated by gradient and depth calculations.

Care should be exercised in determining the static and flowing pressures to be sure they are the equilibrium pressures. If there is any doubt regarding the equilibrium conditions, two or more pressure readings should be made several hours apart to be sure they are the same. Some formations stabilize in one hour but most take four to 24 hours. Tight formation could take several days. In determining the actual J , the flowing rates should have wide enough variation to compensate for any errors in measurement.

When artificial-lift equipment is used, the gauged production tests for determining the J must be lower than the production limitations of the lift equipment.

Methods of determining production rates are: (1) stock-tank measurement; (2) portable well testers, including batch-type meters, positive-displacement meters, turbine meters, and flow meters; and (3) stationary test equipment.

Stock-Tank Measurement

The oldest and most widely accepted means of determin-

ing the amount of liquid produced by an oil or gas well is the manual gauging of the production in stock tanks. A single well producing into a tank battery presents no testing problems, as it is a simple process to measure the liquid in the stock tanks at the start of the test and the liquid in the stock tanks at the end of the test. Most tank batteries are arranged so that one well may be tested at the battery while the other wells are being produced. This requires, of course, the addition of a test separator in addition to the production separator and also sufficient stock-tank volume so that no commingling of the production is required. A separate gas run and meter would also be required for measurement of the gas produced while the well is on test. If this meter run is not available, a portable orifice well tester could be used.

If testing facilities are not available at the lease, it is necessary to shut in the entire lease while individual wells are being tested into the tank battery. In the latter case, it is usually better to use portable test equipment to determine the production rate.

Before the production test is started, with stock tanks as a means of measurement, it is necessary to determine the amount of basic sediment and water (BS&W) at the bottom of the tank, in addition to the liquid level at the start of the test. If at all possible, stock tanks should be clean, since errors may be introduced in determining BS&W. Dirty stock tanks can cause the tank tables to be in error. If possible, produced water should be produced and gauged in separate stock tanks.

After gauging the test tank or gun barrel, the usual procedure would be to proceed to the separator, check and record the operating pressure, and on large-volume separators, if the well being tested has a low productivity, record the liquid level in the separator. The choke size at the wellhead should be carefully determined and if there is a question, the choke should be checked and calibrated.

If a treater or heater is used, its operating characteristics should be noted so that any conditions not uniform may be considered on the gauged production test. All tests should be made after the production has stabilized and under conditions that are as uniform as possible. No change should be made at the wellhead or tank battery during the duration of the test.

Standard tests should range from 24 to 168 hours in length, depending on the well and reservoir characteristics. All data should be observed and recorded at less frequent intervals. The time between intervals will vary depending on the length of test. In cases where short tests (6 to 8 hours' duration) are necessary, consecutive data recordings should be made hourly.

Tests should be for 24 to 168 hours' duration so that fluctuations in the GOR, as a result of heading tendencies and temperature variations, may be considered and the test results averaged. It is not uncommon to observe a 40 to 50°F temperature variation between night and day atmosphere and to observe a 10 to 20% variation in the gas/liquid ratio. Recognizing these facts, it becomes necessary to measure the temperature of either the liquid or vapor section of the separator.

The preferred location to obtain the temperature would be in the flow line immediately before the separator. This latter temperature would more nearly reflect the ac-

Fig. 32.4—Trailer-mounted three-phase well tester with PD meters.

tual liquid-phase temperature prior to the flash liberation process.

The production should be sampled each time the data are recorded during the production test. This interval sampling is very necessary if storage facilities are such that the water produced must be disposed of as it is produced. Refer to Chap. 17 for sampling information. Wells that produce with a high WOR should always be tested at length because of the usual uneven oil-producing rate.

Depending on the separation pressure and the characteristics of the crude for shrinkage, some consideration should be given to determining the amount of gas produced that is not measured by the gas meter but is vented from the stock tanks.

Points to check to ensure the accuracy of stock-tank gauges include:

1. Correct and accurate strapping table is used with the test tank.
2. No dents or damage has occurred to the stock tank since strapping table was made.
3. Tank is clean with no encrustations or deposits on the walls.
4. If foamy crude is being produced the liquid level will be almost impossible to determine correctly with a gauge tape. Chemical addition or settling time may be required to minimize the foam.
5. BS&W at bottom of tank is determined as accurately as possible before and after the test.
6. Gauge tape must not be kinked and plumb bob must be carefully touched at the bottom of tank.
7. Temperature of oil in the stock tank must be considered.
8. The oil level must be steady and undisturbed while a gauge reading is taken.

Portable Well Testers

The trend toward unitization and centralization of tank batteries has increased the demand for a means of determining production rates without requiring the installation of additional expensive stock tanks and test separators. The requirements are being solved by the use of well testers.

The well tester is a combination separating and measuring unit for oil, water, and gas. The well tester can be either two or three phase, can be used for permanent installation, or can be skid or trailer mounted for portable operation (see Figs. 32.4 through 32.8). The well tester may utilize several types of meters for both liquid and gas measurement. Note that the two-phase testers (Figs. 32.5 and 32.8) are not fitted with liquid level controllers (LLC's), but are blanked so LLC's can be added in the field for three-phase testing.

Each established class of metering equipment has survived and advanced in the petroleum industry today because it fits a definite need in the metering field. Each type has won its place in the petroleum industry by fulfilling the requirements of certain applications better than any other type. Selection of the type of meter used on a well tester may be determined by the user, based on the application of the well tester and the limitations and capabilities of the meters available (see Table 32.4 for various sizes and working pressures of standard well testers). Remember that it is better to have a unit that has the capacity to test (pressure and flow capacity) so that modifications to the test can be minimized.

Capacities are based on steady continuous flow for a 24-hour period. Fluid retention time is as follows.

- 0 to 600 psi = 1 minute.
- 600 to 1,000 psi = 50 seconds.
- More than 1,000 psi = 30 seconds.

The type of fluid to be tested must be considered in determining the retention time. If the crude foams, the necessary retention time for the gas to break out of solution may be 5 minutes or longer. For three-phase separation, additional retention time may be required for the oil and water separation depending on the type of emulsion produced. Many times the addition of heat and/or chemicals is required to produce proper separation of the oil and water or gas and oil. Well testers are available in low working pressures that utilize either electric or gas-fired heaters to heat the well fluid and improve the separation processes. The meter used must be of sufficient metering capacity not to limit the capacity of the well tester. Working pressures are available up to 4,000 psi.

The listing in Table 32.4 of sizes and capacities of standard well testers is not complete but may be used as a guide to determine the approximate size and capacity of the unit required for your specific testing purpose.

The types of meter available for use on well testers are (1) batch-type meters, (2) positive-displacement meters, and (3) flow meters, including standard and mass flow meters.

Batch-Type Meters

The batch-type meter works by means of cyclic accumulation, isolation, and discharge of predetermined volumes. Each dump volume is registered on a counter. The counter reading is then multiplied by the dump volume to determine the total measured volume.

When metering vessels such as batch meters are used to measure liquid hydrocarbons, four factors must be ob-

tained and maintained:

1. An unchanging volume in the metering vessel must be maintained consistently. This means that there can be no foreign material deposited in the vessel and that the vessel itself must not change shape or size.

2. Exact upper and lower dumping levels must be obtained and maintained in the metering vessel. These dumping levels must be the same for each cycle.

3. Proper valve arrangement must be maintained so that no liquid may slip through the vessel without being metered. The valve or valves should be arranged so that there is a period of time at the beginning and end of each cycle during which both the inlet and outlet to the metering vessel are closed at the same time. This assures that no unmetered fluid will slip through the metering vessel.

4. An appropriate and accurate "meter factor" must be used to compensate for temperature change of the liquid, shrinkage (volume reduction) of the liquid resulting from pressure reduction, mechanical metering error of the metering vessel, and BS&W content of the liquid.

These various factors are usually combined into one factor known as the "meter factor" or "meter multiplier." These meter factors are usually less than 1.0. In other words, the meter normally reads higher than the net stock-tank volume.

Advantages and Disadvantages of Batch-Type Meters

1. A metering vessel can be used as its own meter proving tank if the vessel is inspected for encrustation, the dumping levels are observed during operations, and valves are checked for leakage.

TABLE 32.5—NOMINAL RATED CAPACITY OF VOLUME-TYPE DUMP METERS

Barrels per discharge	0.25	0.5	1.0	2.0	5.0	10.0	20.0	30.0
Metering capacity, bbl/24-hr day	300	500	720	1,440	2,000	4,000	8,000	15,000

2. A metering vessel will handle more sand and other foreign material without causing trouble than the positive-displacement (PD) meter.

3. A metering vessel will meter from zero flow to maximum rated rate of flow with the same degree of accuracy.

4. Weight-type (hydrostatic-head) metering controls may be used to meter foaming oil.

5. The unit may be adjusted while in operation.

6. Free gas will not register as liquid if the controls should fail to function.

7. Initial and installation cost is slightly higher than with the PD meter.

8. The meter delivers an intermittent discharge of liquid.

9. Gas is required to displace the liquid from the vessel.

10. Paraffin buildup on the vessel wall will cause inaccuracies.

11. The meter requires more space and is heavier than a PD meter.

12. With heavy viscous crudes a larger inlet or differential pressure arrangement between the separator and metering vessel may be required to maintain the rated capacity.

Nominal rated metering capacity of various sizes of volume-type dump meters under normal field conditions is given in Table 32.5. Pressure ratings are up to 3,000 psi. Volume meters are not used for gas measurement.

PD Meters

PD meters are quantitative instruments. They are termed "positive-displacement" because some sensing element is forcibly or positively displaced through a measuring cycle by the hydraulic action of the fluid on the element.¹¹ For a completed measuring cycle a known quantity is displaced by the sensing element. It is necessary to count the number of cycles and multiply them by the displacement volume to get the total liquid quantity that has passed through the meter. This latter function is carried out by the meter's gear train and register.

Fig. 32.9 shows the basic types of PD meters: nutating disk, oscillating piston, oval gear, rotary vane, reciprocating piston, and bi-rotor.

Probably 80 to 90% of all PD meters in service today are of the nutating-disk type. They are most popular because of the relative simplicity of the construction, ruggedness, accuracy over a wide range, and low cost. The accuracy of the nutating-disk type meter is not as high as that of the PD meters of the other types.

Advantages and Disadvantages of PD Meters

1. Discharge of the metered liquid is continuous.
2. PD meters can be used to meter exceptionally viscous liquids.

3. PD meters do not require gas to displace the fluid through the meters.

4. Initial and installation cost is lower.

5. Temperature compensation can be applied with certain types of PD meters less expensively than with batch-type meters.

6. Paraffin may not reduce metering accuracy.

7. Liquids metered must be free of gas, since slugs of gas may damage or wreck the meter. Gas will register as fluid when passing through a PD meter.

8. Sand, mud, salt, or other foreign particles will cause wear on the PD meter and cause inaccurate meter readings.

9. Some type of meter-proving process is required to prove PD meters periodically. Actual stock-tank gauges are used in many cases to determine the accuracy of the meter.

10. Meters must be operated between a minimum and maximum specified rate of flow. High or low rates of flow may affect the accuracy of the PD meter.

PD meters are available in pressure ratings to 5,000 psi. Capacities of PD meters depend on the size and type of meter. If possible the manufacturer of the PD meter should be requested to furnish information regarding the capacity.

Fig. 32.9—Basic types of PD meters.

**TABLE 32.6—AVERAGE CAPACITY
FOR NUTATING-DISK-TYPE PD
METERS**

Size (in.)	Capacity (B/D)	
	Minimum	Maximum
5/8 to 3/4	68	340
3/4	102	510
1	170	850
1 1/2	342	1,710
2	548	2,740

Average Capacity for Nutating-Disk Type PD Meters. The average rates shown in Table 32.6 are based on oil as the fluid being metered. The manufacturer should always furnish information about recommended capacity. When PD meters are used downstream of separators or vessels that are not continually dumping, it is necessary to size the meter on the maximum "rate" of discharge while the vessel is dumping.

PD meters are used in some cases for gas measurement. The types used are the bellows and birotor. High cost and size have held the use of PD meters for gas measurement to a minimum.

Turbine Meter

Today most liquid measurement is done by the use of turbine meters. A turbine meter is a flow rate measuring device which has a rotating element that senses the velocity of the flowing liquid.¹² This liquid causes the rotating device to rotate at a velocity proportional to the volumetric flow. The movement of the rotating device is sensed either mechanically or electrically and is registered. The actual volume is then compared to the registered readout to arrive at a meter or register factor (see Figs. 32.10 and 32.11).

The turbine meter is used because of its simplicity and costs. Each meter application will require different meter or register factors.

Considerations in the selection of turbine meters include (1) properties of the liquid to be metered—viscosity, density, vapor pressure, corrosiveness, and lubricating ability; (2) operating conditions, including pressure, flow rates and whether continuous or intermittent, temperatures (some meters have temperature compensators), and quantity and size of abrasive particles in the fluid; and (3) space availability (see Fig. 32.12). Items or conditions that normally affect the meter factor are shown in Table 32.7. Both turbine and PD meters should be connected so that meter factors may be periodically determined.

Fig. 32.10—Names of typical turbine meter parts.

Fig. 32.11—Turbine meter system schematic.

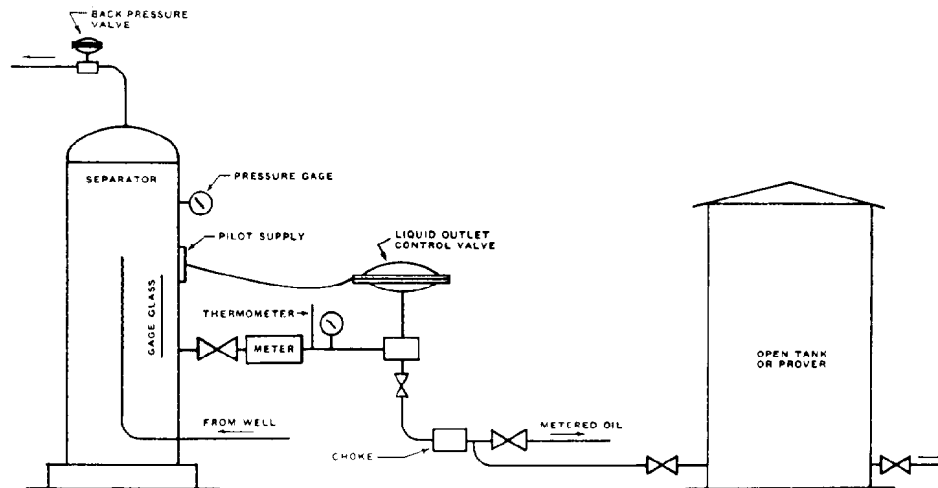

Fig. 32.12—Schematic operation diagram of oilwell production meter installation with stock tank or open prover.

Flowmeters

The standard-type flowmeters are: orifice plate, Venturi tubes, flow nozzle, Pitot tube, drag body, and lift surface. These meters or devices are used to create a flowing differential pressure. This flowing differential pressure is used to solve the flow equation for the rate of flow.

Orifice plate, Venturi tube, flow nozzle, and Pitot tube are commonly used. Drag body and lift surface are not as familiar. The net force resulting from a pressure difference is measured. This pressure difference is used to solve the flow equation. If the force is parallel to the flow direction, the force is called "drag body." If the force is perpendicular to the flow direction, the force is called a "lifting surface."

In addition to differential pressure drop, six other factors must be considered and included in the integration to determine a basic flow rate or quantity. They are (1) static pressure, (2) flowing temperature, (3) specific gravity of the flowing quantity, (4) size of orifice run, (5) size of the orifice plate if orifice plate is used to create the differential pressure, and (6) supercompressibility, if applicable.

These factors may be considered by the solving of the flow equation or they may be applied as a multiplying factor applied to the meter reading.

Mass Flowmeter. In about 1942, W.J.D. VanDijk of The Netherlands constructed and evaluated the first mass flowmeter, as such. The mass flowmeter measures the quantity of matter passed through the meter. This mass is independent of all ambient conditions, which is not true of volumetric meters discussed previously. If any type of flowmeter mentioned above is compensated in any way (electrically, mechanically, or a combination of both) for fluid density, it is a mass flowmeter. As early as 1930, pressure and temperature compensators could be attached to a standard orifice meter. They were mass flowmeters, in a true definition of mass flowmetering, although they were not called by that name.

On well testers, and for measurement of produced

water, oil, and gas, it is most common to use turbine, PD, and batch meters for liquid measurement and the standard orifice meter for gas measurement. Mass flowmeters may be used for both gas and liquid measurement. Because of the cost and special requirements for technicians to operate and maintain these meters, they are seldom used in field operations.

Automation and remote readout requirements can be accomplished with the use of well testers in much the same way as with automatic custody units. The liquid measurement may be relayed by pneumatic or electrical impulses to a transmitter. These impulses in turn may actuate some type of recording unit at a central location. The gas measurement would require some type of pressure transducer to convert the differential pressure to an electrical signal. More often, when remote recording of gas flow is required, an integrating flowmeter is used and the transmitted signal will read in volumetric units.

Fig. 32.13 shows a well tester installed at a tank battery for permanent test or lease automation.

Stationary Metering Installation

Stationary metering installations are those that include metering separators, metering treaters, and any other

TABLE 32.7—CONDITIONS AFFECTING THE METER FACTOR

type of meter used in conjunction with test separators or emulsion treaters. These units are installed as an integral part of the tank battery.

The metering separator combines two functions of separating and metering the produced fluid (see Figs. 32.14 and 32.15). The metering separator is divided into one compartment for separating the liquid and the gas and into one or two other compartments for metering the

Fig. 32.14—Metering separator with free water knockout.

Fig. 32.15—Three-phase metering separator with integral metering compartments. Gauge glasses and valves are furnished for separating chamber and both metering chambers. Automatic BS&W samples can be furnished as an option.

oil and water. PD meters may be used for metering all produced fluids.

Pressure ratings range to 3,000 psi. Capacities will be the same as shown for standard oil and gas separators in Chapter 12. The metering capacity will be as shown for the type of meter used.

GOR

The GOR may be defined as the rate of gas production divided by the rate of oil production. It is usually expressed as standard cubic feet of gas per barrel of stock-tank oil produced under stabilized flowing conditions for a 24-hour period.

The term "cubic feet of gas" or "standard cubic feet of gas" means the volume of gas contained in one cubic foot of space at a standard pressure base and standard temperature base. This standard base is normally 14.65 psia and 60°F. Most tables published for orifice well testers, Pitot tubes, flow provers, and other gas measurement means are referred to a base pressure of 14.65 psia and 60°F temperature. Whenever the conditions of pressure and temperature vary they may be converted to a standard or base condition by the use of the real gas law.

The volume of gas used should be the total gas produced from the reservoir through either the casing or tubing. Any gas that is injected back into the reservoir for artificial lifting purposes such as gas lift should be subtracted from this total gas produced.

The volume of oil produced should be determined by any of the means discussed in the first part of this chapter.

Procedures for Well Testing

Flowing Wells. The oil flow should be stabilized during the 24-hour period immediately preceding the test. This stabilized flow should be very close to the assigned allowable or the daily producing rate. If the well being tested is a discovery well, the producing rate should be as close to the assigned discovery allowable as possible. Any adjustments should be made during the first 12 hours of the stabilization period and no adjustment made during the last 12 hours or during the time the well is on test. All gas withdrawn from the reservoir must be included as produced gas. If the oil has a great deal of shrinkage after it is placed in the stock tanks, some means should be considered for measurement of the gas that breaks out of solution. Any gas used for operation of machinery or for any other purpose must be considered as produced gas. Tests should range from 24 to 168 hours' duration to consider any uneven flow.

Intermittent Flowing Wells (Stopcocked). The procedure for testing should be as outlined for flowing wells, except the shut-in casing and tubing pressures should be approximately equal to the pressures recorded at the beginning of the test. The Texas Railroad Commission states, "The closed-in casing pressure at the end of the 24-hour test period shall not exceed the closed-in casing pressure at the beginning of the test by more than six-tenths (0.6) pounds per square inch per barrel of oil produced during the test." This rule also applies to flowing wells. This is true because of the "loading" characteristic of some wells while shut-in. Before an accurate test can be made the flow must be stabilized and stabilization cannot occur while producing from a loaded annulus or tubing.

Gas-Lift or Jetting Wells. The volume of gas used should be the net produced gas or formation gas. Formation gas will be equal to the total gas produced minus the injection gas.

Pumping Wells. In computing the GOR for pumping wells, the total volume of gas produced during the 24-hour period, ending with the closing in of the well at the conclusion of the tests, and the total barrels of oil that are produced in order to obtain the daily allowable must be used regardless of the actual pumping time in the 24-hour period. If the gas produced is not enough to measure accurately, this should be indicated on the test report as gas "too low to measure."

In some states the regulatory agencies will lower the assigned allowable of the well if the daily or producing allowable is not produced while making GOR tests.

Average GOR

To obtain an average GOR for several wells or for all the wells in a field, one cannot take the arithmetic average value of the ratios. For example, two wells with GOR's of 2,000 and 4,000 would not necessarily have an

Fig. 32.16—Typical performance curve for an internal gas-driven reservoir.

average ratio of 3,000. For the average ratio to be 3,000 the wells would have to produce the same amounts of oil. The average GOR of several wells must be obtained by dividing the total gas production of all wells involved. For example, if the 2,000-ratio well produced 50 B/D oil and the 4,000-ratio well produced 200 B/D oil, the average GOR for the two wells would be

$$\bar{R} = \frac{(2,000 \times 50) + (4,000 \times 200)}{50 + 200} = 3,600 \text{ cu ft/bbl.}$$

For a large number of wells, the average ratio can be figured as

$$\bar{R} = \frac{\sum (R_{iw} \times q_{iw})}{\sum q_{iw}} \quad \dots \dots \dots (8)$$

where

\bar{R} = average GOR, cu ft/bbl,

R_{iw} = individual well GOR, cu ft/bbl, and

q_{iw} = individual well daily production, STB/D.

Cumulative GOR

The cumulative GOR is defined as the total amount of gas produced and kept from the reservoir up to a certain time divided by the cumulative oil produced up to the same time. Therefore,

$$R_p = \frac{G_p - G}{N_p}, \quad \dots \dots \dots (9)$$

where

R_p = cumulative GOR, cu ft/bbl,

G_p = total gas produced, cu ft,

G = gas reinjected, cu ft, and

N_p = total oil produced, bbl.

GOR as a Criterion of Reservoir Performance

The producing GOR is often used as an indication of the efficiency of a producing well, and the increase in the ratio is looked on as a danger signal in the control of the reservoir performance. The GOR should be kept as low as possible (see Fig. 32.16). The area under the curve, shown as the surface ratio, will be the total amount of produced gas. This is by the previous definition of

GOR. This shows that maintaining the GOR as low as possible will increase the cumulative production for the same amount of produced gas.

Consider the internal-gas-drive reservoir. As oil is produced from the reservoir the space is taken over by gas volume. The presence of gas within the reservoir decreases the ability of oil to flow and increases the ability of gas to flow. After a certain minimum gas saturation (about 5 to 10%) is exceeded, the ease with which gas flows increases to such an extent that it flows concurrently with the oil. This process continues until finally the only flow is almost all gas. This allows the reservoir energy to escape and causes the reservoir to cease production by natural means. Fig. 32.16 shows how the stock-tank cumulative production almost ceases as the reservoir/GOR increases.

Key Equations in SI Metric Units

$$q_o = \frac{5.427 \times 10^{-4} kh(p_e - p_{wf})}{\mu_o B_o [\ln(r_e/r_w) + s]}, \dots\dots\dots (1)$$

$$J = \frac{q_o}{\Delta p} = \frac{5.427 \times 10^{-4} kh}{\mu_o B_o [\ln(r_e/r_w) + s]}, \dots\dots\dots (2)$$

where

- q_o = oil production rate, m³/d
- k = permeability of formation, m²
- h = thickness of formation, m
- p_e = pressure at the effective drainage radius r_e , normally approximated by p_R , kPa
- p_{wf} = flowing bottomhole pressure, kPa
- μ_o = oil viscosity, Pa·s

B_o = oil formation volume factor, res m³/STm³

r_e = effective drainage radius, m

r_w = wellbore radius, m

Chapter 33

Open Flow of Gas Wells

R. V. Smith, Petroleum Consultant*

Introduction

The gauging or testing of gas wells arose from the need to measure the productive capacity of a well. The earliest response to this need was to open the well to flow to the atmosphere and then to measure the flow rate. However, it soon became apparent that such practices were wasteful of gas, dangerous for personnel and well equipment, and frequently damaging to the reservoir. In addition, such tests provided very little information for estimating production rates into a pipeline. As a result, the practice of gauging gas wells by opening the well to flow to the atmosphere decreased and now is almost completely confined to stripper gas areas where pressures are very low and the rates of flow are small.

Pitot-Tube Gauging of Low-Pressure Wells

The pitot tube is one of the simplest instruments for measuring the rate of flow of gas. As such, the pitot has been used extensively to obtain an approximate gauge of the open-flow capacity of low-pressure gas wells. The well is opened to flow to the atmosphere through a flow nipple, and the producing rate is measured with a pitot tube. The producing rate is influenced by the hydrostatic head of the column of flowing gas and the friction between the flowing gas and the walls of the flow string. Thus the observed rate of flow to the atmosphere may be a very close measure of the ability of shallow low-capacity reservoirs to deliver gas into the wellbore. However, it may be more nearly a measure of the flow capacity of the flow string in the case of a well producing from a high-capacity reservoir. This is especially true where the flow is through a small-diameter flow string.

Historically, gauging of wells with pitot-tube measurements has been useful in the drilling and completion of low-pressure gas wells. During the drilling of many wells in the Hugoton field of Kansas, Oklahoma, and Texas, it was the practice to take pitot gauges after

every bailer run or at the end of each 5 ft of formation drilled. Upon completion, data were available to construct a chart showing a relationship between the rate of flow and depth. The chart is useful in determining the depth of the major gas-producing zones. Such data were valuable in planning remedial work that may be necessary during the life of the well. Pitot-tube gauges were useful in determining rate-of-flow increases resulting from each stage of acid treatment. In many cases the pitot-tube gauge after acid treatment provided data from which the desired flow rates for a backpressure test could be selected.

Fig. 33.1 shows a pitot-tube and flow nipple arrangement that is suitable for gas measurement. The pitot tube should be made of 1/8-in.-ID pipe shaped to measure impact pressure at the center and in the plane of the opening of the flow nipple. The flow nipple should be at least eight pipe diameters long, free from burrs or other obstructions, and must be round. The impact pressures are measured with water or mercury manometers or a pressure gauge, depending on the pressure to be measured.

The impact pressure is converted to rate of flow by suitable equations or tables such as those published by Reid.¹ Subsequent experimental work by the USBM² is in reasonable agreement with the Reid data. The equations published by Reid were investigated by Binckley,³ who concluded that they were based on sound theoretical principles. Reid's equations and tables have been adjusted to a pressure base of 14.65 psia for the purposes of this handbook. The adjusted equations for impact pressures less than 15 psig are

$$q_g = 34.81 d_i^2 \sqrt{h_w}, \dots\dots\dots (1)$$

$$q_g = 128.4 d_i^2 \sqrt{h_m}, \dots\dots\dots (2)$$

and

$$q_g = 183.2 d_i^2 \sqrt{p_i}, \dots\dots\dots (3)$$

*This author also wrote the original chapter on this topic in the 1962 edition.

Fig. 33.1—Typical flow nipple and pitot tube for gas measurement.

where

- q_g = rate of gas flow, Mcf/D (14.65 psia and 60°F),
- d_i = ID of flow nipple, in.,
- h_w = height (manometer reading), in. water,
- h_m = height (manometer reading), in. mercury, and
- p_i = impact pressure, psig.

For impact pressures more than 15 psig, the adjusted Reid equation is

$$q_g = 23.89 d_i^2 p_1, \dots (4)$$

where p_1 is impact pressure, psia. Values of rates of flow for various impact pressures are given in Table 33.1 for a flow nipple with an ID of 1.000 in. Rates of flow in Table 33.1 were computed by Eqs. 1 through 3. The range of impact pressures is from 0.1 in. of water to 15 psig. Rates of flow for impact pressures from 15 to 200 psig were computed by Eq. 4 and are given in Table 33.2 for a flow nipple with an ID of 1.000 in. Impact pressures measured on larger flow nipples can be converted to rates of flow by multiplying the rate of flow from the table corresponding to the impact pressure by the square of the ID (in.) of the larger nipple.

Rates of flow taken from Tables 33.1 and 33.2 or computed by Eqs. 1, 2, 3, and 4 are for gases with a specific gravity of 0.600 (air = 1.000), flowing temperatures of

60°F, and for discharge into an atmospheric pressure of 14.65 psia. Corrections can be made when desirable by multiplying values from the equations or tables by the following factors.

$$F_g = \sqrt{\frac{0.600}{\gamma_g}}$$

and

$$F_T = \sqrt{\frac{520}{(460 + T_f)}},$$

where

F_g = specific gravity correction factor,

γ_g = specific gravity of gas being measured, air = 1.000,

F_T = flowing-temperature correction factor, and

T_f = temperature of flowing gas, °F.

The atmospheric-pressure correction factor for values from Table 33.1 and Eqs. 1, 2, and 3 is

$$F_{bar} = \sqrt{\frac{p_a}{14.65}},$$

where F_{bar} is barometric correction factor and p_a is atmospheric pressure, psia. The value of pressure used for p_i in Eq. 4 is the absolute pressure and is computed by adding the barometric pressure to the gauge pressure. The correction factor for barometric pressure for Table 33.2 is

$$F_{bar} = \frac{p_i + p_a}{p_i + 14.65}.$$

In ordinary usage, rates of flow are taken from pitot tables or formulas without correction.

Example Problem 1. Given an impact pressure of 27.2 in. of water on a flow nipple with ID = 2.441 in., determine the rate of flow.

Rate of flow from Table 33.1 for ID = 1.000 = 182 Mcf/D.

Rate of flow for ID = 2.441 in. is

$$q_g = 182(2.441)^2 = 182 \times 5.958 = 1,080 \text{ Mcf/D.}$$

Or, by Eq. 1, the rate of flow is

$$\begin{aligned} q_g &= 34.81(2.441)^2 \sqrt{27.2} \\ &= (34.81)(5.958)(5.215) = 1,080 \text{ Mcf/D.} \end{aligned}$$

Example Problem 2. Given an impact pressure of 65 psig on a flow nipple with ID = 4.082 in. with discharge into a barometric pressure of 13.2 psia, determine the rate of flow.

Rate of flow from Table 33.2 for ID of 1.000 and atmospheric pressure of 14.65 psia is 1,904 Mcf/D.

For ID of 4.082 in. and barometric pressure of 13.2 psia, the rate of flow is

$$\begin{aligned} q_g &= 1,904(4.082)^2 (65 + 13.2) / (65 + 14.7) \\ &= (1,904)(16.663)(0.9812) = 31,100 \text{ Mcf/D.} \end{aligned}$$

Or by Eq. 4,

$$q_g = 23.89(4.082)^2(65 + 13.2) \\ = 31,100 \text{ Mcf/D.}$$

Backpressure Testing

Before the development of the backpressure method for testing gas wells, the open-flow capacities of gas wells were determined by actual "open-flow" tests. The flowing of wells at their wide-open rate results in waste and possible damage to the well. In addition, the open-flow

test yields very little information regarding the capacity of a well to deliver gas into a pipeline system.

The backpressure method of testing gas wells was developed by Rawlins and Schellhardt.² Results of tests on 582 wells as reported in their study and other work on many wells reported elsewhere show that when the rates of flow are plotted on logarithmic coordinates against corresponding values of $(\bar{p}_R^2 - p_{wf}^2)$ —the difference of squares of the shut-in pressure \bar{p}_R and the flowing sand-face (bottomhole) pressure (BHP) p_{wf} —the relationship may be represented empirically by a straight line.

*Multiply rate of flow from table by the square of the diameter for flow nipples with ID's more than 1.000 in.

The backpressure method of testing wells requires that a series of flow rates and corresponding pressure measurements be obtained under stabilized conditions or at certain fixed time intervals. Testing under stabilized pressure and rate-of-flow conditions or according to a fixed time interval has become known as multipoint or "flow-after-flow" backpressure testing.

As the original backpressure or multipoint method came into general use, it became evident that the method of testing was applicable to those wells that approached stabilized producing conditions within a relatively short time. However, performance characteristics could not be determined by this method for wells that approached stabilized producing conditions slowly over a considerable period. This characteristic of slow stabilization has been associated generally with wells producing from reservoirs with low permeability and resulted in the development of the isochronal method of backpressure testing by Cullender.⁴

The procedure used to obtain the necessary performance data for the isochronal testing method is to open the well from a shut-in condition and allow the well to flow without disturbing the rate by changing the mechanical adjustment of chokes or valves for a specific period of time. The well is then shut in and allowed to return to a shut-in pressure comparable with that existing before the well was first opened, after which the well is again opened at a different rate of flow. In isochronal testing, each rate of flow starts from a comparable shut-in condition, which provides a means of maintaining a simple pressure gradient throughout the drainage area of the well during testing. The isochronal method of testing

Fig. 33.2—Multipoint test showing bottomhole performance for Well B.

is especially suitable for determining the performance characteristics of wells producing from reservoirs with low permeability.

High-Pressure Gas and Gas-Condensate Wells

All the instructions for testing wells in this chapter apply to gas wells that produce a single-phase gas into the wellbore or to wells that are predominantly gas wells and the fluid flowing in the reservoir has a high in-place gas/liquid ratio (GLR). However, these methods for testing gas wells have been applied to high-ratio oil wells with some degree of success.

The chief difference between testing methods for high-pressure gas and gas-condensate wells and low-pressure wells is the care used in taking the data and methods used in computing the results. The effect of liquids is usually more pronounced in high-pressure than in low-pressure wells. Consequently, special care should be used to measure GLR's in high-pressure wells. Often it is necessary to determine the GLR at each rate of flow during a backpressure test. If the ratio was not constant during testing, the well probably was accumulating liquid in the wellbore during testing or unloading liquid. In either case the test is probably not acceptable and the well should be cleaned by flowing at a high rate and retested at rates of flow high enough to keep the well free of liquid.

Temperature effects during testing of high-pressure wells may be troublesome in interpreting test results. For example, Well B (Fig. 33.2) has a shut-in wellhead pressure of 4,173 psia at a wellhead temperature of 117°F. Maximum wellhead pressure was observed 3 minutes after the well was shut in. If wellhead pressure has been observed for an extended period of time, the wellhead pressure would have decreased to about 4,140 psia. The decrease in wellhead pressure is caused by the cooling of the gas in the well. In general, better tests can be obtained on such large-capacity wells if the testing is done after a preflow period. The preflow period should be run long enough to bring wellhead temperatures to a normal operating range of temperature. Wellhead

temperatures should be recorded during testing at periodic intervals so that actual measured temperatures can be used in computing subsurface pressures by methods outlined under Example 3 in the section on computing subsurface pressures.

Official Testing

Official testing of gas wells for state *regulatory bodies* is usually a multipoint test of short duration. In addition to the multipoint test, a single rate of flow for a period of 24 to 72 hours is required in some cases. The tester is referred to the test manuals of the various states, provinces of Canada, or appropriate countries for exact procedures, and no attempt is made here to outline official testing.

Backpressure Equations

In either multipoint or isochronal backpressure testing, the rates of flow and the corresponding values of the difference of squares of the average formation (reservoir) pressure \bar{p}_R and the sandface pressure [bottomhole flowing pressure (BHFP)] p_{wf} are plotted on logarithmic coordinates and a straight line is drawn through the points. The equation for the relationship is

$$q_g = C(\bar{p}_R^2 - p_{wf}^2)^n, \dots\dots\dots (5)$$

where the performance coefficient is represented by C and the exponent of the backpressure curve by n . The industry by common usage has referred to n as the "slope" of the backpressure curve, even though n is the reciprocal of the mathematical slope of the line. Here n is referred to as the "exponent" of the backpressure curve. Eq. 5 is an empirical relationship for both the multipoint test and the isochronal test and has resulted from the study of results of many tests. Values of the exponent vary for individual wells in the range of 0.5 to 1.0. Tests that result in exponents less than 0.5 or more than 1.0 should be rerun. Exponents of less than 0.5 resulting from multipoint tests may be caused by the slow-stabilization characteristics of the reservoir or by the accumulation of liquids in the wellbore. Exponents greater than 1.0 may be caused by the removal of liquid from the well during testing or by a cleaning of the formation around the well, such as the removal of drilling mud or stimulation fluids. Also, a multipoint test run in decreasing rate sequence may have an exponent of more than 1.0 for wells in slow-stabilizing reservoirs. Erratic exponents in isochronal testing are caused by either accumulation or cleaning of liquids from around the well. Erratic alignment of data points from multipoint or isochronal testing is usually caused by changes in actual well capacity during testing. Such changes may be caused by accumulation of liquids or the cleaning of the wells. The effects of the liquids in the well on multipoint testing have been given in detail by Rawlins and Schellhardt.²

Eq. 5 represents the capacity of a well to deliver gas into the wellbore, and it is useful especially in evaluating reservoir conditions. The capacity of a well to deliver gas at the wellhead may be represented by

$$q_g = C(p_{ts}^2 - p_{wf}^2)^n, \dots\dots\dots (6)$$

where C , the performance coefficient, and n , the exponent, are different from those in Eq. 5 for a given well. p_{ts} and p_{wf} represent wellhead shut-in (static tubing) pressure and working (flowing tubing) pressure on the flowing-gas column at the wellhead, respectively. Eq. 6 is useful especially in estimating the capacity of a well to deliver gas into a pipeline under specified conditions.

Gas Well Inflow Equation, Pseudosteady State

Reservoir engineers have realized for many years that interpretation of multipoint and isochronal tests by means of Eq. 5 gave no insight into the effect of reservoir or gas properties on the rate of flow into a well. Thus, Eq. 5 proved inadequate for reservoir engineering purposes. An equation that describes the pseudosteady-state flow of gas into a well has been presented in the literature.⁵⁻⁸ It is

$$q_g = \frac{703 \times 10^{-6} k_g h (\bar{p}_R^2 - p_{wf}^2)}{\mu_g T_R z (\ln r_e/r_w - 0.75 + s + F_{nD} q_g)}, \dots\dots\dots (7)$$

where

- q_g = gas-production rate, 10^3 cu ft/D,
- k_g = permeability, effective to gas, md,
- h = formation thickness, ft,
- \bar{p}_R = average reservoir pressure, psia,
- p_{wf} = flowing bottomhole pressure, psia,
- μ_g = gas viscosity, cp,
- T_R = reservoir temperature, °R,
- z = compressibility factor of gas,
- r_e = effective drainage radius, ft,
- r_w = wellbore radius, ft,
- s = skin factor, and
- F_{nD} = non-Darcy flow factor.

If we let

$$\frac{703 \times 10^{-6} k_g h (\bar{p}_R^2 - p_w^2)}{\mu_g T z} = C_1,$$

and

$$\ln r_e/r_w - 0.75 + s = C_2,$$

Eq. 7 becomes

$$q_g = \frac{C_1}{C_2 + F_{nD} q_g},$$

or

$$F_{nD} q_g^2 + C_2 q_g - C_1 = 0.$$

From this we get

$$q_g = \frac{-C_2 + \sqrt{C_2^2 + 4F_{nD} C_1}}{2F_{nD}}, \dots\dots\dots (8)$$

The maximum rate of flow [open-flow potential (OFP)] is given when C_1 is a maximum—that is, when $p_{wf} = 0$. Eq. 7 incorporates the properties of the reservoir and the gas and can be extended to noncircular areas as given in Ref. 5.

Determination of Absolute Open Flow (AOF)

The terms "calculated absolute open flow" (CAOF) and OFP are the rate of flow in thousands of cubic feet of gas per 24 hours that would be produced by a well if the pressure against the face of the producing formation in the wellbore were zero. The value of the OFP is usually determined graphically by plotting rates of flow q_g against the corresponding values of $\bar{p}_R^2 - p_{wf}^2$. The straight-line relationship between q_g and $\bar{p}_R^2 - p_{wf}^2$ is extended so the rate of flow q_g corresponding to the value of \bar{p}_R^2 can be read by extrapolation. Then q_g is the AOF of the well in cubic feet per 24 hours. The AOF can be computed from Eq. 5 or read directly from plotted relationships.

In wells producing from reservoirs with low permeability, the reported AOF must be identified further by the time involved in the test and the type of test. For example, the OFP of such a well as determined by a 3-hour multipoint test (each rate of flow lasting 3 hours) would be less than that determined by a 2-hour multipoint test. The open flow determined by an isochronal test of 3 hours would be different from that determined by a multipoint test. A good example of the relationship between AOF and type of test is given by Cullender.⁴ Reported OFP's on wells in low-permeability reservoirs are more or less meaningless without an indication of the type of test involved.

Determination of the Exponent n

The calculation of the exponent n is based on Eq. 5 and the relationship

$$n = \frac{\log q_{g2} - \log q_{g1}}{\log(\bar{p}_R^2 - p_{wf}^2)_2 - \log(\bar{p}_R^2 - p_{wf}^2)_1} \quad \dots \dots (9)$$

Values of q_g and corresponding values of $\bar{p}_R^2 - p_{wf}^2$, either actual experimental points or values read from the straight-line relationship, are substituted in Eq. 9. Usually the data points do not fall exactly on a straight line; so the best practice is to read values of q_g and $\bar{p}_R^2 - p_{wf}^2$ directly from the straight line.

Determination of the Performance Coefficient C

After the value of the exponent n has been determined, the value of the performance coefficient C may be determined by substitution of a corresponding set of values for q_g and $\bar{p}_R^2 - p_{wf}^2$ and the value of n into Eq. 5. The value of C is found by solution of the resulting equation. Graphically the value of C may be determined by extension of the straight-line relationship to $\bar{p}_R^2 - p_{wf}^2 = 1$ and reading the corresponding q_g . When $\bar{p}_R^2 - p_{wf}^2$ is unity, C is equal to q_g . In practice, a determination of the value of C is seldom necessary for routine analysis of backpressure tests.

Preparation of Well for Testing

The wellbore should be cleaned of liquids by flowing at a high rate to a pipeline for a period of 24 hours. If the well does not have a pipeline connection, it may be blown to the air for a short period of time, provided blowing is considered safe. Extra precautions should be taken on new wells to remove drilling mud, solids, and stimulation fluids from the wellbore. The well should be shut in

for 24 hours or longer to equalize the reservoir pressure in the vicinity of the well. Wells with slow pressure-buildup characteristics should be shut in 48 to 72 hours, if possible.

While the well is shut in, the gas-measurement equipment should be prepared for use. If the gas is to be measured with an orifice meter, the meter should be calibrated, the diameters and condition of the run and plate verified, and the differential pen should be zeroed in accordance with good meter practice. If a critical-flow prover (see later section on gas measurement) is used, it should be placed in a vertical position at the wellhead or downstream from the separator so that the gas will flow up and away from the test area. If a separator is used, control the rate of flow with a production choke and maintain pressure on the separator with a critical-flow prover or backpressure regulator when an orifice meter is used. If a separator is not used, control rate of flow and pressure at the wellhead with the critical-flow prover. Always install thermometer wells at the wellhead and at gas-measuring equipment so that temperatures may be measured with a thermometer or calibrated recording device. The thermometer wells should be filled with water or oil to obtain accurate temperature measurement.

Shut-In Pressure

All shut-in or flowing pressures should be measured with a dead-weight or piston gauge, because spring gauges are usually not accurate enough for backpressure tests. Determine and record the pressure at the end of the shut-in period, prepare the well for testing, and redetermine the shut-in pressure as a check on the first measurement and to obtain the rate of pressure buildup. Report each pressure and time the well was shut in prior to each pressure measurement. After the second pressure measurement, either the isochronal or multipoint test may be started.

Subsurface pressures in gas wells may be measured directly with pressure gauges or computed from wellhead pressures. Subsurface-pressure gauges are very useful in wells where liquids accumulate in the wellbore during shut-in. However, the use of subsurface gauges limits the rates of flow during the backpressure test to velocities that will not lift the gauge in the flow string. The use of subsurface gauges is limited to rather low rates of flow in 2 3/8-in. OD tubing, but there is practically no limitation on their use in 7-in. casing. The use of subsurface gauges in the annular spaces of dual completions is practically impossible. In cases where large-capacity wells are being tested, correction must be made for the effect of hysteresis on gauge readings, or the BHP must be measured at each rate of flow by a separate run of the gauge.

The accumulation of liquid in the wellbore is probably the most serious cause of erroneous calculated BHP's. Other sources of error are uncertainties in temperature gradients and specific gravities of the fluids flowing in the well. Before a backpressure test is begun, special care should be taken to remove the liquids from the wellbore by flowing at rates large enough to lift the liquid. If possible, each rate of flow used in the backpressure test should be large enough to lift continuously any liquid that may move into the wellbore during production. Temperature gradients can be

established for a new area only by actual measurement. Usually a flowing-temperature gradient can be estimated by assuming a straight-line gradient between flowing wellhead temperature and bottomhole temperature. Uncertainty in the specific gravity of the fluid flowing in the well can be eliminated to a large degree by careful measurement of gas/hydrocarbon liquid ratio and determination of the specific gravity of the separator gas, separator liquid, and stock-tank liquid.

Multipoint Test and Example

A four-point multipoint test of constant duration for each rate taken in increasing rate sequence is normally satisfactory for establishing the performance of a well. In the case of high-liquid-ratio wells or high-flowing-temperature conditions, a decreasing-rate-sequence test may be used if an increasing-rate-sequence test would not result in alignment of points. In the case of high-liquid-ratio wells, the low flow rates will not clean the wellbore of liquids that accumulate during production. In the case of wells with exceptionally high flowing temperature, it may be desirable to start the test at the highest rate of flow that will result in more nearly constant wellhead temperatures during the test rather than starting at the lowest rate of flow. However, a test in decreasing-rate sequence should not be run unless it is known that an increasing-rate-sequence test will not give a satisfactory test.

The four rates of flow for the test should be evenly distributed over the test range. For average- to low-capacity gas wells, the first rate of flow should lower the pressure at the wellhead about 5%, and the pressure reduction for the fourth rate should be 25%. The rate of flow required to reduce the working pressure to 5% for the first test rate can be approximated from pressure readings obtained while the well is being cleaned before the well is shut in. These recommended pressure reductions may not be possible for large-capacity wells with large flow strings.

After the well is opened for the first rate of flow, the test rate should be continued for 3 hours but no more than 4 hours. Each succeeding flow rate should be for the same period of time. During each flow rate, the wellhead working pressure and temperature, meter or prover pressure and differential, and temperature should be reported at the end of each 15-minute period. If separator and tanks are used during testing, the rate of liquid accumulation, both hydrocarbon and water, should be reported. If a critical-flow prover alone is used, the presence or absence of liquids in the gas stream should be noted and reported. The specific gravity of the separator gas or the specific gravity of the gas flowing from the critical-flow prover should be measured and reported, or a gas sample should be taken for analysis and calculation of the specific gravity. More representative gas specific gravities can be obtained after the well has been flowing at least an hour.

Table 33.3 is an actual copy of the field data sheet for a multipoint backpressure test for Well A in the Guymon Hugoton gas field in Texas County, OK.* The form on which the data are reported has proved convenient for recording test data. The times at which each plate was

changed and when the well opened on each rate of flow were carefully reported. The "remarks" column gives the results of the specific-gravity measurement and the condition of the flow with regard to whether the well was producing water. All the observations recorded in Table 33.3 are necessary for accurate analysis of test results.

Computation of the results of a backpressure test on a gas well involves the following steps.

1. Compute rates of flow and pressures at the face of the producing formation from pressure and volume observations made at the wellhead.
2. Determine values of $p_{ts}^2 - p_{wf}^2$ and $\bar{p}_R^2 - p_{wf}^2$ and rates of flow corresponding to these pressure factors. Then, p_R and \bar{p}_{wf} are calculated at the midpoint of the sandface in wells without tubing. If the well has tubing, they are determined at the entrance to the tubing, provided the entry to the tubing is no more than 100 ft from the midpoint of the sandface.
3. Plot values of q_g and corresponding values of $\bar{p}_R^2 - p_{wf}^2$ and $p_{ts}^2 - p_{wf}^2$ on logarithmic coordinates.
4. Determine values of the exponent n and the performance coefficient C of the flow equations

$$q_g = C(\bar{p}_R^2 - p_{wf}^2)^n$$

and

$$q_g = C(p_{ts}^2 - p_{wf}^2)^n.$$

For most routine analyses of backpressure tests, determination of the value of C is not necessary.

5. Determine the CAOF. Computations for rate of flow and pressures at the producing formation are explained in separate sections.

A convenient form for reporting the results of a multipoint test is illustrated in Table 33.4 for the test data taken on Well A and reported in Table 33.3. Table 33.4 shows general well information, a summary of test data, calculation of rates of flow, data for determining compressibility, and the difference of squares of pressures for wellhead and bottomhole conditions. The calculated OFP of $25,000 \times 10^3$ cu ft/D was determined in Fig. 33.3 where the rate of flow is the abscissa and $\bar{p}_R^2 - p_{wf}^2$ (in thousands) is the ordinate on logarithmic coordinates. The data points were connected by a straight line and extrapolated to a value of $\bar{p}_R^2 - p_{wf}^2$, where p_{wf}^2 is zero. In this case, the value is $\bar{p}_R^2 = 230.9$ (thousands). The corresponding rate of flow is $25,000 \times 10^3$ cu ft/D. The AOF of $25,000 \times 10^3$ cu ft/D for Well A is for a 3-hour four-point test. If the test were for a lesser-time four-point test, the resulting AOF would have been more than $25,000 \times 10^3$ cu ft/D.

The exponent n was determined by taking values of q_g and $\bar{p}_R^2 - p_{wf}^2$ from the straight line in Fig. 33.3 and Eq. 7 as follows.

$q_g, 10^3 \text{ cu ft/D}$	$\bar{p}_R^2 - p_{wf}^2 \text{ (thousands)}$
20,000	168
4,000	16.8

$$n = \frac{\log 20,000 - \log 4,000}{\log 168 - \log 16.8} = \frac{\log 5.00}{\log 10.0} = \frac{0.699}{1.000}$$

$$= 0.699.$$

* This test, used in the 1962 edition of the handbook, was run many years ago. It still stands as a classic multipoint test example today.

PAGE 1 OF 1 DATA BY J. R. J.

The performance coefficient C was determined from the exponent $n=0.699$, Eq. 5, and one of the corresponding values of q_g and $\bar{p}_R^2 - p_{wf}^2$ as follows.

$$\begin{aligned}
 20,000 &= C(168)^{0.699} \\
 C &= 20,000/(168)^{0.699} \\
 \log C &= \log 20,000 - 0.699 \log 168 \\
 \log C &= 4.3010 - 1.5555 \\
 C &= 557.
 \end{aligned}$$

The value of 557 may be checked by extrapolating the straight line on Fig. 33.3 to $\bar{p}_R^2 - p_{wf}^2 = 1$ and reading the corresponding value of q_g . Note that the value of $C=557$ is for q_g in units of 10^3 cu ft/D and for $\bar{p}_R^2 - p_{wf}^2$ in units of thousands.

The backpressure equation for the results of the multipoint test on Well A given in Table 33.4 and illustrated in Fig. 33.3 is

$$q_g = 557(\bar{p}_R^2 - p_{wf}^2)^{0.699}.$$

The wellhead performance of Well A as determined by the test results given in Table 33.4 is illustrated in Fig.

33.4 where q_g and corresponding $p_{ts}^2 - p_{tf}^2$ values are plotted on logarithmic coordinates. The straight line has been extended to show a wellhead OFP of $22,000 \times 10^3$ cu ft/D. The exponent is 0.672 and C is 627. The backpressure relationship corresponding to Eq. 6 is

$$q_g = 627(p_{ts}^2 - p_{tf}^2)^{0.672}.$$

This wellhead performance equation for Well A, illustrated in Fig. 33.4, is a measure of the ability of Well A to deliver gas at the wellhead through 5½-in. casing as indicated by the multipoint test given in Table 33.4. The relationship is influenced by the size of the flow string and hydrostatic head of the gas column as well as the productive capacity of the well.

An example of the bottomhole performance as indicated by a multipoint test is given in Fig. 33.2 for an extremely large-capacity well. Well B (Fig. 33.4) had a shut-in pressure \bar{p}_R of 5,169 psia at a depth of 10,658 ft and a wellhead pressure of 4,173 psia. The calculated OFP was $280,000 \times 10^3$ cu ft/D. The corresponding wellhead performance for Well B producing through 2½-in.-OD, 6.5-lbm/ft tubing is illustrated in Fig. 33.5 where the data points for the test are plotted as circles.

Fig. 33.3—Multipoint test showing bottomhole performance for Well A.

Fig. 33.4—Multipoint test showing wellhead performance for Well A.

Fig. 33.5—Multipoint test showing wellhead performance for Well B.

Data points represented as squares (Fig. 33.5) are flow tests of several days' duration with Point 1 taken shortly after production started and Point 3 taken over a year later. The position of the data points in Fig. 33.5 indicated that the performance of Well B improved after the well was placed on production, which was probably caused by the removal of drilling fluids from the area around the wellbore.

The wellhead OFP of Well B was $41,000 \times 10^3$ cu ft/D, which was the approximate capacity of the tubing. A different wellhead performance curve would result if the tubing were changed in Well B. The wellhead performance for a different string of tubing can be calculated by starting with the bottomhole performance curve in Fig. 33.2 and calculating the pressure drop caused by friction for the different string of tubing.

Isochronal Test and Example

The isochronal method of backpressure testing as defined by Cullender⁴ considers the performance coefficient C in Eqs. 5 and 6 to be a variable with respect to time until the well stabilizes but a constant with respect to a specific time. Thus the backpressure performance of a well producing from a reservoir with low permeability is a series of parallel curves. Each curve represents the performance of the well at the end of a given time interval. Isochronal performance curves for wells producing from reservoirs with relatively higher permeability are closely spaced. For example, the isochronal curves for various times for Well B (Fig. 33.5) are for all practical purposes one curve, and Well B is said to stabilize rapidly.

The isochronal method of testing permits the determination of the true exponent n of the performance curve for a given gas well. This is accomplished by the

establishment of a simple pressure gradient around a producing well during the test period, which prevents the variation of the performance coefficient with time from obscuring the true value of the exponent. The determination of the relationship between performance coefficient and time permits the estimation of the rate of flow of a given well into a pipeline over long periods of time.

The term "isochronal" was adopted as being descriptive of the method, because only those conditions existing as a result of a single disturbance of constant duration are considered as being related to each other by Eqs. 5 and 6. The expression "single disturbance of constant duration" is defined as those conditions existing around a well as a result of a constant flow rate for a specific period of time from shut-in conditions. Under actual test conditions this requirement is rarely satisfied. However, this condition may be approximated by starting a well on production and allowing the well to produce without further outside or mechanical adjustments in rate of flow. Thus a simple pressure gradient is established around the wellbore as opposed to a complex pressure gradient resulting from a multipoint backpressure test.

The presentation of isochronal test data as a series of parallel curves with a constant exponent n and a constant performance coefficient C for a specific time interval involves certain assumptions. The exponent of the performance curves for a gas well is assumed independent of the drainage area. It is established immediately after the well is opened. The variations of the performance coefficient with respect to time are believed to be independent of the rate of flow and the pressure level under simple gradient conditions.

The procedure employed to obtain the necessary performance data for an isochronal test is to open a well from shut-in conditions and obtain rate-of-flow and pressure data at specific time intervals during the flow period without disturbing the rate of flow. After sufficient data have been obtained, the well is shut in and allowed to return to a shut-in condition comparable with that existing at the time the well was first opened. The well is again opened at a different rate of flow with data being obtained at the same time intervals as before. The procedure may be repeated as many times as necessary to obtain the desired number of data points.

With the exception of starting each rate of flow from shut-in conditions, the procedure for running isochronal tests is the same as that for the multipoint test. The necessity for cleaning the well, calibrating the gas-measuring equipment, and accurately measuring pressures and temperatures remains the same. At least four rates of flow should be taken; the lowest rate should reduce the pressure at the wellhead about 5% and the highest rate of flow should reduce the pressure about 25%.

The results of an isochronal test are computed in the same manner as those for a multipoint test. The data points are plotted on logarithmic coordinates as illustrated in Figs. 33.6 and 33.7. The isochronal curves are drawn so that the points taken at a constant time for the various rates of flow are joined by a straight line. For example, all the points on the line labeled "Time, 3 hr" in Fig. 33.6 represent the performance of Well A after flowing at the various rates of flow for 3 hours from shut-in conditions.

Fig. 33.6—Isochronal test showing bottomhole performance for Well A.

Fig. 33.7—Isochronal test showing wellhead performance for Well A.

The results of isochronal tests can be analyzed in two ways. One way is to use Eqs. 7 and 8 and the properties of the gas to determine the properties of the reservoir and the skin factor. The second way is to use the results as a basis for comparison of well performance at the time of the test with performance as measured previously or to set a base against which future performance is to be compared.

The isochronal type curves shown on Fig. 33.6 can be used to estimate the pressures that would have been observed if the test had been a constant-rate drawdown test. Test periods longer than the 3-hour periods on Fig. 33.6 are much more desirable for this purpose. With this information the $k_g h$ value for the reservoir and the total skin value ($s_t = s + F_{nD} q_g$) are calculated as given in Chap. 35. This results in several values for the total skin, s_t , as a function of the rate of flow, q_g , from which s and F_{nD} can be obtained for use in Eq. 7.⁶ The multipoint test can be analyzed to obtain $k_g h$, s , and F_{nD} as indicated by Ref. 7. A discussion of the performance-comparison method follows.

A copy of actual field data for an isochronal test is given in Table 33.5 for Well A, which is the same well used in the example of a multipoint test.* Four rates of flow of 3 hours' duration were used with each flow starting from shut-in conditions. Shut-in pressures reported varied from 359.6 psig after 48 hours for the first rate of flow to 357.6 psig, which was just previous to the fourth rate of flow. The results of the isochronal test are summarized in Table 33.6. Bottomhole and wellhead performance curves are illustrated on Figs. 33.6 and 33.7, respectively.

The isochronal test on Well A (Fig. 33.6) shows that the calculated OFP for a BHP of 399.1 psia was 51,500, 41,500, 35,000, and 31,500 $\times 10^3$ cu ft/D at the end of 0.5, 1.0, 2.0, and 3.0 hours, respectively. The calculated potential after 3 hours' flow was only 61% of the potential after 0.5 hour of flow. A similar figure for the wellhead performance of Well A is 66% (Fig. 33.7). If Well A were opened into a pipeline with a constant

pressure, the rate of flow at the end of 3 hours would be 66% of the rate of flow at 0.5 hour. Experimental data not given here show that the production at the end of 72 hours has decreased to about 48% of that at 0.5 hour. The figures showing change-of-performance characteristics with time illustrate the need for isochronal test data for estimating the delivery from a particular well into a pipeline. Accurate estimation of pipeline deliveries from wells producing from reservoirs with low permeability is practically impossible without isochronal test data.

Examination of the field notes under the "Remarks" column in Table 33.5 indicates that Well A started to produce water during the flow test taken on Dec. 20, 1951, which was the largest rate of flow. The effect of water production on well performance is illustrated by the irregularities in the corresponding data in Figs. 33.6 and 33.7. Water production and accumulation of water or liquids in the wellbore cause the performance characteristics of a well to deteriorate.

The data represented as squares in Fig. 33.5 are isochronal points taken after Well B has been flowing from 5 to 30 days. Their close agreement with the data from the multipoint test indicates that the performance of Well B does not vary appreciably with time. Well B produces from a reservoir with high permeability and the radius of drainage is established quickly after the well is opened to flow.

Comparison of Multipoint With Isochronal Test

Either the multipoint or the isochronal test is suitable for wells producing from reservoirs with high permeability. The isochronal method of testing is especially suitable for testing wells in low-permeability reservoirs. However, for wells producing from extremely low-permeability reservoirs where the unsteady-state effects last for days or even weeks, economic considerations may limit the testing to only one point of the isochronal type (starting flow from a shut-in condition). Multipoint tests should be limited to reservoirs where the unsteady-state effects are of very short duration. Otherwise the results of the multipoint test are difficult to analyze.

*This test, used in the 1962 edition, was run many years ago. It still stands as a classic isochronal test example today.

The results of the 3-hour multipoint test and the 3-hour isochronal test on Well A are shown together in Fig. 33.8 as wellhead performance curves. The exponent (0.672) for the multipoint test is less than the exponent (0.848) of the isochronal test. In general, exponents of multipoint curves run in increasing rate sequence are less than those for isochronal curves for the same well. The first data point on the multipoint test ($q_k = 4,928$ Mcf/D) is on the isochronal curve (Fig. 33.8) because the first rate of flow for the multipoint curve was started from shut-in conditions. Thereafter, the position of each succeeding point of the multipoint test is influenced not only by the rate of flow but also by each preceding point.

The initial points of each multipoint test on wells producing from reservoirs with low permeability represent the formation characteristics, while other points represent complex conditions that are almost impossible to interpret. The characteristic exponent of the isochronal curve still applies to the complex points, with the only difference in performance being in the performance coefficient C . If the exponent of 0.848 is applied to the complex points of the multipoint test (Fig. 33.8), it can be

Fig. 33.8—Comparison of multipoint with isochronal test for Well A.

seen that the coefficient obtained in each case can be considered the result of an "effective" time, which has no permanent significance because it is not equal to the elapsed time or to the elapsed time since the last change in flow rate.

An examination of the multipoint and isochronal data presented in Fig. 33.5 for Well B shows that there are certain gas wells that stabilize so rapidly that there is no necessity for obtaining isochronal performance data. As the time required for stabilization increases, the differences between data obtained by the isochronal test and the multipoint test increase.

Gas Measurement

Orifice Meters

The recommended specifications for orifice meters and methods for computing rates of flow are those published by the American Gas Assn.⁹ It should be noted that the basic orifice factors are for a pressure base of 14.73 psia. Multiplying the basic orifice factors in Ref. 9 by 1.0055 changes volumes to a pressure base of 14.65 psia. Basic orifice factors for a pressure base of 14.65 psia have been published in the test manual of the Corporation Commission of the State of Kansas¹⁰ and the Interstate Oil Compact Commission.¹¹

Critical-Flow Provers

The following method for measurement and computation of rates of flow for critical-flow provers is a modification of the method published by Rawlins and Schellhardt.² The equation computing rates of flow from measurements with a critical-flow prover is

$$q_g = p_s F_p F_g F_T F_{pv}, \quad (10)$$

where p_s is static pressure on critical-flow prover, psia. Basic orifice factors, F_p , for 2- and 4-in. critical-flow provers are given in Table 33.7. These factors apply only to plates designed according to USBM specifications.

The adjustment factor (Table 33.8) to correct for an assumed specific gravity of 1.000 to the actual specific gravity of the gas flowing through the prover may be computed by

TABLE 33.7—BASIC ORIFICE FACTORS FOR CRITICAL-FLOW PROVER (USBM plate design) F_p —Mcf/D

1 1/8	22.45	2 1/2	110.6
1 1/4	28.34	2 3/4	136.9
1 3/8	34.82	3	168.3
1 1/2	43.19		

$$F_g = \sqrt{\frac{1}{\gamma_g}}, \quad (11)$$

where γ_g is specific gravity of the flowing gas, air = 1.000.

Factors to correct for an assumed flowing temperature of 60°F to the actual flowing temperature of the gas at the point of measurement are given in Table 33.9 and may be computed by

$$F_T = \sqrt{\frac{520}{T_f}}, \quad (12)$$

where T_f is actual flowing temperature of the gas, (°F+460).

The supercompressibility factor to correct for the effect of gas compressibility is computed from the compressibility by

$$F_{pv} = \sqrt{\frac{1}{z}}, \quad (13)$$

where z is compressibility of the gas at p_s and T_f or the pressure and temperature at point of measurement.

Methods for estimating gas compressibilities are given in Chap. 20.

Calculation of Subsurface Pressures

Specific Gravity of Flowing Fluid

Calculation of either shut-in or flowing pressures in gas wells requires a knowledge of the specific gravity of the fluid in the wellbore. In the case of a gas-condensate well, the specific gravity of the separator gas and the gravity of the stock-tank liquid are measured, and it is

usually necessary to compute the specific gravity of the fluid flowing in the wellbore. The shrinkage of the liquid between the separator and the stock tank is usually unknown and apparently can be neglected. The equation for computing the specific gravity of the flowing fluid, γ_{ff} , is:

$$\gamma_{ff} = \frac{R_{gL}\gamma_g + 4603 \gamma_L}{R_{gL} + V_L}, \dots\dots\dots (14a)$$

where

R_{gL} = gas to hydrocarbon liquid ratio, cu ft/bbl,

γ_L = specific gravity of hydrocarbon liquid referred to water, and

V_L = vapor volume equivalent of 1 bbl (60°F) of hydrocarbon liquid, cu ft/bbl.

The specific gravity and the approximate vapor volume of the hydrocarbon liquid can be calculated from the API gravity by

$$\gamma_L = \frac{141.5}{131.5 + \gamma_{API}} \dots\dots\dots (14b)$$

and

$$V_L = 369 + 5\gamma_{API} + 0.04(\gamma_{API})^2, \dots (14c)$$

where γ_{API} is stock-tank oil gravity, °API. The derivations of Eqs. 14a and 14c were given by Smith.¹²

Equations for Computing Subsurface Pressures

Pressures at the sandface or at the inlet to the tubing in shut-in or flowing gas wells may be measured with BHP gauges or computed from wellhead pressures. However, most subsurface pressures in gas wells are calculated by equations. The most usable and realistic equations available are those of Cullender and Smith,¹³ which have been adopted by the Kansas Corp. Commission, the Interstate Oil Compact Commission, and the New Mexico Conservation Commission, and by the Railroad Commission of Texas for certain fields. The equations were revised¹² recently for use with programmable calculators and small computers.

The revised flow equation for gas wells is

$$\frac{1,000 \gamma_g L}{53.356} = \int_{p_2}^{p_1} \frac{\left(\frac{p}{T_z} - 2.082 \frac{\gamma_g q_g^2}{d_i^4 p} \right) dp}{F^2 + \frac{H}{L} \frac{(p/T_z)^2}{1,000}}, \dots (15)$$

where

L = length of flowstring in well corresponding to H , ft,

H = vertical depth in well, ft, and

q_g = rate of gas flow at 14.65 psia and 60°F, 10^6 scf/D.

$$F^2 = \frac{2.6665 f q_g^2}{d_i^5} = (F_r q_g)^2 \dots (16a)$$

and

$$\sqrt{\frac{1}{f}} = \frac{4 \log 7.4 r_i}{K}, \dots (16b)$$

where

f = coefficient of friction (friction factor),

r_i = internal radius of pipe, in.,

K = absolute roughness characteristic = 0.0006 in., and

r/K = relative roughness.

Refer to Ref. 12 for the background of Eqs. 15, 16a, and 16b. The second term in the numerator on the right side of Eq. 15 is the kinetic energy term that heretofore has been set at zero because the computations were made manually. Although the kinetic energy term can be neglected without appreciable error in the majority of cases, there is no need to do so when programmable

							10.750	54.00	9.784	1,630,000	0.0002852

calculators or computers are used. Eq. 15 is based on the assumptions that the flow is completely turbulent, the coefficient of friction, f , is a constant, the compressibility of the gas at base pressure and temperature conditions (14.65 psia and 60°F) is 1.000, and only a gas phase is flowing.

Eq. 15 has a subtle but important concept in the value of the quantity H/L at the wellhead, where both H and L are zero. For a vertical wellbore, $H = L$ and

$$\frac{H}{L} = \lim_{H \rightarrow 0} \left(\frac{H}{L} \right) = 1.000.$$

In a deviated wellbore, H is less than L , and for a horizontal pipeline, $H = 0$, and as a result the term for the head of gas drops out of Eq. 15. For a complete guide to the algebraic convention for H and L , refer to Ref. 12.

Eq. 15 does not lend itself to mathematical integration without making assumptions regarding T and z , but it may be integrated over definite limits by the trapezoidal rule.

If we let

$$\int_{p_1}^{p_n} \frac{\left[\frac{p}{Tz} - 2.082 \frac{\gamma_g q_g^2}{d_i^4 p} \right] dp}{F^2 + \frac{H}{L} \frac{(p/Tz)^2}{1,000}} = \int_{p_1}^{p_n} Idp = \frac{1,000 \gamma_g L}{53.356}$$

$$= \frac{1}{2} [(p_2 - p_1)(I_2 + I_1) + (p_3 - p_2)(I_3 + I_2) + \dots + (p_n - p_{n-1})(I_n + I_{n-1})], \dots (17)$$

then

$$37.484 \gamma_g L = [(p_2 - p_1)(I_2 + I_1) + (p_3 - p_2)(I_3 + I_2) + \dots + (p_n - p_{n-1})(I_n + I_{n-1})], \dots (18)$$

where $I_1, I_2, I_3 \dots I_n$ is the trapezoidal rule interval corresponding to the respective pressure. If we make the assumptions that the kinetic energy term is zero or that the temperature, T , and the gas compressibility factor, z , are constant, the equations given in Chap. 30 of this handbook can be derived. However, the numerical examples that follow will make use of Eqs. 15 through 18.

The details of computations of a BHFP and a shut-in BHP by Eqs. 16a, 16b, 17, and 18 are illustrated by Example Problem 3 on Page 33-18. To utilize the equations, it is necessary to evaluate the factor F_r for various flow strings. The value may be determined by several correlations; however, the values given in Tables 33.10 and

33.11 were calculated by the methods published by Smith.¹²

To compute subsurface pressures where the well is equipped with tubing set without a packer, the preferred practice is to calculate the flowing subsurface pressure from the wellhead pressure measured on the static gas column by means of the static column equations. If the well has a packer, it is necessary to calculate the flowing subsurface pressure by means of the equations for flowing gas columns.

Depths for calculating or measuring subsurface pressures in wells are determined in practice by the equipment installed in the well. Where a well is equipped without tubing or with tubing set without a packer, the proper depth for pressure determinations is the distance to the midpoint of the productive sandface. If the well has tubing set with a packer, the pressures are determined at the entrance to the tubing provided the entry to the tubing is no more than 100 ft from the midpoint of the productive sandface. Otherwise, appropriate corrections would be made to determine the pressure at the midpoint of the sandface.

An explanation of the computational procedures used in Tables 33.12 and 33.13 will be helpful before going into the details of the calculations. The recent advances in computing equipment or, more realistically, the dramatic decrease in the cost of computations have given the average engineer access at least to a handheld programmable calculator or more likely a microcomputer. Therefore, the emphasis in the past has been to simplify equations by making assumptions regarding pressure, temperature, and gas compressibility, but that has not been done here. Now the factor F_r and compressibility factor, z , become subroutines, the results of which are never seen by the user. In this case, Tables 33.10 and 33.11 may seem redundant. The compressibility factors given in Tables 33.12 and 33.13 were calculated by the equation of state published by Hall and Yarborough¹⁴ and Yarborough and Hall.¹⁵ The results of the computations in Tables 33.10 through 33.13 have been rounded,

and the rules for rounding vary from one piece of computing equipment to another. The algorithm used for solving Eqs. 15, 17, and 18 seems to work for all cases, but users may wish to devise their own algorithm.

Example Problem 3—Flowing Well. Details of the method for calculating a flowing subsurface pressure for Well B are given in Table 33.12.

The wellhead flowing pressure for Well B was 3,913 psia at a flow rate of 11.299×10^6 cu ft/D. The annular space between the tubing and casing was packed off and filled with mud so that it is necessary to calculate the flowing subsurface pressure at a depth of 10,658 ft down the flowing column of gas. Gas properties are those given in Table 33.12.

The flow string measures 10,490 ft of 2½-in.-OD, 6.50-lbm/ft tubing with 168 ft of 2½-in.-OD, 4.70-lbm/ft tubing at bottom of flow string. Also, $H = L$, or the flow string is vertical.

Computation of the required pressure is done in two major steps because of the change in size of the flow string at a depth of 10,490 ft. Computations are given in the following steps.

Step 1. Obtain the ID's from Table 33.10 and enter at top of Table 33.12

2½ in. OD—ID = 2.441 in.

2½ in. OD—ID = 1.995 in.

Step 2. Determine the temperature gradient applicable to the problem. In this example, the flowing temperature of the gas at the wellhead was 117°F, and the subsurface temperature at 10,658 ft was 170°F. The temperature was assumed to be a straight-line relationship between 117°F at $H = 0$ and 170°F at $H = 10,658$ ft for a temperature gradient of 5°F per 1,000 ft.

Step 3. Enter wellhead data on Line 1 where H and L are zero. Calculate I_1 from definition of I in Eq. 17.

From Eq. 17, I is:

$$\frac{p}{Tz} - 2.082 \left(\frac{\gamma_g q_g^2}{d_i^4 p} \right) \\ F^2 + \frac{H}{L} \frac{(p/Tz)^2}{1,000}$$

$$\frac{p}{Tz} = (3913)/(577)(0.8776) = 7.72747.$$

Note that z was calculated by methods given in Refs. 14 and 15 (see also Chap. 20).

$$2.082(\gamma_g q_g^2 / d_i^4 p) = \frac{2.082(0.615)(11.299)^2}{(2.441)^4 (3913)} \\ = 0.00118.$$

$$[p/Tz - 2.082(\gamma_g q_g^2 / d_i^4 p)] = 7.72629.$$

Using Eqs. 16a and 16b:

$$F^2 = 2.6665(q_g)^2 / \{ (d_i)^5 [4 \log(d_i/K) + 2.27281]^2 \} \\ = 2.6665(11.299)^2 / \{ (2.441)^5 \cdot [4 \log(2.441/0.0006) + 2.27281]^2 \} \\ = 340.425/24,200 = 0.014067,$$

or, from Table 33.10:

$$F^2 = (F, q_g)^2 = (0.01050 \times 11.299)^2 = 0.014075.$$

This value of F^2 will be used later for comparison.

$$(p/Tz)^2 / 1,000 = (7.72747)^2 / 1,000 = 0.059714.$$

At the wellhead, where $H=0$ and $L=0$ for a vertical wellbore $H=L$, then

$$H/L = \lim_{H \& L \rightarrow 0} (H/L) = 1.000.$$

For a deviated wellbore, H is less than L , and for a horizontal pipeline, $H = 0$, and the term for the head of gas drops out of the term for I .

$$F^2 + \frac{H}{L} (p/Tz)^2 / 1,000$$

$$= 0.014067 + (1.000)(0.059714)$$

$$= 0.073781.$$

Then

$$I = (7.72629) / (0.073781) = 104.719.$$

If the F^2 value determined from F_r (taken from Table 33.10) is substituted above, I becomes 104.708, which compares well with 104.719.

Step 4. Determine trial Δp (Line 2) for a depth of 1,000 ft by

$$\Delta p_1 = \frac{37.484 \times \gamma_g \times L}{2 I_1} = \frac{37.484(0.615)(1,000)}{2(104.719)} \\ = 110.1 \text{ psi.}$$

Step 5. Complete calculation of first trial I_2 (104.346) on Line 2 where the temperature is 122°F, and the first trial pressure is 3913.0 + 110.1 = 4023.1 psia. At these conditions, the compressibility factor, z , is 0.8894. Estimate the second trial Δp by:

$$\Delta p_2 = \frac{37.484(0.615)(1,000)}{104.719 + 104.346} = 110.3.$$

Step 6. Complete calculation of second trial I_2 (104.343) on Line 3 where the temperature remains at 122°F, and the second trial pressure is $3913.0 + 110.3 = 4023.3$ psia. Under these conditions, the compressibility factor, z , remains at 0.8894. Estimate the third trial Δp by

$$\Delta p_3 = \frac{37.484(0.615)(1,000)}{104.719 + 104.343} = 110.3.$$

Since the third trial Δp is the same to within 0.04 psi, the pressure at a depth of 1,000 ft was determined by trial and error to be $3,913.0 + 110.3 = 4,023.3$ psia. (Note that the third trial was not entered in Table 33.12.)

Step 7. Repeat Steps 4 through 6 to calculate the pressure at a depth of 2,000 ft. Only the final step was given in Table 33.12.

Table 33.13 illustrates the calculation of subsurface shut-in pressures in a gas well by Eqs. 15, 16a, and 16b by the same procedure used in Example 1. The only difference is that for the shut-in well the rate of flow, q_g , is zero and, as a result, the pressure loss caused by friction is zero. Therefore, the inside diameter of the pipe has no effect on the calculations.

Size of Integration Interval

The integration interval was 1,000 ft in Tables 33.12 and 33.13 for a moderately high-pressure well and, for the flowing example (Table 33.12), the rate of 11.299×10^3 cu ft/D gave an effective or average velocity of 14.7 ft/sec near the wellhead. Also, the compressibility factor, z , of the gas at wellhead conditions is in that portion of the z vs. pressure curve where z is very nearly a linear function of pressure. At this low velocity and the nearly linear relationship of z with pressure, an integration interval of 1,000 ft is probably more than enough. Likewise, at low pressures where z is again almost a straight-line function of pressure and at low velocities, the integration interval could be extended to 3,000 ft without undue error. However, even moderate computational facilities eliminate the necessity for expanding the integration interval to more than 1,000 ft.

Application of Backpressure Tests to Producing Problems

Backpressure tests taken properly are useful in predicting delivery rates into a pipeline and in reconditioning studies. For these purposes, either the multipoint or the isochronal test is suitable for wells producing from reservoirs with high permeability such as Well B (Fig. 33.5). The isochronal-type test is necessary for an accurate analysis of producing problems for wells producing from low-permeability reservoirs such as Well A (Fig. 33.7). Although multipoint tests can be used, such analyses are much more difficult.

Well performance at the bottom of the well is a measure of the capacity of the reservoir to deliver gas into the wellbore and is useful in analysis of reservoir problems. A wellhead performance curve is a measure of the capacity of the well to deliver gas into a pipeline and is useful in equipment and reconditioning problems. Usually, an analysis of producing problems can be completed with wellhead backpressure data.

Production Rate

Estimation of the steady production rate of a well into a pipeline operating at a relatively constant pressure requires both test data and a general knowledge of the producing characteristics of the well. For example, an estimate is required of the capacity of Well A (Fig. 33.7) to deliver gas into a pipeline operating at a pressure so that $p_{ts}^2 - p_{tf}^2$ in thousands equals 20. Starting from shut-in conditions, the delivery rates would be 6,950, 6,000, 5,150, and $4,730 \times 10^3$ cu ft/D. The rate at 72 hours would be $3,340 \times 10^3$ cu ft/D from data given in the text. The steady production rate would be about $2,000$ to $2,400 \times 10^3$ cu ft/D. Although theoretical methods have been published for estimation of stabilized production rates, they would require more data than is available for the well.

Well B (Fig. 33.5) would produce about $4,300 \times 10^3$ cu ft/D into a pipeline when

$$p_{ts}^2 - p_{tf}^2 = 500$$

as long as the well remained in good condition. Actually, the performance of Well B increased during production and the rate of flow would have increased. The performance of Well B did not deteriorate with time.

Estimation of the sustained production rate of a particular well against fixed pipeline conditions requires a general knowledge of well performance and a definite knowledge of the performance characteristics of the particular well. The accuracy of such estimations is dependent to a large extent on the amount of proper test data available for study.

Causes of Deterioration in Performance

The principal causes of deterioration in gas-well performance are hydrates, liquids, cavings, deposition of salts, equipment leaks, foreign objects, and damage to the producing formation. Any one or a combination of these causes may result in loss of productive capacity and in decreased income. The determination of the cause of deterioration in performance and the recommendation of remedial measures require a history of the performance of the particular well.

The tests illustrated in Fig. 33.8 for Well A give a history of the performance between the date (June 17, 1947) of the multipoint test and the date (Dec. 17, 1951) of the isochronal test. The performance indicated by the first point of the multipoint test ($q_g = 4,928 \times 10^3$ cu ft/D) is the same as that of the isochronal test. Thus it is concluded that the performance of Well A was maintained for about 4½ years. Nothing occurred that harmed the well. Similar conclusions regarding Well B are indicated for the time interval represented by the data on Fig. 33.5.

A regular program of testing gas wells is essential to planning remedial action.

Hydrates

The formation of gas hydrates in the flow string or in the reservoir may cause a well to cease flowing. The author knows of no remedial action to remove hydrates from the producing formation except that of allowing the natural heat of the reservoir to melt the hydrates. The formation of hydrates in the flow string may be prevented by use of

Fig. 33.9—Effect of tubing installation on performance of Well C; Points 1 through 4 are before tubing installation, Point 5 is after.

bottomhole chokes, injection of chemicals such as the alcohols or glycols into the flow string, or by the installation of downhole heating equipment. The accumulation of hydrates in the flow strings may be alleviated to some extent by elimination of obstructions in the flow string, use of proper valve sizes at the surface, elimination of sharp bends in surface lines, and proper placement of chokes in surface lines. Remedial action consists in lowering of hydrate-formation temperatures by chemicals or by maintaining the temperature of the flowing gas above the hydrate-formation temperature. Heating of the flow string in a well is usually accomplished by the circulation of hot oil in the casing around the tubing of the well. However, it must be emphasized that hydrate troubles are very easily confused with liquid troubles in low-temperature wells. A careful study should be made of flowing temperatures in a well before recommendations are made for hydrate prevention.

Liquids

Most performance difficulties in gas wells are caused by the accumulation of liquids in the wellbore. Liquid troubles may be caused by hydrocarbons (condensate and crude oil), salt water, or brines coming into the wellbore from the producing formation, brines from foreign sources through casing leaks, or fresh water. Occasionally, the production of formation water or crude oil may be eliminated by plugback operations. Liquids in wellbores may be removed by tubing strings of proper design, siphon strings (tubing with jet holes or gas-lift valves), and plunger lifts. Periodic flowing of the well at high rates to the pipeline may eliminate liquid troubles.

Remedial action for water troubles requires an identification of the source of the water. This is done by water analyses. If it is decided from analyses that the water is native to the formation, there is a choice between plugback work and water removal by various means. Salt water that is foreign to the producing forma-

Fig. 33.10—Effect of obstruction in tubing on performance of Well D; Points 1 through 6 are before removal, Point 7 is after.

tion or fresh water in excessive amounts indicates a casing leak that should be repaired. However, moderate amounts of fresh water usually condense in the flow strings of gas wells. Fresh water that occurs naturally should not be confused with fresh water from a foreign source.

Cavings

Cavings that consist of shale and pieces of the formation are usually most troublesome in openhole completions. The presence of cavings in wells without tubing can be determined easily by comparison of measured depth with drilled depth. Remedial action consists of cleaning out, installation of liners in openhole, and acid washes where the formation is soluble in acid.

Unconsolidated sand is troublesome in many Gulf Coast wells. Sand may damage the performance of a well in addition to causing severe damage to equipment. Remedial action consists of cleaning out, installation of special liners, or consolidation treatment for the formation.

Deposition of Salts

Salts (sodium chloride or other chemical compounds) may be deposited in the flow strings or wellbores of gas wells. Sodium chloride and water-soluble salts often may be removed by water or light acid washes. Occasionally it is necessary to replace the flow string with clean pipe. Heavy crude oil (not a salt) may be removed from the flow string and to a limited extent from the face of the wellbore by washing with kerosene.

Casing and Tubing Leaks

Casing leaks usually permit the migration of gas into another formation, but occasionally in low-pressure areas water may come into the wellbore through leaks. The migration of gas into another formation is wasteful. Casing leaks, depending on their size in relation to well

capacity, cause deterioration in well performance. Positive identification usually can be made with subsurface temperature surveys or special techniques supplied by service companies.

Tubing leaks, where there is no packer, tend to defeat the purpose of the tubing. Liquid removal becomes difficult if the hole in the tubing is large. Small leaks in tubing are usually the result of corrosion. In wells where the annular space is packed off, tubing leaks may allow casing pressures to build up to dangerous levels.

Foreign Objects

Foreign objects such as swab rubbers, stud bolts, or pieces of metal may remain in the flow string of a well after completion. Such objects should be removed from the flow string because they can seriously affect the delivery capacity of a well. The removal of foreign objects from the upstream side of chokes is common.

Examples of Remedial Operations

The effect of water production and the installation of tubing on the performance of Well C in the Texas Hugoton field is illustrated in Fig. 33.9. The curve ($n=0.860$) shows the 3-hour isochronal test results taken immediately after completion. Numbered points are 72-hour isochronal tests taken at yearly intervals, except for Points 4 and 5, which were immediately before and after installation of tubing. Point 1, taken after completion, and Point 2, taken about a year after completion, represent good performance. Points 3 and 4 show poor performance with the result that Well C was producing about 30% of its assigned allowable. A study of Well C indicated that salt water was causing the poor performance. A string of 1 1/4-in. tubing with a 3/32-in. jet hole 100 ft from the bottom of the tubing was installed. The well was then produced continuously through the tubing string. At the time Point 5 was taken, the performance of the well had not only been restored but it had been improved over what it had been originally, which is shown by the relative positions of Points 1, 2, and 5 with respect to the 3-hour isochronal curve. Conclusions regarding Well C are that there was a minor water problem from completion through the time that performance data were taken for Points 1 and 2 (Fig. 33.9). Water movement into the wellbore had seriously damaged the performance of the well at the times Points 3 and 4 were taken. The installation of tubing after Point 4 permitted the removal of water from the well and even allowed the water saturation to be reduced in the formation around the wellbore. The position of Point 5 indicates better 72-hour performance than the well had originally as it is closer to the 3-hour isochronal curve than Points 1 and 2.

An example of the effect of a tubing obstruction on the performance of a well is illustrated in Fig. 33.10 for Well D, where the performance points (indicated by circles with and without numbers) were taken at intervals of a month after start of production. Well D was an extremely high-capacity well as indicated by the position of the original multipoint test. As the numbered points were of long-time-flow duration, it was thought that position of Points 1, 2, and 3 indicated some sort of liquid blockage in the reservoir. However, the tubing appeared to be free of liquids when the well was shut in and pressures were normal. Water-gas and condensate-gas

ratios were normal. Thus it was concluded that liquids were not the source of trouble. After Points 4, 5, and 6 were taken, it was decided to blow the well. Shortly after the well was opened, a swab rubber and several pieces of metal were blown from the well. Afterward, the performance of Well D returned to normal, as indicated by the positions of Point 7 and later performance points that are not numbered on Fig. 33.10.

Space does not permit a complete description of reconditioning procedures. However, it is hoped that this brief outline does illustrate the importance of adequate performance tests in the maintenance of well productivity and planning reconditioning procedures.

Nomenclature

- C = performance coefficient
- d_i = internal diameter, in.
- f = coefficient of friction (friction factor)
- F = term in Eq. 16a
- F_g = specific-gravity adjustment factor
- F_{nD} = non-Darcy flow factor
- F_p = basic orifice factor for critical-flow prover, 10^3 cu ft/D at 14.65 psia, 60°F, specific gravity = 1.000
- F_{pv} = supercompressibility adjustment factor
- F_r = factor defined by Eq. 16a
- F_T = flowing-temperature adjustment factor
- h_m = height (manometer reading), in. mercury
- h_w = height (manometer reading), in. water
- H = vertical depth in a well, ft (in untubed wells H is the vertical depth to the midpoint of the productive formation; in tubed wells H is the vertical depth to the entrance to the tubing)
- I = terms in Eq. 17
- K = absolute roughness characteristic, in.
- L = length of flow string in well corresponding to H , ft
- n = exponent of the backpressure equation or slope of the backpressure curve
- p = pressure, psia
- p_i = impact pressure on a pitot tube, psig
- p_1 = impact pressure on a pitot tube, psia
- p_{pc} = pressure, pseudocritical, psia
- \bar{p}_R = average pressure in the reservoir at vertical depth H
- p_s = static pressure on critical flow prover, psia
- p_{wf} = flowing pressure at wellhead measured on a flowing column of gas, psia
- p_{is} = shut-in pressure at wellhead, psia
- p_{wf} = subsurface (bottomhole) flowing pressure in the wellbore at vertical depth H , psia
- q_g = rate of flow, 10^3 cu ft/D or 10^6 cu ft/D (14.65 psia and 60°F)
- r_i = internal radius of pipe, in.
- R_{gL} = gas to hydrocarbon liquid ratio, cu ft/bbl
- T = temperature, °F+460
- T_f = temperature of flowing gas, °F+460

- T_{pc} = temperature, pseudocritical, °F+460
 T_R = reservoir temperature
 V_L = vapor volume equivalent of 1 bbl (60°F) of hydrocarbon liquid, cu ft/bbl
 z = compressibility factor for gas
 Δ = difference between two values
 γ_g = specific gravity of separator gas or gas being measured, air = 1.000
 γ_{ff} = specific gravity of the flowing fluid, air = 1.000
 γ_L = specific gravity of hydrocarbon liquid referred to water

Wellbore Hydraulics

A.F. Bertuzzi, Phillips Petroleum Co.*

M.J. Fetkovich, Phillips Petroleum Co.

Fred H. Poettmann, Colorado School of Mines*

L.K. Thomas, Phillips Petroleum Co.

Introduction

Wellbore hydraulics is defined here as the branch of production engineering that deals with the motion of fluids (oil, gas, and water) in tubing, casing, or the annulus between tubing and casing. Consideration is given to the relationship among fluid properties, fluid motion, and the well system. More specifically, the material presented is intended to describe methods for solving problems associated with the determination of the relationship among pressure drop, fluid rates, and pipe diameters and length.

To maintain the scope of this section within prescribed limits, some material and data that are pertinent to the solving of wellbore problems, but which can be found conveniently elsewhere, are not presented. The material not covered includes (1) methods of measurement and (2) complete data on fluid properties (See Chaps. 13, 16–19, 24).

The theoretical discussion that follows provides a basis for the development of correlations and calculation procedures in subsequent parts of the section.

Theoretical Basis

Fluids in Motion

Energy Relationships. The energy relationships for a fluid flowing through tubing, casing, or annulus may be obtained by an energy balance. Energy is carried with the flowing fluid and also is transferred from the fluid to the surroundings or from the surroundings to the fluid. Energy carried with the fluid includes (1) internal energy, U , (2) energy of motion or kinetic energy ($mv^2/2g_c$), (3) energy of position (potential energy mgZ/g_c), and (4) pressure energy, pV . Energy transferred between a fluid and

its surroundings includes (1) heat absorbed or given up, Q , and (2) work done by the flowing fluid or on the flowing fluid, W .

The conservation of mass, or the first law of thermodynamics, states that the change in internal energy plus kinetic energy plus potential energy plus pressure energy is equal to zero. The following energy balance between points 1 and 2 in Fig. 34.1 and the surroundings illustrates the relationship for the previously listed energy terms for unit mass of fluid.

$$U_2 + \frac{v_2^2}{2g_c} + \frac{g}{g_c}Z_2 + p_2V_2 = U_1 + \frac{v_1^2}{2g_c} + \frac{g}{g_c}Z_1 + p_1V_1 + Q - W, \dots\dots\dots (1)$$

where

U = internal energy,

v = velocity,

g_c = conversion factor of 32.174,

g = acceleration of gravity,

Z = difference in elevation,

p = pressure,

V = specific volume,

Q = heat absorbed by system from surroundings, and

W = work done by the fluid while in flow.

This energy-balance equation is based on a unit mass of fluid flowing and assumes no net accumulation of material or energy between points 1 and 2 in the system.

*Authors of the original chapter on this topic in the 1962 edition included these authors and J.K. Welchon (deceased).

Fig. 34.1—Illustration of energy-balance relationship.

Eq. 1 also can be put in the form

$$\Delta U + \frac{\Delta v^2}{2g_c} + \frac{g}{g_c} \Delta Z + \Delta(pV) = Q - W. \quad (2)$$

since

$$\Delta U = \int_{S_1}^{S_2} T dS + \int_{V_1}^{V_2} p(-dV)$$

and

$$\int_{S_1}^{S_2} T dS = Q + E_t$$

where

T = temperature,
 S = entropy, and
 E_t = irreversible energy losses, and

$$\Delta(pV) = \int_{V_1}^{V_2} p dV + \int_{p_1}^{p_2} V dp.$$

Eq. 2 can be put in the more familiar form

$$\int_{p_1}^{p_2} V dp + \frac{\Delta v^2}{2g_c} + \frac{g}{g_c} \Delta Z = -W - E_t. \quad (3)$$

Since, in the system shown in Fig. 34.1, there is no work done by or on the flowing fluid, W is equal to zero and the following equation results.

$$\int_{p_1}^{p_2} V dp + \frac{\Delta v^2}{2g_c} + \frac{g}{g_c} \Delta Z = -E_t. \quad (4)$$

If flow is isothermal and the fluid is incompressible, Eq. 4 may be simplified to

$$\frac{\Delta p}{\rho} + \frac{\Delta(v^2)}{2g_c} + \frac{g}{g_c} \Delta Z = -E_t, \quad (5)$$

where ρ = density.

The dimensions of the energy terms in Eq. 5 are energy per unit mass of fluid, such as foot-pounds per pound. Quite often the force term is canceled (incorrectly) with that of the mass term resulting in the dimensions of length as of a column of fluid. For this reason, these terms frequently are referred to as "head," such as feet of the fluid. For most practical cases, the ratio g/g_c is essentially unity. Although the terms in Eq. 5 are sometimes expressed as feet of fluid, no serious error is involved. In fact, one can derive a very similar expression where the terms are expressed in feet of "head."

Eqs. 4 and 5 are the energy relationships that provide the basis for the computational methods of the sections to follow.

Irreversibility Losses. The use of Eqs. 4 and 5 requires a knowledge of E_t , the term that accounts for irreversibilities (such as friction) in the system. The term E_t can be expressed as follows¹:

$$E_t = \frac{fLv^2}{2g_cd}, \quad (6)$$

where f commonly is referred to as a friction factor, L is length, and d is pipe diameter. The friction factor, f , usually is expressed in terms of the physical variables of the system by correlations of experimental data.

For single-phase flow, the dimensionless friction factor, f , has been correlated in terms of the dimensionless Reynolds number $dv\rho/\mu$ with μ being viscosity. A relationship is also suggested by application of dimensional analysis to the variables involved. In either case the result is

$$f = F_1 \frac{(dv\rho)}{\mu}, \quad (7)$$

where F_1 is a function of Reynolds number.

Eq. 7 has been the basis for correlation of considerable experimental data for single-phase flow over the past years. Eqs. 5, 6, and 7 have been adapted to multiphase flow. Consideration of the character of pipe surfaces as absolute roughness, ϵ (that is, the distance from peaks to valleys in pipe-wall irregularities), which may be expressed as a dimensionless relative roughness factor, ϵ/d , has led to improvements in correlations of single-phase flow experimental data

$$f = F_2 \left[\left(\frac{dv\rho}{\mu} \right) \left(\frac{\epsilon}{d} \right) \right], \quad (8)$$

where F_2 is a function of Reynolds number and relative roughness.

Fig. 34.2—Friction factor as a function of Reynolds number with relative roughness as a parameter.

Fig. 34.2 shows the correlation for single-phase flow according to Eq. 8.² Similar plots are found in the literature in which other friction factors are plotted as a function of Reynolds number. Care must be taken to avoid confusion, as the same name and symbol are used for various multiples of f as plotted in Fig. 34.2.

The laminar-flow region, which extends up to a Reynolds number of 2,000, is represented by a straight-line relationship $f = 64/N_{Re}$ on Fig. 34.2. Between 2,000 and 4,000, flow is unstable. Above 4,000, turbulence prevails and the influence of the physical properties decreases as the Reynolds number increases. In fact, it is shown that at very high Reynolds numbers the friction factor depends solely on the relative roughness factor ϵ/d .

The preceding theoretical discussion concerning irreversibility losses is based on considerations involving single-phase flow. Nevertheless, the material presented will provide a basis for considerations involving both single- and multiphase flow that appear in the following sections.

Static Fluids

Many wellbore problems are associated with static-fluid columns, either oil, water, or gas, or combinations thereof. In the case of static-fluid columns, Eq. 4 is applicable in general and reduces to

$$\int_{p_1}^{p_2} V dp + \frac{g}{g_c} \Delta Z = 0 \quad (9)$$

or

$$\int_{p_1}^{p_2} \frac{dp}{\rho} + \frac{g}{g_c} \Delta Z = 0, \quad (10)$$

since $v^2/2g_c$ and E_t are equal to zero. Since g/g_c is assumed to be unity,

$$\int_{p_1}^{p_2} \frac{dp}{\rho} + \Delta Z = 0. \quad (11)$$

For the case of a static-liquid column, it is usually satisfactory to use an average density for the column of liquid. Eq. 11 then can be expressed in the more convenient and familiar form as

$$\Delta p = \rho \Delta Z. \quad (12)$$

The preceding equations will provide a basis for the calculation procedures of the following sections for static-fluid columns.

Producing Wells

Gas Wells

Calculation of Static Bottomhole Pressures (BHP's).

Static BHP's are used to determine the deliverability of gas wells (backpressure curve) and to develop reservoir information for predicting reservoir performance and deliverability. Several methods for calculating static BHP's have appeared in the literature.³⁻⁶ The methods differ primarily as a result of the assumptions made. All start with Eq. 9 assuming g/g_c is unity for a static column:

$$\int_{p_1}^{p_2} V dp + \Delta Z = 0.$$

Fig. 34.3—Pseudocritical properties of condensate well fluids and miscellaneous natural gases.

If the column is vertical, $\Delta Z = L$, where L is the length of the pipe string, and Eq. 9 can be put in the form

$$\int_{p_2}^{p_1} V dp = L. \quad (13)$$

If the column is not vertical, but inclined with the vertical by an angle θ ,

$$\Delta Z = L \cos \theta$$

and again using L , Eq. 9 becomes

$$\int_{p_2}^{p_1} V dp = L \sin \theta. \quad (14)$$

Subsequently, only the vertical column will be considered and Eq. 13 will be used. Since

$$V = \frac{zRT}{Mp}, \quad (15)$$

where

z = compressibility factor,
 R = gas constant, and
 M = molecular weight,

Eq. 13, upon substitution, becomes

$$\int_{p_2}^{p_1} \frac{zRT}{M} \frac{dp}{p} = L. \quad (16)$$

For a particular gas, R/M , which is equal to $53.241/\gamma_g$ where γ_g is the gas gravity (air=1.0), is a constant. Therefore, Eq. 16 can be simplified to

$$\frac{53.241}{\gamma_g} \int_{p_2}^{p_1} zT \frac{dp}{p} = L. \quad (17)$$

It is at this point where certain assumptions are made and calculation procedures differ. Assumptions are made in regard to z and T .

For any calculation procedure, four "surface" properties must be known: well-effluent composition, well depth, wellhead pressure, and well temperature. The gas composition is used to calculate the pseudocritical properties p_{pc} and T_{pc} of the gas, from which is estimated the value of the compressibility factor z used in the calculations. Quite often, gas composition is not available and gas gravity must be used to estimate the pseudocritical properties (Fig. 34.3).⁴

A recommended method assumes constant and average temperature T and allows z to vary with pressure. With temperature being constant, Eq. 17 becomes

$$\frac{53.241 \bar{T}}{\gamma_g} \int_{p_2}^{p_1} \frac{z}{p} dp = L. \quad (18)$$

The method using Eq. 18 was suggested by Fowler.³ Poettmann⁴ made the solution of Eq. 18 practical by presenting tables of the function

$$\int_{0.2}^{p_{pr}} \frac{z}{p_{pr}} dp_{pr}$$

in terms of p_{pr} and T_{pr} . The tables are presented here as Table 34.1.

It can be shown that

$$\int_{p_2}^{p_1} \frac{z}{p} dp = \int_{(p_{pr})_2}^{(p_{pr})_1} \frac{z}{p_{pr}} dp_{pr} = \int_{0.2}^{(p_{pr})_1} \frac{z}{p_{pr}} dp_{pr} - \int_{0.2}^{(p_{pr})_2} \frac{z}{p_{pr}} dp_{pr}. \quad (19)$$

An advantage of this method is that it is a *direct method of calculating BHP*. No trial and error is involved. In terms of p_{pr} and T_{pr} Eq. 18 becomes

$$L = \frac{53.241 \bar{T}}{\gamma_g} \left[\int_{0.2}^{(p_{pr})_1} \frac{z}{p_{pr}} dp_{pr} - \int_{0.2}^{(p_{pr})_2} \frac{z}{p_{pr}} dp_{pr} \right]. \quad (20)$$

By rearranging,

$$\int_{0.2}^{(p_{pr})_1} \frac{z}{p_{pr}} dp_{pr} = \frac{L \gamma_g}{53.241 \bar{T}} + \int_{0.2}^{(p_{pr})_2} \frac{z}{p_{pr}} dp_{pr}. \quad (21)$$

Eq. 21 permits a direct solution for the static BHP.

Example Problem 1.⁴ Calculate the static BHP of a gas well having a depth of 5,790 ft; the gas gravity is 0.60, and the pressure at the wellhead is 2,300 psia. The average temperature of the flow string is 117°F.

From Fig. 34.3,

$$T_{pc} = 358^\circ\text{R},$$

$$p_{pc} = 672 \text{ psia},$$

$$T_{pr} = \frac{T}{T_{pc}} = \frac{117 + 460}{358} = 1.612, \text{ and}$$

$$(p_{pr})_z = \frac{2,300}{672} = 3.423.$$

From Table 34.1,

$$\int_{0.2}^{(p_{pr})_z} \frac{z}{p_{pr}} dp_{pr} = 2.629$$

and

$$\frac{L\gamma_g}{53.241\bar{T}} = \frac{(5,790)(0.60)}{(53.241)(577)} = 0.113.$$

Therefore, from Eq. 21

$$\int_{0.2}^{(p_{pr})_z} \frac{z}{p_{pr}} dp_{pr} = 2.629 + 0.113 = 2.742.$$

From Table 34.1, 2.742 at a T_{pr} of 1.612 corresponds to a p_{pr} of 3.918. Then

$$p = 3.918(672) = 2,633 \text{ psia}.$$

If temperature is linear with depth,

$$T = aL + b \quad \dots\dots\dots (22)$$

and

$$dT = a \, dL, \quad \dots\dots\dots (23)$$

where a and b are constants. By substituting Eq. 23 in Eq. 17 and putting in the differential form, the following is obtained:

$$\frac{dT}{aT} = \frac{53.241z}{\gamma_g} \frac{dp}{p}, \quad \dots\dots\dots (24)$$

Integrating,

$$\frac{1}{a} \ln \frac{T_1}{T_2} = \frac{53.241}{\gamma_g} \int_{p_2}^{p_1} z \frac{dp}{p}, \quad \dots\dots\dots (25)$$

Since $a = (T_1 - T_2)/L$,

$$\frac{L/(T_1 - T_2)}{\ln T_1/T_2} = \frac{L}{T_{LM}} = \frac{53.241}{\gamma_g} \int_{p_2}^{p_1} z \frac{dp}{p}, \quad \dots\dots\dots (26)$$

then

$$L = \frac{53.241 T_{LM}}{\gamma_g} \int_{p_2}^{p_1} z \frac{dp}{p}, \quad \dots\dots\dots (27)$$

where

$$T_{LM} = \frac{T_1 - T_2}{\ln T_1/T_2};$$

T_1 and T_2 are, respectively, bottomhole and wellhead temperatures. It can be seen that Eq. 27 differs from Eq. 18 only in that here a log mean temperature T_{LM} is used, whereas Eq. 18 uses the arithmetic average temperature, \bar{T} .

Referring to the example as an illustration of the calculation procedure using the log-mean-temperature concept, T_{LM} merely is substituted for \bar{T} .

Another method of calculating static BHP in gas wells is based on the following equation.

$$p_1 = p_2 e^{0.01877 \gamma_g L / (\bar{T} \bar{z})}, \quad \dots\dots\dots (28)$$

Eq. 28 can be derived from Eq. 17 if an arithmetic average temperature \bar{T} and an arithmetic average compressibility factor \bar{z} are used. *The method using Eq. 28 is a trial-and-error procedure.* Values of p_1 are assumed to obtain a value of \bar{z} . p_1 then is calculated. The procedure is repeated until the values of p_1 are in agreement.

Example Problem 2. (Data used are from Ref. 5.) Given:

Well A

$$p_2 = 2,600 \text{ psia},$$

$$\gamma_g = 0.744,$$

$$L = 7,500 \text{ ft},$$

$$\bar{T} = 152.5^\circ\text{F} = 612.5^\circ\text{R},$$

$$p_{pc} = 663.8 \text{ psia (from Fig. 34.3), and}$$

$$T_{pc} = 385.6^\circ\text{R (from Fig. 34.3)}.$$

First Trial. Assume:

$$p_1 = 3,100 \text{ psia},$$

$$\bar{p} = 2,850 \text{ psia},$$

$$p_{pr} = 2,850/663.8 = 4.30,$$

$$T_{pr} = 612.5/385.6 = 1.59, \text{ and}$$

$$\bar{z} = 0.820.$$

Therefore,

$$\begin{aligned} e^{0.01877 \gamma_g L / (\bar{T} \bar{z})} &= e^{[(0.01877)(0.744)(7,500)] / [(612.5)(0.820)]} \\ &= e^{0.2082} \\ &= 1.2239. \end{aligned}$$

$$p_1 = (2,600)(1.2239) = 3,182 \text{ calculated.}$$

Second Trial. Assume:

$$\begin{aligned} p_1 &= 3,182 \text{ psia,} \\ \bar{p} &= 2,891 \text{ psia,} \\ p_{pr} &= 2,891/663.8 = 4.36, \\ T_{pr} &= 1.59, \text{ and} \\ \bar{z} &= 0.821. \end{aligned}$$

Therefore,

$$\begin{aligned} p_1 &= (2,600)(e^{0.2082}), \\ &= (2,600)(1.2239) \\ &= 3,182 \text{ psia calculated check.} \end{aligned}$$

Measured pressure at 7,500 ft equals 3,193 psia.

Calculation of Flowing BHP's: Flow in Tubing. Flowing BHP (BHFP) of a gas well when used with the known static formation pressure provides the basis for evaluating the well's deliverability. In wells that produce through tubing and have no packer, the static column of gas in the tubing-casing annulus is exposed to the producing formation. In this case, BHFP, or sandface pressure, can be determined by the relatively simple procedure of calculating the pressure at the bottom of the static column of gas in the annular space. The preceding section describes this calculation procedure. Where a gas well is equipped with a tubing-casing packer, it becomes necessary to use the flowing-gas column in calculating the BHFP.

Use of the flowing-gas column means that energy changes resulting from frictional effects, as well as the energy differences caused by the compressional effects and potential-energy changes, enter into the calculations.

Several methods have been developed for calculating the pressure drop in flowing-gas columns.^{4,6,7} Sukkar and Cornell's method⁶ is described in detail. Raghaven and Ramey⁸ extended Sukkar and Cornell's method to cover reduced temperatures to 3.0 and reduced pressures to 30. In a subsequent section that deals with gas flow in injection wells, Poettmann's⁴ method is described. Poettmann's method can be used for upward flow also.

The basic energy equation, Eq. 3, for any flowing fluid in differential form is

$$Vdv + \frac{g}{g_c} dZ - dE_f - dW = 0. \quad (29)$$

Assuming that the kinetic-energy term is small and can be taken as zero, and recognizing that dW , work done by or on the fluid, is zero, Eq. 29 reduces to

$$Vdv + \frac{g}{g_c} dZ + dE_f = 0. \quad (30)$$

For vertical gas flow, $dZ = dL$. Since

$$V = \frac{zRT}{Mp} \quad (15)$$

and

$$\frac{g}{g_c} = 1.0$$

and

$$dE_f = \frac{fv^2 dL}{2g_c d}, \quad (31)$$

Eq. 30, upon substitution, becomes

$$\frac{RzTd p}{Mp} + \left(1 + \frac{fv^2}{2g_c d}\right) dL = 0. \quad (32)$$

Velocity can be expressed in terms of volumetric flow rate and pipe diameter. Pressure can be expressed in terms of reduced pressure. Substituting these terms in Eq. 32, integrating the equation, and converting to common units results in

$$\int_{(p_{pr})_1}^{(p_{pr})_2} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2} = -0.01877 \gamma_g \int_{L_1}^{L_2} \frac{dL}{T} \quad (33)$$

where

$$B = \frac{667 f q_g^2 \bar{T}^2}{d_i^5 p_{pc}^2},$$

γ_g = gas gravity (air=1.0),

L = length of flow string, ft,

T = temperature, °R,

\bar{T} = average temperature, °R,

f = friction factor, dimensionless,

q_g = flow rate, 10⁶ cu ft/D referred to 14.65 psia and 60°F,

d_i = inside diameter of pipe, in.,

p_{pc} = pseudocritical pressure, psia, and

p_{pr} = pseudoreduced pressure p/p_{pc} .

At this point, it is further assumed that temperature is constant at some average value. This permits direct integration of the right side of Eq. 33, as

$$\int_{(p_{pr})_2}^{(p_{pr})_1} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2} = \frac{0.01877}{\bar{T}} \gamma_g L, \quad (34)$$

where the limits of the integral are inverted to change the sign. If the temperature is linear with depth, the use of log mean temperature as the average temperature provides a rigorous solution to the right side of Eq. 34. This use of log mean temperature confines the effect of the assumption of constant temperature to the left side of the equation, where, for practical purposes, it is extremely small. Thus, errors introduced by the assumption of constant temperature are negligible.

(continued on Page 34-23)

TABLE 34.2—EXTENDED SUKKAR-CORNELL INTEGRAL FOR BHP CALCULATION

$$\int_0^{p_{pr}} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2}$$

Pseudoreduced temperature for $B = 0.0$

The integral function on the left side of Eq. 34 can be evaluated by use of Table 34.2 from Ref. 8. These tables were prepared by using an arbitrary reference point of p_{pr} of 0.2. Evaluation of the integral is based on the following relationships:

$$\int_{(p_{pr})_1}^{(p_{pr})_2} \frac{(z/p_{pr}) dp_{pr}}{1+B(z/p_{pr})^2} = \left[\int_{0.2}^{(p_{pr})_1} \frac{(z/p_{pr}) dp_{pr}}{1+B(z/p_{pr})^2} \right] - \left[\int_{0.2}^{(p_{pr})_2} \frac{(z/p_{pr}) dp_{pr}}{1+B(z/p_{pr})^2} \right] = \frac{0.01877 \gamma_g L}{\bar{T}} \quad \dots (35)$$

Since the tables and charts provide numerical values for the bracketed terms in Eq. 35, a calculation of flowing BHP can be obtained directly, with only simple mathematics being involved.

In the previous and subsequent calculation procedures, the diameter of the flow string enters into the calculations as the fifth power. It is important, therefore, that the exact dimensions of the flow string be used rather than nominal flow-string sizes. Table 34.3 lists the pertinent information on various flow-string sizes.

The effect of assuming a constant average temperature over the entire gas column in Eqs. 17, 21, and 35 can be mitigated by taking only small increments of depth from top to bottom and using a constant temperature for each increment of depth. Assuming a linear temperature gradient, the average temperature for each depth increment can be calculated. The larger the number of depth increments taken in calculating the pressure traverse, the closer one approximates the rigorous integration of the equations.

Example Problem 3. Calculate the BHP of a flowing-gas well. Given:

length of vertical pipe, $L = 10,000$ ft,
tubing ID, $d_{ti} = 2.00$ in.,
gas-flow rate, $q_g = 4.91 \times 10^6$ cu
ft/D,

flowing wellhead pressure, $p_2 = 1,980$ psia,
average flowing temperature, $\bar{T} = 636^\circ\text{R}$,
gas gravity (air=1.0), $\gamma_g = 0.750$,
 $p_{pc} = 660$ psia,
 $T_{pc} = 400^\circ\text{R}$, and
 $f = 0.016$.

Solution.

1. Calculate B .

$$B = \frac{667 f q_g^2 \bar{T}^2}{d_{ti}^5 p_{pc}^2} = \frac{(667)(0.016)(4.91)^2 (636)^2}{(2.00)^5 (660)^2} = 7.48.$$

2. Calculate $\frac{0.01877 \gamma_g L}{\bar{T}}$.

$$\frac{0.01877 \gamma_g L}{\bar{T}} = \frac{(0.01877)(0.750)(10,000)}{636} = 0.2213.$$

3. Calculate pseudoreduced wellhead pressure and pseudoreduced average temperature,

$$(p_{pr})_1 = \frac{1,980}{660} = 3.0$$

and

$$\bar{T}_{pr} = \frac{636}{400} = 1.59.$$

4. For $\bar{T}_{pr} = 1.59$, read from Table 34.2.

$$\int_{0.2}^{(p_{pr})_1} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2} = 0.4246.$$

$$5. \text{ Add } \frac{0.01877\gamma_g L}{\bar{T}} \text{ to } \int_{0.2}^{(p_{pr})_1} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2}.$$

$$0.4246 + 0.2213 = 0.6459.$$

6. From Table 34.2 find the pseudoreduced pressure corresponding to

$$\int_{0.2}^{(p_{pr})_1} \frac{(z/p_{pr}) dp_{pr}}{1 + B(z/p_{pr})^2} = 0.6459.$$

$$(p_{pr})_1 = 4.358.$$

7. Multiply $(p_{pr})_1$ by p_{pc} to obtain BHP.

$$p_1 = 4.358 \times 660 = 2,876 \text{ psia.}$$

Another procedure for calculating the BHP of flowing gas wells that has found widespread use since its adoption by various state regulatory agencies is that of Cullender and Smith.⁷ The method avoids the assumption of a constant average temperature by including the temperature within the integral.

$$18.75\gamma_g L = \int_{p_2}^{p_1} \frac{[p/(Tz)] dp}{F^2 + 0.001[p/(Tz)]^2}, \quad (36)$$

where

$$F^2 = (2.6665 f_f q_g^2) / d_i^5, \quad (37)$$

f_f is the Fanning friction factor and is equal to $f_f = f/4$, and f is the Moody friction factor from Fig. 34.2

Eq. 37 can be simplified by using the Nikuradse friction factor equation for fully turbulent flow and for an absolute roughness of 0.0006 in.:

$$F = F_r q_g = \frac{0.10797 q_g}{d_i^{2.612}}, \quad (38)$$

where $d_i < 4.277$ in. and

$$F = F_r q_g = \frac{0.10337 q_g}{d_i^{2.582}}, \quad (39)$$

where $d_i > 4.277$ in. Values of F_r are presented in Table 34.4 for various tubing and casing sizes.⁷

The right side of Eq. 36 may be integrated numerically by employing a two-step trapezoidal integration:

$$18.75\gamma_g L = \frac{(p_m - p_2)(I_m + I_2)}{2} + \frac{(p_1 - p_m)(I_1 + I_m)}{2}, \quad (40)$$

where

$$I = \frac{p/(Tz)}{F^2 + 0.001[p/(Tz)]^2}$$

and

$$p_m = p_1 + (p_1 + p_2)/2.$$

Eq. 40 may be separated into two expressions, one for each half of the flow string.

$$18.75\gamma_g L = (p_m - p_2)(I_m + I_2) \quad (41)$$

for the upper half, and

$$18.75\gamma_g L = (p_1 - p_m)(I_1 + I_m) \quad (42)$$

for the lower half.

By trial and error, p_m is calculated from Eq. 41. p_1 then is calculated in a similar manner by using the value of I_m from Eq. 41 and substituting in Eq. 42.

Simpson's rule then is employed to obtain a more accurate value of the BHP.

$$18.75\gamma_g L = \left(\frac{p_2 - p_1}{6} \right) (I_2 + 4I_m + I_1). \quad (43)$$

Rather than using the two-step trapezoidal integration to make the first estimate of the BHP, Simpson's rule may be used directly and the BHP calculated by trial and error.

As this indicates, the Cullender and Smith method involves tedious trial and error solution if hand calculated. The method is best solved by computer. Quoting Ref. 8,

Because the Cullender and Smith method considers both temperature and Z to be functions of pressure, it might appear that this method is somewhat more accurate than the Sukkar-Cornell approach. This is only an apparent advantage. If temperature is known in the gas column, it is possible to break the depth into several increments, each with one appropriate mean temperature.

This was alluded to previously. The Sukkar-Cornell method is an accurate, fast hand calculation procedure that avoids trial and error calculations. It is also amenable to computer solution.

Example Problem 4.⁹ Calculate the flowing BHP by the method of Cullender and Smith from the following well data:

gas gravity, $\gamma_g = 0.75$,
length of vertical pipe, $L = 10,000$ ft,
wellhead temperature, $T_2 = 570^\circ\text{R}$,
formation temperature, $T_1 = 705^\circ\text{R}$,
wellhead pressure, $p_2 = 2,000$ psig,
flowrate, $q_g = 4.915 \times 10^6$ cu
ft/D,
tubing ID, $d_{ti} = 2.441$ in.,
pseudocritical temperature, $T_{pc} = 408^\circ\text{R}$, and
pseudocritical pressure, $p_{pc} = 667$ psi.

$$\bar{T} = \frac{T_1 + T_2}{2} = \frac{570 + 705}{2} = 638^\circ\text{R},$$

$$\text{wellhead } T_{pr} = \frac{T_2}{T_{pc}} = \frac{570}{408} = 1.397,$$

$$\text{midpoint } T_{pr} = \frac{\bar{T}}{T_{pc}} = \frac{638}{408} = 1.564,$$

$$\text{bottom } T_{pr} = \frac{T_1}{T_{pc}} = \frac{705}{408} = 1.728,$$

$$\text{wellhead } p_{pr} = \frac{p_2}{p_{pc}} = \frac{2,000}{667} = 2.999,$$

$$F = \frac{(0.10797)(4.915)}{(2.441)^{2.612}} = 0.05158,$$

and $F^2 = 0.00266$.

Left side of Eq. 36,

$$18.75 \gamma_g L = (18.75)(0.75)(10,000) \\ = 140,625.$$

Calculate I_2 . From the compressibility factor chart (see Chap. 20) $z_2 = 0.705$. Therefore,

$$\frac{p_2}{T_2 z_2} = \frac{2,000}{(570)(0.705)} = 4.977$$

and

$$I_2 = \frac{4.977}{0.00266 + 0.001(4.977)^2} = 181.44.$$

Assume $I_2 = I_m$. Solving Eq. 41 for p_m ,

$$140,625 = (p_m - 2,000)(181.44 + 181.44),$$

$$p_m = 2,388 \text{ psia.}$$

TABLE 34.4—VALUES OF F_r FOR VARIOUS TUBING AND CASING SIZES

* Use only for internal diameters less than 4.277 in.

** Use only for internal diameters greater than 4.277 in.

Second trial:

$$p_{pr} = \frac{p_m}{p_{pc}} = \frac{2,388}{667} = 3.580,$$

$$z_m = 0.800 \text{ at } T_{pr} = 1.564, p_{pr} = 3.580,$$

$$\frac{p_m}{T_m z_m} = \frac{2,388}{(638)(0.800)} = 4.679,$$

and

$$I_m = \frac{4.679}{(0.00266) + 0.001(4.679)^2} = 190.57.$$

Solving Eq. 41 for p_m ,

$$140,625 = (p_m - 2,000)(190.57 + 181.44)$$

and

$$p_m = 2,378 \text{ psia.}$$

Third trial:

$$p_{pr} = \frac{p_m}{p_{pc}} = \frac{2,378}{667} = 3.565,$$

$$z_m = 0.800 \text{ at } T_{pr} = 1.564, p_{pr} = 3.565,$$

$$\frac{p_m}{T_m z_m} = \frac{2,378}{(638)(0.800)} = 4.659,$$

and

$$I_m = \frac{4.659}{0.00266 + 0.001(4.659)^2} = 191.21.$$

Solving Eq. 41 for p_m ,

$$140,625 = (p_m - 2,000)(191.21 + 181.44),$$

therefore

$$p_m = 2,377 \text{ psia.}$$

For the lower half of the flow string assume $I_1 = I_m = 191.21$. Solving Eq. 42 for p_1 ,

$$140,625 = (p_1 - 2,377)(191.21 + 191.21),$$

$$p_1 = 2,745 \text{ psia.}$$

Second trial:

$$p_{pr} = \frac{p_1}{p_{pc}} = \frac{2,745}{667} = 4.115,$$

$$z_1 = 0.869 \text{ at } T_{pr} = 1.728, p_{pr} = 4.115,$$

$$\frac{p_1}{T_1 z_1} = \frac{2,745}{(705)(0.869)} = 4.481$$

and

$$I_1 = \frac{4.481}{0.00266 + 0.001(4.481)^2} = 197.06.$$

Solving Eq. 42 for p_1 ,

$$140,625 = (p_1 - 2,377)(197.06 + 191.21),$$

$$p_1 = 2,739 \text{ psia.}$$

Third trial:

$$p_{pr} = \frac{p_1}{p_{pc}} = \frac{2,739}{667} = 4.106,$$

$$z_1 = 0.869 \text{ at } T_{pr} = 1.728, p_{pr} = 4.106,$$

$$\frac{p_1}{T_1 z_1} = \frac{2,739}{(705)(0.869)} = 4.471,$$

and

$$I_1 = \frac{4.471}{0.00266 + 0.001(4.471)^2} = 197.40.$$

Solve Eq. 42 for p_1 .

$$140,625 = (p_1 - 2,377)(197.40 + 191.21),$$

$$p_1 = 2,739 \text{ psia.}$$

Using Simpson's rule from Eq. 43,

$$140,625 = \frac{(p_1 - p_2)}{6} \times [181.44 + 4(191.21) + 197.40],$$

$$p_1 - p_2 = 738,$$

and

$$p_1 = 738 + 2,000 = 2,738 \text{ psia.}$$

A simplified method for calculating flowing BHP of gas wells results if an effective average temperature and an effective average compressibility are used over the length of the flow string. Low-pressure wells at shallow depths or wells where pressure drop is small are especially well suited for this method. With the usual assumptions that kinetic energy is negligible, g/g_c equals unity, etc., the following equation for vertical gas flow has been developed by Smith¹⁰:

$$p_{bh}^2 - e^s p_{th}^2 = \frac{25 f q_g^2 \bar{T}^2 \bar{z}^2 (e^s - 1)}{0.0375 d_i^5}, \dots \dots \dots (44)$$

where

$$\begin{aligned} p_{bh} &= \text{BHP, psia,} \\ p_{th} &= \text{tophole pressure, psia,} \\ f &= \text{friction factor, dimensionless, from Fig. 34.2,} \\ q_g &= \text{gas flow rate, } 10^6 \text{ cu ft/D referred to 14.65 psia and } 60^\circ\text{F,} \\ s &= \text{exponent of } e = \frac{0.0375\gamma_g L}{T\bar{z}}, \\ \gamma_g &= \text{gas gravity (air=1.0),} \\ L &= \text{length of vertical flow string, ft,} \\ \bar{T} &= \text{average temperature, } ^\circ\text{R,} \\ \bar{z} &= \text{average compressibility of gas, dimensionless,} \\ d_i &= \text{internal diameter of flow string, in., and} \\ e &= \text{natural logarithm base=2.71828.} \end{aligned}$$

The method using Eq. 44 is also a trial and error procedure.

In evaluating the friction factor for commercial pipe, Smith¹⁰ and Cullender and Binckley¹¹ have shown from an analysis of flow data that average absolute values of roughness, 0.00065 and 0.0006 in., respectively, are the correct values to use for clean commercial pipe. For an absolute roughness of 0.0006 in., Cullender and Binckley¹¹ derived an expression for the friction factor as defined in Fig. 34.2, as a power function of the Reynolds number and pipe diameter. In terms of field units,

$$f = 30.9208 \times 10^{-3} \frac{q_g^{-0.065} d_i^{-0.058} \gamma_g^{-0.065}}{\mu_g^{-0.065}}, \quad (45)$$

where

$$\begin{aligned} q_g &= \text{gas flow rate, } 10^6 \text{ cu ft/D,} \\ d_i &= \text{internal diameter of flow string, ft,} \\ \gamma_g &= \text{gas gravity (air=1.0), and} \\ \mu_g &= \text{gas viscosity, lbm/ft-sec.} \end{aligned}$$

Flow Through a Tubing-Casing Annulus. The flow equations that relate to flow through a circular pipe, when properly modified, can be used for conditions where flow is through an annular space. This modification involves determining the hydraulic radius of the annular cross section and using the friction factor obtained for an "equivalent" (i.e., having the same hydraulic radius) circular pipe. The hydraulic radius is defined as the area of flow cross section divided by the wetted perimeter. For a circular pipe,

$$r_H = \frac{\pi d_i^2 / 4}{\pi d_i} = \frac{d_i}{4}. \quad (46)$$

For a tubing-casing annulus,

$$r_H = \frac{(\pi/4)(d_{ci}^2 - d_{to}^2)}{\pi(d_{ci} + d_{to})} = \frac{d_{ci} - d_{to}}{4}, \quad (47)$$

where

$$\begin{aligned} d_{ci} &= \text{inside diameter of casing, ft,} \\ d_{to} &= \text{outside diameter of tubing, ft, and} \\ r_H &= \text{hydraulic radius, ft.} \end{aligned}$$

The diameter of an equivalent circular pipe, thus, would be

$$d_{eq} = d_{ci} - d_{to}. \quad (48)$$

Modification of Eq. 32 for annular flow involves only substituting d_{eq} for d_i . Likewise d_{eq} replaces d_i when determining friction factor (from the Reynolds-number plot, Fig. 34.2). However, the simplification of Eq. 32 includes velocity expressed as a function of diameter and volumetric flow rate, and so d_i^5 in B of Eq. 33 and in Eq. 44 becomes

$$d_i^5 = (d_{ci} + d_{to})^2 (d_{ci} - d_{to})^3. \quad (49)$$

Gas/Water Flow

The effect of water production on calculated pressure drop for gas wells operating in mist flow can be included by using an average density assuming zero slip velocity and by using total rate in the friction loss term. The volumetric average density can be calculated as

$$\bar{\rho} = \frac{q_g \rho_g + q_w \rho_w}{q_g + q_w}$$

where $\bar{\rho}$ is the average density at flowing conditions and q is the volumetric flow rate at flowing conditions. To include the effect of water in the Cullender and Smith calculation, modify the integrand, I , as follows (see Page 24):

$$I = \frac{[p/(Tz)](\bar{\rho}/\rho_g)}{F^2 \left(\frac{q_g + q_w}{q_g} \right)^2 + 0.001[p/(Tz)]^2 (\bar{\rho}/\rho_g)^2}$$

Gas-Condensate Wells

Calculation of BHP. Calculations of BHP on gas-condensate wells are based on equations previously presented for gas wells. The application of these equations may be limited somewhat by the amount of liquid present in the flow string.

Upon shutting in a gas-condensate well, part of the liquids that were being carried in the flow stream may fall back and accumulate in the bottom of the wellbore. For this reason, it is advisable to determine whether or not such a static liquid level exists in a gas-condensate well before relying on a BHP calculated from surface measurements. When the location of the static liquid level is known, the gas calculations can be used to determine the pressure at the gas-liquid interface and the length of the liquid column. An estimated liquid density will provide the additional pressure needed to determine pressure at formation level.

Fig. 34.4—Gas/gravity ratio vs. condensate/gas ratio as a function of condensate gravity.

In the flow equations for gas, the gas gravity is the flow-stream gravity. This is calculated for condensates from the following¹²:

$$\gamma_g = \frac{(\gamma_g)_{sp} + (4,591\gamma_L/R_{gL})}{1 + (1.123/R_{gL})}, \quad (50)$$

where

$(\gamma_g)_{sp}$ = separator gas gravity (air=1),
 γ_L = specific gravity of condensate, and
 R_{gL} = gas-liquid ratio, cu ft/bbl.

Nisle and Poettmann¹³ published a simple correlation based on field data (Fig. 34.4) that can be used to calculate the flow-stream gravity of the entrained mixture such as occurs in the case of a flowing gas-condensate well.

Accuracy of the flow equations for gas, as modified for gas-condensate wells, is influenced by the amount of liquid in the flow stream. The higher the gas-liquid ratio, the more accurate the calculated results will be.

Injection Wells

Petroleum-production operations often involve the injection of fluids into the subsurface formation, as is the case in waterflooding, pressure maintenance, gas cycling, and designing gas lift installations. Therefore, it becomes desirable to have a means of predicting the variation of pressure with depth for the vertical downward flow of fluids. Eqs. 29 and 30, previously discussed, form the basis of any specific fluid-flow relationship. They contain no limiting assumptions other than those arrived at in deriving Eq. 30 from Eq. 29. The only difference in applying Eq. 30 to vertical downward flow when compared with upward flow is that the integration limits are changed; that is, the sign of the *absolute values* of potential energy then changes and, depending on the rate of injection in the case of gas injection, the absolute value of the compressional energy change may vary from positive to negative. In other words, at low flow rates, the BHP is greater than the surface pressure; whereas, at high flow rates, the BHP is less than the surface pressure.

Liquid Injection

Calculation of Injection BHP. For isothermal flow of incompressible fluid, assuming $g/g_c = 1$, and integrating between limits of the top and bottom of the hole, Eq. 30 may be written as follows:

$$\frac{\Delta p}{\rho} + \Delta Z + E_f = 0, \quad (51)$$

(Since the datum plane is at the surface, ΔZ will be a negative number.) Then

$$p_2 = p_1 - \Delta Z \rho - E_f \rho, \quad (52)$$

since $-\Delta Z = D$, the depth. Therefore,

$$p_2 = p_1 + D\rho - E_f \rho. \quad (53)$$

Since $E_f = fv^2 D / 2g_c d_i$ (Fig. 34.2),

$$p_2 = p_1 + D\rho - \frac{fv^2 D \rho}{2g_c d_i}. \quad (54)$$

Converting pressure units to pounds per square inch,

$$p_2 = p_1 + \frac{D\rho}{144} - \frac{fv^2 D \rho}{288g_c d_i}, \quad (55)$$

where

p_2 = bottomhole pressure, psia, at depth D ,
 p_1 = surface pressure, psia,
 D = depth of well, ft,
 ρ = density of injected fluid, lbm/cu ft,
 f = friction factor (Fig. 34.2),
 v = fluid velocity, ft/sec,
 d_i = internal diameter of pipe, ft, and
 g_c = 32.2 conversion factor.

Eq. 55 reveals that the BHP for the case of incompressible flow as assumed for liquid injection into a wellbore is simply the surface pressure plus the pressure from the "weight of the liquid column" minus the pressure drop caused by frictional effects. For no flow, it reduces to the well-known expression for a static-fluid column

$$p_2 = p_1 + \frac{D\rho}{144}. \quad (56)$$

Gas Injection

Calculation of Injection BHP. Starting with the general differential equation, Eq. 30, Poettmann⁴ derived an expression for calculating the sandface pressure of flowing-gas wells in which the variation of the compressibility factor of the gas with pressure is taken into consideration. The same integral factor as given in Table 34.1 is employed for the calculation of static BHP in Table 34.5.

By following the same reasoning as in the previous section, the equation can be rearranged so that the pressure traverse for vertical flow downward can be calculated as follows:

$$D = \frac{D_s}{\{0.9521 \times 10^{-6} [f q_g^2 \gamma_g^2 D_s^2 / d_{ti}^5 (\Delta p)^2]\} - 1}, \quad (57)$$

where

$$\begin{aligned} D &= \text{depth of well, ft,} \\ \Delta p &= p_2 - p_1, \text{ psia,} \\ d_{ti} &= \text{ID of tubing, ft,} \\ q_g &= \text{gas flow, } 10^6 \text{ cu ft/D at 14.65 psia and } 60^\circ\text{F,} \\ f &= \text{friction factor (Fig. 34.2), and} \\ D_s &= D \text{ under static conditions (static equivalent depth for pressures encountered at flowing conditions)} \\ &= \frac{53.241 \bar{T}}{\gamma_g} \end{aligned}$$

$$\times \left[\int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} - \int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} \right].$$

Using the expression for the friction factor as derived by Cullender and Binckley¹¹ (Eq. 45) and substituting in Eq. 57 gives

$$D = \frac{D_s}{\{2.944 \times 10^{-8} [q_g^{1.935} \gamma_g^{1.935} D_s^2 / (d_{ti}^{5.058} \mu^{0.065}) (\Delta p)^2]\} - 1}, \quad (58)$$

Cullender and Smith's Eq. 36 also can be rearranged to calculate the BHP for the case of gas injection as follows:

$$18.75 \gamma_g D = \int_{p_1}^{p_2} \frac{[p/(Tz)] dp}{0.001 \left(\frac{p}{Tz} \right)^2 - F^2}. \quad (59)$$

The solution of this equation is identical to that previously described for flowing gas wells. D , depth of well, can be used interchangeably with L , length of flow string, when the well is vertical.

Similarly, by considering the downward flow of gas, the simplified equation developed by Smith¹⁰ for upward flow (Eq. 44) can be rearranged so that the pressure traverse for vertical flow downward can be calculated.

$$e^s p_{th}^2 - p_{bh}^2 = \frac{25 f q_g^2 \bar{T}^2 z (e^s - 1)}{0.0375 d_i^5}. \quad (60)$$

The nomenclature is the same as used in the corresponding Eq. 44.

In the case of gas injection down the annulus of a well, d_{ti}^5 of Eq. 57 (or d_i^5 of Eq. 60) is replaced as defined in Eq. 49; that is,

$$d_i^5 = (d_{ci} + d_{to})^2 (d_{ci} - d_{to})^3.$$

In the case of annulus injection using Eq. 58, $d_{ti}^{5.058}$ is replaced as follows:

$$d_i^{5.058} = (d_{ci} + d_{to})^{1.935} (d_{ci} - d_{to})^{3.123}. \quad (61)$$

Eqs. 57 through 60 provide a basis for calculating the BHP in a gas-injection well. In solving Eqs. 57 and 58, the calculating procedure is to assume a pressure p_2 and solve for the corresponding depth, D . The depth, D , so found will be the depth at which pressure p_2 occurs. By calculating several such points, a pressure-depth traverse can be plotted from which the pressure at the desired depth can be determined.

It is apparent that BHP during gas injection can be either greater or less than tophole pressure depending on the energy losses encountered. At low rates of flow, the pressure gradient is positive, whereas at high flow rates, the pressure gradient is negative. This is because, as flow rate increases, energy or frictional losses increase and they can be overcome only by a decrease in the change of compression energy or pV energy of the system. The decrease in potential energy resulting from elevation is constant and the change in kinetic energy is negligible. This can be illustrated by examining and rearranging Eq. 4 and considering the kinetic energy negligible.

$$\int_{p_1}^{p_2} V dp + E_f = - \frac{g}{g_c} \Delta Z. \quad (62)$$

For low flow rates,

$$\int_{p_1}^{p_2} V dp$$

is positive and E_f is always positive; thus, the sum of the compression energy and energy losses must equal the change in potential energy, which for a given depth is constant (the absolute value of $-\Delta Z$ is positive for gas injection since the absolute value of ΔZ is negative).

As E_f increases with flow rate, the

$$\int_{p_1}^{p_2} V dp$$

must decrease for the sum to remain constant. When E_f is equal to $(g/g_c) \Delta Z$, the pressure at the top and bottom of the hole is the same. This means that the decrease in potential energy is equal to the frictional losses. As E_f further increases, the added energy to overcome friction losses must come from the compressional energy since $-(g/g_c) \Delta Z$ is constant. This then means that the pressure gradient is negative.

TABLE 34.5—SAMPLE CALCULATIONS

Δp	p	p_{pr}	$\int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr}$	$\int_{(p_{wf})}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr}$	D_s	D	Depth corresponding to p of column (2)
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
	680	1.015	1.586				0
20	700	1.045	1.611	0.025	1.278	-1.460	1,460
20	720	1.074	1.636	0.025	1.278	-1.460	2,920
20	740	1.104	1.662	0.026	1.329	-1.532	4,452

Example Problem 5. Calculate the pressure at 4,000 ft in a gas injection well. Given:

tubing ID, $d_{ti} = 0.1663$ ft,
gas flow rate, $q_g = 0.783 \times 10^6$ cu
ft/D,

average temperature, $T = 600^\circ\text{R}$,
wellhead injection pressure, $p_1 = 680$ psia,
gas gravity, $\gamma_g = 0.625$, and
gas viscosity, $\mu_g = 8.74 \times 10^{-6}$
lbm/ft-sec.

Solution.

1. Substitute given values in Eq. 58.

$$D = \frac{D_s}{\frac{2.944 \times 10^{-8} (0.783)^{1.935} (0.625)^{1.935} D_s^2}{(0.1663)^{5.058} (8.75 \times 10^{-6})^{-0.065} (\Delta p)^2} - 1}$$

$$= \frac{D_s}{\frac{(3.00 \times 10^{-5}) D_s^2}{(\Delta p)^2} - 1}$$

and

$$D_s = \frac{53.241(600)}{0.625} \left[\int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} - \int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} \right] = 51,100 \left[\int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} - \int_{0.2}^{(p_{pr})} \frac{z}{p_{pr}} dp_{pr} \right]$$

2. Determine p_{pc} and T_{pc} (Fig. 34.3).

$$p_{pc} = 670 \text{ psia}$$

and

$$T_{pc} = 365^\circ\text{R},$$

therefore,

$$T_{pr} = \frac{\bar{T}}{T_{pc}} = \frac{600}{365} = 1.64.$$

3. Assume values for Δp and solve for D (Table 34.5).
4. From plot of Col. 2 vs. Col. 8 read pressure at 4,000 ft to be 734 psia.

Oil Wells

Inflow Performance

The simplest and most widely used inflow performance or backpressure equation used to determine stabilized or pseudosteady-state flow at any backpressure p_{wf} is given by the productivity index (PI) equation as

$$q_o = J(\bar{p}_R - p_{wf}), \quad (63)$$

In terms of measured data the PI is represented as

$$J = \frac{q_o}{\bar{p}_R - p_{wf}}, \quad (64)$$

where

J = stabilized productivity index, STB/D-psi,

q_o = measured stabilized surface oil flow rate, STB/D,

p_{wf} = wellbore stabilized flowing pressure, psia, and

\bar{p}_R = average reservoir pressure, psia.

J is defined specifically as a PI determined from flow rate and pressure drawdown measurements. It normally varies with increasing drawdown (i.e., is not a constant value). In terms of reservoir variables, the stabilized or pseudosteady-state PI J^* at zero drawdown or as $p_{wf} \rightarrow p_R$ can be written as

$$J^* = \frac{7.08kh}{\left[\ln \left(\frac{r_e}{r_w} \right) - \frac{3}{4} + s \right]} \left(\frac{k_{ro}}{\mu_o B_o} \right)_{p_R}, \quad (65)$$

where

J^* = stabilized PI at zero drawdown, STB/D-psi,

k = effective permeability, darcy,

k_{ro} = relative permeability to oil, fraction,

h = formation thickness, ft,

μ_o = oil viscosity, cp (evaluated at \bar{p}_R),

B_o = oil formation volume factor, RB/STB (evaluated at \bar{p}_R),

r_e = external boundary radius, ft,

r_w = wellbore radius, ft, and

s = skin effect, dimensionless.

J^* is the special definition of PI J at a vanishing pressure drawdown (i.e., as p_{wf} approaches \bar{p}_R). PI for a well is defined uniquely only at a zero drawdown.

Although this discussion will be limited to the pseudo-steady state, a transient form of the flow coefficient $J_{(t)}^*$ also is given for completeness.

$$J_{(t)}^* = \frac{7.08kh}{\left(\ln \sqrt{\frac{14.23kt}{\phi \mu c_t r_w^2}} + s\right)} \left(\frac{k_{ro}}{\mu_o B_o}\right)_{p_R}, \dots (66)$$

where t is time, days, ϕ is porosity, fraction, and c_t is total compressibility, psi^{-1} .

The above equations are perfectly valid for single-phase flow (i.e., p_R and p_{wf} are always greater than the reservoir bubblepoint pressure, p_b). However, it has long been recognized that in reservoirs existing at or below the bubblepoint pressure, producing wells do not follow the simple PI Eqs. 63 and 64. Actual field tests indicate that oil flow rates obtained at increasing drawdowns decline much faster than would be predicted by Eq. 63.

Evinger and Muskat¹⁴ first derived a theoretical PI for steady-state radial flow in an attempt to account for the observed nonlinear flow behavior of oil wells. They arrived at the following equation:

$$q_o = \frac{7.08kh}{\ln\left(\frac{r_e}{r_w}\right)} \int_{p_{wf}}^{p_e} f(p) dp, \dots (67)$$

where p_e is the reservoir pressure at the external boundary, psia, and

$$f(p) = \left(\frac{k_{ro}}{\mu_o B_o}\right).$$

Calculations using Eq. 67 with typical reservoir and fluid properties indicated that PI at a fixed reservoir pressure p_e decreases with increasing drawdown. This apparently complex form of an inflow-performance-relationship (IPR) equation found little use in the field.

In a computer study by Vogel,¹⁵ results based on two-phase flow theory were presented to indicate that a single empirical IPR equation might be valid for most solution-gas-drive reservoirs. He found that a single dimensionless IPR equation approximately held for several hypothetical solution-gas drive reservoirs even when using a wide range of oil PVT properties and reservoir relative permeability curves. The fact that his study covered a wide range of fluid properties and relative permeability curves to obtain a single reference curve cannot be overemphasized. Vogel proposed that his simple equation be used in place of the linear PI relationship for solution-gas-drive reservoirs when the reservoir pressure is at or below the bubblepoint pressure.

The proposed equation (IPR) in dimensionless form was given as

$$\frac{q_o}{q_{o(\max)}} = 1 - 0.20 \left(\frac{p_{wf}}{\bar{p}_R}\right) - 0.80 \left(\frac{p_{wf}}{\bar{p}_R}\right)^2, \dots (68)$$

where $q_{o(\max)}$ is the maximum producing rate at $p_{wf}=0$ psia.

Fetkovich,¹⁶ in an attempt to verify the Vogel IPR relationship, obtained isochronal and flow-after-flow multipoint backpressure test field data on some 40 different oil wells. The reservoirs in which oilwell multipoint backpressure tests were obtained ranged from highly undersaturated, to saturated at initial reservoir pressure, to a partially depleted field with a gas saturation existing above the critical (equilibrium) gas saturation. A form of an IPR equation similar to that used for gas wells was found to be valid for tests conducted in all three reservoir fluid states, even for the conditions where flowing pressures were well above the bubblepoint pressures. Permeabilities of the reservoirs ranged from 6 to >1,000 md.

In all cases, oilwell backpressure curves were found to follow the same general form as that used to express the rate-pressure relationship of a gas well:

$$q_o = J'(\bar{p}_R^2 - p_{wf}^2)^n, \dots (69)$$

For the 40 oilwell backpressure tests examined, the exponent n was found to lie between 0.568 and 1.000—that is, within the limits commonly accepted for gas well backpressure curves.

In terms of measured data, J' is defined by

$$J' = \frac{q_o}{(\bar{p}_R^2 - p_{wf}^2)^n}, \dots (70)$$

where J' is the stabilized PI, STB/D $(\text{psi}^2)^n$. The exponent n usually is determined from a multipoint or isochronal backpressure test and is an indicator of the existence of non-Darcy flow. If $n=1$, non-Darcy flow is assumed not to exist.

With PI expressed in terms of pressures squared, \bar{p}_R^2 and p_{wf}^2 ,

$$J' = \frac{J^*}{2\bar{p}_R}, \dots (71)$$

Expressing the pseudosteady state J' in terms of reservoir variables,

$$J' = \frac{7.08kh}{2\bar{p}_R \left[\ln\left(\frac{r_e}{r_w}\right) - \frac{3}{4} + s \right]} \left(\frac{k_{ro}}{\mu_o B_o}\right)_{p_R}, \dots (72)$$

or

$$q_o = \frac{7.08kh}{\left[\ln\left(\frac{r_e}{r_w}\right) - \frac{3}{4} + s \right]} \left(\frac{k_{ro}}{\mu_o B_o}\right)_{p_R} \cdot \frac{(\bar{p}_R^2 - p_{wf}^2)^{1.0}}{2\bar{p}_R}, \dots (73)$$

Expressed in a form with reservoir variables and a non-Darcy flow term, F_{Da} , where the resulting n would be less than 1.0 and a function of F_{Da} ,

$$q_o = \frac{7.08kh}{\left[\ln\left(\frac{r_e}{r_w}\right) - \frac{3}{4} + s + F_{Da} \right]} \left(\frac{k_{ro}}{\mu_o B_o} \right)_{p_R} \cdot \frac{(\bar{p}_R^2 - p_{wf}^2)}{2\bar{p}_R} \quad (74)$$

When \bar{p}_R is equal to or less than the bubblepoint pressure p_b and n is less than 1, a non-Darcy flow factor, F_{Da} , is indicated. When $F_{Da}=0$, $n=1$. The term F_{Da} normally is developed from multipoint test data. As shown in a later example, it is possible to have $F_{Da}=0$ and n less than 1.0 for undersaturated wells producing at flowing pressures below the bubblepoint pressure. (See Fig. 8 of Ref. 16.) This is strictly a result of the shape of the $k_{ro}/(\mu_o B_o)$ pressure function.

Expressing the backpressure form of the IPR equation in terms similar to that of Vogel's equation (instead of Vogel's equation in terms of the backpressure curve), we have, from Eq. 69,

$$q_o = J'(p_R^2 - p_{wf}^2)^n$$

and

$$q_{o(max)} = J'(p_R^2)^n$$

or

$$J' = \frac{q_{o(max)}}{(p_R^2)^n} \quad (75)$$

Substituting and rearranging yields

$$\frac{q_o}{q_{o(max)}} = \left(\frac{p_R^2 - p_{wf}^2}{p_R^2} \right)^n = \left[1 - \left(\frac{p_{wf}}{p_R} \right)^2 \right]^n \quad (76)$$

For $n=1$, we have the simplest possible form of a multiphase IPR equation based on results obtained from actual field data:

$$\frac{q_o}{q_{o(max)}} = 1 - \left(\frac{p_{wf}}{p_R} \right)^2 \quad (77)$$

Comparing Eq. 77 to Vogel's Eq. 68, which was derived only from computer simulation data, we see that the coefficient for p_{wf}/\bar{p}_R is 0, and the coefficient for $(p_{wf}/p_R)^2$ is equal to 1. This results in an IPR Eq. 77 that yields a slightly more conservative answer than given by Vogel's original equation. (Actually, Vogel's Fig. 7 shows computer model calculated IPR results less than obtained from his reference equation.¹⁵) Not included in any of Vogel's simulation runs were effects of non-Darcy flow in the reservoir or perforation restrictions, which in the field result in n values less than 1.0 and an even more severe IPR rate reduction relationship.

Example Problem 6 (IPR). The following example illustrates the various possible methods of computing inflow rates.

An oil well is producing at a stabilized rate of 70 STB/D at a flowing BHP $p_{wf}=1,147$ psia. The average reservoir shut-in static pressure, $p_R=1,200$ psia. Calculate the maximum possible flow rate, q_o , at 0 psig, and the producing rate if artificial lift were installed to lower the flowing BHP to 550 psia. Make the calculations using the PI Eq. 63, Vogel's method, and the backpressure curve method with $n=1.0$ and $n=0.650$. (The data are from an actual IPR test reported in Ref. 16.)

Productivity Index (PI)

$$J = \frac{70}{1,200 - 1,147} = 1.32 \text{ STB/D-psi;}$$

$$q_o (15 \text{ psi}) = J(\bar{p}_R - p_{wf})$$

$$= 1.32 (1,200 - 15) = 1,564 \text{ STB/D;}$$

$$q_o (550 \text{ psi}) = 1.32(1,200 - 550) = 858 \text{ STB/D.}$$

Vogel IPR

$$q_o = 70 \text{ BOPD; } \frac{p_{wf}}{p_R} = \frac{1,147}{1,200} = 0.9558;$$

$$\left(\frac{p_{wf}}{\bar{p}_R} \right)^2 = 0.9136;$$

$$\frac{q_o}{q_{o(max)}} = 1 - 0.20 \left(\frac{p_{wf}}{\bar{p}_R} \right) - 0.80 \left(\frac{p_{wf}}{\bar{p}_R} \right)^2$$

$$= 1 - 0.19116 - 0.73088 = 0.07796;$$

$$q_{o(max)} = \frac{70}{0.07796} = 898 \text{ BOPD;}$$

and q_o at $p_{wf}=15$ psia.

$$\frac{q_o(15 \text{ psi})}{q_{o(max)}} = 1 - 0.20 \left(\frac{15}{1,200} \right)$$

$$- 0.80 \left(\frac{15}{1,200} \right)^2 = 0.99738;$$

$$q_o(15 \text{ psi}) = q_{o(max)}(0.99738)$$

$$= 898(0.99738) = 896 \text{ BOPD;}$$

q_o at $p_{wf}=550$ psia.

$$\frac{q_o(550 \text{ psi})}{q_{o(max)}} = 1 - 0.20 \left(\frac{550}{1,200} \right)$$

$$-0.80 \left(\frac{550}{1,200} \right)^2 = 0.740277;$$

$$q_o(550 \text{ psi}) = q_{o(\max)}(0.740277)$$

$$= 898(0.740277) = 665 \text{ BOPD.}$$

Backpressure Curve ($n=1.0$) IPR

$$q_o = 70 \text{ BOPD}; \bar{p}_R^2 = (1,200)^2 = 1,440,000;$$

$$p_{wf}^2 = (1,147)^2 = 1,315,609;$$

$$J' = \frac{70}{(1,200)^2 - (1,147)^2}$$

$$= \frac{70}{124,391} = 0.00056274 \text{ STB/D-psi}^2;$$

$$q_o(15 \text{ psi}) = J'(\bar{p}_R^2 - p_{wf}^2)$$

$$= 0.00056274 (1,440,000 - 225) = 810 \text{ BOPD};$$

$$q_o(550 \text{ psi}) = 0.00056274 (1,440,000 - 302,500)$$

$$= 640 \text{ BOPD.}$$

Using the dimensionless backpressure curve form in terms of $q_o/q_{o(\max)}$ and p_{wf}/\bar{p}_R with $n=1.0$,

$$q_o = 70 \text{ BOPD}; \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 = \left(\frac{1,147}{1,200} \right)^2 = 0.9136;$$

$$\frac{q_o}{q_{o(\max)}} = 1 - \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 = 1 - 0.9136 = 0.0864;$$

$$q_{o(\max)} = \frac{70}{0.0864} = 810 \text{ BOPD};$$

q_o at $p_{wf}=550$ psia.

$$\frac{q_o(550 \text{ psi})}{q_{o(\max)}} = 1 - \left(\frac{550}{1,200} \right)^2$$

$$= 1 - 0.168056 = 0.78993;$$

$$q_o(550 \text{ psi}) = 810(0.78993) = 640 \text{ BOPD.}$$

Backpressure Equation ($n=0.650$) IPR

$$q_o = 70 \text{ BOPD}; \bar{p}_R^2 = (1,200)^2 = 1,440,000;$$

$$p_{wf}^2 = (1,147)^2 = 1,315,609;$$

$$J' = \frac{70}{(1,440,000 - 1,315,609)^{0.650}} = \frac{70}{2,049.3}$$

$$= 0.0341580 \text{ STB/D-psi}^{2n};$$

$$q_o(15 \text{ psi}) = J'(\bar{p}_R^2 - p_{wf}^2)^{0.650}$$

$$= 0.0341580(1,440,000 - 225)^{0.650};$$

$$q_o(15 \text{ psi}) = 0.0341580(10,066.8) = 344 \text{ BOPD};$$

$$q_o(550 \text{ psi}) = 0.0341580(1,440,000 - 302,500)^{0.650}$$

$$= 295 \text{ BOPD.}$$

Using the dimensionless backpressure curve form in terms of $q_o/q_{o(\max)}$, p_{wf}/\bar{p}_R , and $n=0.650$,

$$q_o = 70 \text{ BOPD}; \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 = \left(\frac{1,147}{1,200} \right)^2 = 0.9136;$$

$$\frac{q_o}{q_{o(\max)}} = \left[1 - \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 \right]^{0.650}$$

$$= (1 - 0.9136)^{0.650} = 0.203579;$$

$$q_{o(\max)} = \frac{70}{0.203579} = 344 \text{ BOPD};$$

q_o at $p_{wf}=550$ psia.

$$\frac{q_o(550 \text{ psi})}{q_{o(\max)}} = \left[1 - \left(\frac{550}{1,200} \right)^2 \right]^{0.650} = 0.857892;$$

$$q_o = 344(0.857892) = 295 \text{ BOPD.}$$

Again, this example is based on field data where several rates were measured to establish the real IPR relationship of the well. The real absolute open flow of the well was 340 BOPD. This is 38% of the rate predicted by Vogel's IPR equation and 42% of the rate predicted by the backpressure equation with $n=1$. A value of $n=0.650$ as illustrated in this example is required to match the field data. A non-Darcy flow factor F_{Dd} is indicated for this test.

Single-Phase and Two-Phase IPR Equation. Fetkovich¹⁶ gives a general equation that treats flow both above and below the bubblepoint pressure for an undersaturated oil well.

$$q_o = J^*(\bar{p}_R - p_b) + J'(p_b^2 - p_{wf}^2), \dots \dots \dots (78)$$

where

$$J' = J^*(\mu_o B_o)_{p_R, p_b} \left(\frac{a_2}{2} \right), \dots \dots \dots (79)$$

Assuming $(\mu_o B_o)$ is a constant value above the bubblepoint pressure equal to $(\mu_o B_o)_b$ (the basis of the constant PI assumption for flow above the bubblepoint pressure, p_b), then $a_2 = 1/[p_b(\mu_o B_o)_b]$ (see Appendix of Ref. 16).

Then

$$J' = \frac{J^*(\mu_o B_o)_b}{2p_b(\mu_o B_o)_b} = \frac{J^*}{2p_b} \quad \dots \dots \dots (80)$$

Substituting Eq. 80 into 78 we obtain the final form of the single-phase and two-phase IPR equation:

$$q_o = J^*(\bar{p}_R - p_b) + \frac{J^*}{2p_b}(p_b^2 - p_{wf}^2) \quad \dots \dots \dots (81)$$

Example Problem 7. The following example illustrates the method of computing inflow rates for flows both above and below the bubblepoint pressure of an undersaturated oil well.

An oil well is producing at a rate of 50 STB/D at a flowing BHP of 2,100 psia. The reservoir average shut-in pressure is 3,200 psia with a bubblepoint pressure of 1,800 psia.

Calculate the maximum possible flow rate, q_o , at $p_{wf}=0$ psig and the producing rate at 550 psia flowing BHP. (For flows above p_b , $J=J^*$.)

$$J = J^* = \frac{q_o}{(\bar{p}_R - p_{wf})},$$

therefore,

$$J^* = \frac{50}{(3,200 - 2,100)} = \frac{50}{1,100}$$

$$= 0.045454 \text{ STB/D-psi}$$

and

$$q_o(15 \text{ psi}) = J^*(\bar{p}_R - p_b) + \frac{J^*}{2p_b}(p_b^2 - p_{wf}^2),$$

$$= 0.045454(3,200 - 1,800)$$

$$+ \frac{0.045454}{2(1,800)}(1,800^2 - 15^2),$$

$$= 64 + 0.000012626(3,240,000 - 225),$$

$$= 64 + 41 = 105.$$

This compares to 145 BOPD if the regular PI equation is assumed valid to 15 psia.

q_o at $p_{wf}=550$ psia

$$q_o(550 \text{ psi}) = J^*(\bar{p}_R - p_b) + \frac{J^*}{2p_b}(p_b^2 - p_{wf}^2)$$

$$= 0.045454(3,200 - 1,800)$$

$$+ \frac{0.045454}{2(1,800)}(1,800^2 - 550^2),$$

$$= 64 + 0.000012626(3,240,000 - 302,500),$$

$$= 64 + 37 = 101 \text{ BOPD.}$$

The additional 535-psi pressure drop from 550 psia to 15 psia results in only 4 BOPD increase. It is significant to point out that if several flows, all with flowing pressure p_{wf} below the bubblepoint pressure p_b , were calculated using the above equation and example and then plotted as a backpressure curve but with $\bar{p}_R^2 - p_{wf}^2$, it would indicate a value of $n=0.820$. We would have an indicated n less than 1.0 without a non-Darcy flow term F_{Da} . With the uncertainty involved in really knowing the *true* bubblepoint pressure of a particular well, we could obtain test n values less than 1.0 without non-Darcy flow existing.

To illustrate more clearly a case of drawdown data obtained at flowing pressures below the bubblepoint pressure to obtain J^* , we will use the 550 psia rate obtained above and the previously specified data. Actual unrounded calculated rate is 100.73 BOPD.

$$q_o = J^* \left[(\bar{p}_R - p_b) + \frac{(p_b^2 - p_{wf}^2)}{2p_b} \right]$$

$$J^* = \frac{q_o}{\left[(\bar{p}_R - p_b) + \frac{(p_b^2 - p_{wf}^2)}{2p_b} \right]},$$

$$= \frac{100.73}{\left[(3,200 - 1,800) + \frac{(1,800^2 - 550^2)}{2(1,800)} \right]},$$

$$= \frac{100.73}{(1,400 + 816)} = \frac{100.73}{2,216}$$

$$= 0.045450 \text{ STB/D-psi (good check).}$$

Future Inflow Performance. Standing¹⁷ presented a method for adjusting IPR by using Vogel's equation from a measured condition to a future reservoir pressure \bar{p}_R . It is based on the fact that PI can be defined uniquely only at a zero drawdown, $p_{wf} \rightarrow \bar{p}_R$.

$$J^* = \lim_{\Delta p \rightarrow 0} J \quad \dots \dots \dots (82)$$

Fig. 34.6—Flow regime classifications for vertical two-phase flow.

Multiphase flow may be categorized into four different flow configurations or flow regimes, consisting of bubble flow, slug flow, slug-mist transition flow, and mist flow. In bubble flow, the liquid is continuous with the gas phase existing as bubbles randomly distributed (Fig. 34.6). The gas phase in bubble flow is small and contributes little to the pressure gradient except by its effect on the density. A typical example of bubble flow is the liberation of solution gas from an undersaturated oil at and above the point in the flow string where its bubblepoint pressure is reached.

In slug flow, both the gas and liquid phases significantly contribute to the pressure gradient. The gas phase in slug flow exists as large bubbles almost filling the pipe and separated by slugs of liquid. The gas bubbles are rounded on their leading edge, fairly flat on their trailing edge, and are surrounded on their sides by a thin liquid film. Liquid entrainment in the gas phase occurs at high flow velocities and small gas bubbles occur in the liquid slug. The velocity of the gas bubbles is greater than that of the liquid slugs, thereby resulting in a liquid holdup that not only affects well friction losses but also flowing density. Liquid holdup is defined as the in-situ flowing volume fraction of liquid. Slug flow accounts for a large percentage of two-phase production wells and, as a result, a good deal of research has been concentrated on this flow regime.

In transition flow, the liquid slugs between the gas bubbles essentially disappear, and at some point the liquid phase becomes discontinuous and the gas phase becomes continuous. The pressure losses in transition flow are partly a result of the liquid phase, but are more the result of the gas phase.

Mist flow is characterized by a continuous gas phase with liquid occurring as entrained droplets in the gas stream and as a liquid film wetting the pipe wall. A typical example of mist flow is the flow of gas and condensate in a gas condensate well.

Complete sets of pressure traverses for specific flow conditions and oil and gas properties have been published by service companies and others. These pressure gradient curves can be used for quick hand calculations.

Theoretical Considerations

As discussed in the Theoretical Basis section, the basis of any fluid-flow calculation consists of an energy balance on the fluid flowing between any two points in the system under consideration. The energy entering the system by virtue of the flowing fluid must equal the energy leaving the system plus the energy interchanged between the fluid and its surroundings.

The pressure drop in a vertical pipe associated with either single- or multiphase flow is given by

$$-dp = \frac{\tau_f dD}{144} + \frac{g\rho}{144g_c} dD + \frac{g v}{144g_c} dv, \quad (87)$$

where

p = pressure, psia.

τ_f = friction loss gradient, lbf/sq ft-ft.

D = depth, ft.

g = acceleration of gravity, ft/sec².

g_c = gravitational constant, (ft-lbm)/(lbf sec²).

ρ = fluid density, lbm/cu ft, and

v = fluid velocity, ft/sec.

Eq. 87 states that the fluid pressure drop in a pipe is the combined result of friction, potential energy, and kinetic energy losses.

The friction loss gradient and average density term for multiphase flow are evaluated using specific relationships for each flow regime. The kinetic energy term is usually small except for large flow rates. Duns and Ros¹⁸ have shown that for two-phase flow the kinetic energy term is significant only in the mist flow regime. Under this flow condition, $v_g \gg v_L$, and the kinetic energy term can be expressed as

$$\frac{\rho v}{g_c} dv = -\frac{w_t q_g}{g_c A^2} \frac{dp}{p}, \quad (88)$$

where

A = pipe area, sq ft,

w_t = total mass flow rate, lbm/sec, and

q_g = gas volumetric flow rate, cu ft/sec.

Eq. 87 now can be written in difference form for any depth increment, i , by assuming an average temperature and pressure exists over the increment. Making this assumption we have

$$\Delta p_i = \frac{1}{144} \left(\frac{\bar{\rho} + \tau_f}{1 - \frac{w_t q_g}{4637 A^2 \bar{p}}} \right) \Delta D_i, \quad (89)$$

where

$\bar{\rho}$ = average fluid density, lbm/cu ft.

Δp_i = pressure drop for increment i , psi.

\bar{p} = average pressure, psia, and

ΔD_i = the i th depth increment, ft.

Eq. 89 can be solved incrementally either by setting Δp_i and solving for ΔD_i or by setting ΔD_i and solving for Δp_i . Since pressure usually has more effect on average fluid properties than temperature and since temperature can be expressed as a function of depth, Δp_i should be set and ΔD_i calculated. The calculation procedure described here is an iterative process for each section and generally is programmed for solution on a computer.

Correlations

Since the original work in this area, which was presented by Poettmann and Carpenter,³³ several studies have been undertaken to collect additional experimental multiphase flow data and to develop new multiphase pressure drop correlations.¹⁸⁻²⁹ Also, various statistical studies have been performed comparing recent multiphase flow correlations³⁰⁻³² for large sets of flowing and gas lift cases.

Espanol *et al.*³⁰ selected the Hagedorn and Brown,²⁴ Duns and Ros,¹⁸ and Orkiszewski²⁵ methods as three of the best correlations for calculating multiphase pressure drops. An analysis of results calculated on 44 wells was used to determine the best overall correlation. This work concluded that the Orkiszewski correlation was the most accurate method over a large range of well conditions and it was the only correlation of the three considered suitable for evaluating three-phase flow for wells producing significant quantities of water.

Lawson and Brill³² point out that the Poettmann and Carpenter method is still a base line for comparing new multiphase flow correlations. Their original work is based on flow conditions similar to those found in many gas lift conditions and, therefore, is briefly discussed.

Poettmann and Carpenter.³³ Poettmann and Carpenter used data on flowing and gas lift wells to correlate the combined energy losses resulting from liquid holdup, frictional effects caused by the surface of the tubing, and other energy losses as a function of flow variables.

No attempt was made to evaluate the various components making up the total energy loss. The flowing fluid was treated as a single homogeneous mass, and the energy loss was correlated on this basis. A total flowing density or specific volume was used rather than an in-situ density or specific volume. That is, the energy of the fluid entering and leaving the tubing is a function of the pressure-volume properties of the total fluid entering and leaving the tubing, and not of the pressure-volume properties of the fluid in place, which would be different because of slippage or liquid-holdup effects. Lastly, in calculating flowing density or flowing specific volume, mass transfer between phases as the fluid flows up the tubing was taken into consideration, as well as the entire mass of the gas and liquid phases.

Viscosity as a correlating function was neglected. The degree of turbulence is of such a magnitude, in general, for a two-phase flowing oil well that the portion of the total energy loss resulting from viscous shear is negligible. This is not surprising since it is also true for single-phase turbulent flow. There the energy loss is independent of the physical properties of the flowing fluid. A

number of others* working on the same problem of multiphase flow have made the same observation.

Baxendell extended Poettmann and Carpenter's correlation by using large-volume flow data from wells on casing flow.³⁴ A detailed discussion of the Poettmann and Carpenter development can be found in the original 1962 edition of this handbook and in Ref. 33. The Poettmann and Carpenter correlation has served as the take-off point for many of the newer multiphase flow correlations.

Orkiszewski. To obtain a set of calculation procedures covering all flow regimes in two-phase flow, Orkiszewski²⁵ made a thorough review of the literature, tested various methods against a few sets of experimental data by hand calculations, and then selected the two methods, Griffith and Wallis¹⁹ and Duns and Ros,¹⁸ for his final evaluation. Orkiszewski programmed both methods and tested them against data from 148 wells. Neither method was accurate over the entire set of flow conditions. Griffith and Wallis's method, however, appeared to provide the better foundation for a general solution in slug flow, and, thus, Orkiszewski elected to modify their work.

Orkiszewski called his calculation procedures the Modified Griffith and Wallis method since their work was involved strictly with fully developed slug flow and since 95% of the 148 wells used by Orkiszewski in developing his method were in slug flow. Duns and Ros' method was used for mist flow and partly for transition flow since it appeared to be more fundamental than the Lockhart and Martinelli³⁵ method recommended by Griffith.

Orkiszewski's method essentially establishes which flow regime is present and then applies (1) Griffith's procedure for bubble flow, (2) Griffith's procedure modified by a liquid distribution coefficient parameter based on field data for slug flow, (3) a combination of the modified Griffith method and the Duns and Ros method for transition flow, or (4) Duns and Ros' method for mist flow. Accuracy claimed for this correlation is about $\pm 10\%$ for a wide range of flow conditions.

The determination of which flow regime applies for a given pipe segment is accomplished by checking the various dimensionless groups that define the boundaries of each flow regime (Fig. 34.7). Griffith and Wallis are responsible for defining the boundary between the bubble and slug flow regimes. Duns and Ros have defined the boundaries between the slug and transition flow regimes and between the transition and mist flow regimes. These boundaries are given by the inequalities listed below.

1. For the bubble flow regime, the boundary limits are $q_g/q_t < L_B$.
2. For the slug flow regime, the boundary limits are $q_g/q_t > L_B$, $v_{gD} < L_S$.
3. For the transition flow regime, the boundary limits are $L_M > v_{gD} > L_S$.
4. For the mist flow regime, the boundary limits are $v_{gD} > L_M$.

In these equations the subscripts *B*, *M*, and *S* indicate bubble, mist, and slug flow, respectively.

*Early investigators of this problem were T.V. Moore and H.D. Wilde Jr., "Experimental Measurement of Slippage in Flow Through Vertical Pipes," *Trans., AIME* (1931) 92, 296-313; and T.V. Moore and R.J. Schilthuis, "Calculation of Pressure Drops in Flowing Wells," *Trans., AIME* (1933) 103, 170-86.

Fig. 34.7—Flow regime map.

These dimensionless groups are given by the following set of equations.

$$v_{gD} = \frac{q_g [\rho_L / (g\sigma)]^{0.25}}{A}, \quad (90)$$

at the bubble-slug boundary

$$L_B = 1.071 - \frac{0.2218 v_t^2}{d_H}, \quad (91)$$

but

$$L_B \geq 0.13,$$

at the slug-transition boundary

$$L_S = 50 + \frac{36 v_{gD} q_L}{q_g}, \quad (92)$$

and at the transition-mist boundary

$$L_M = 75 + 84 \left(\frac{v_{gD} q_L}{q_g} \right)^{0.75}, \quad (93)$$

where

- v_{gD} = dimensionless gas velocity,
- v_t = total fluid velocity (q_t/A), ft/sec,
- ρ_L = liquid density, lbm/cu ft,
- σ = liquid surface tension, lbm/sec²,
- L = flow regime boundary, dimensionless,
- d_H = hydraulic pipe diameter, ft,
- q_g = gas flow rate, cu ft/sec,
- g = acceleration of gravity, ft/sec², and
- A = flow area of pipe, sq ft.

The average density and friction loss gradient is defined later for each of the four possible flow regimes. These terms are evaluated for each pipe segment and are then substituted into Eq. 89 to calculate the pressure drop over the segment.

Bubble Flow. The average flowing density in *bubble flow* is calculated from the following equation, which volumetrically weights the gas and liquid densities.

$$\bar{\rho} = \rho_g f_g + (1 - f_g) \rho_L. \quad (94)$$

The flowing gas fraction, f_g , in bubble flow is given by

$$f_g = \frac{1}{2} \left[1 + \frac{q_t}{v_s A} - \sqrt{\left(\frac{1 + q_t}{v_s A} \right)^2 - \frac{4 q_g}{v_s A}} \right], \quad (95)$$

where the slip velocity, v_s , is the difference between the average gas and liquid velocities. Griffith suggests the use of an approximate value of $v_s = 0.8$ ft/sec for bubble flow.

The friction loss gradient for bubble flow is based on single-phase liquid flow.

$$\tau_f = \frac{f \rho_L v_L^2}{2 g_c d_H \cos \theta}, \quad (96)$$

where

$$v_L = \frac{q_L}{A(1 - f_g)}. \quad (97)$$

The friction factor, f , in Eq. 96 is the standard Moody² friction factor, which is a function of Reynolds number and relative roughness factor. The Reynolds number that is used for bubble flow is the liquid Reynolds number.

$$N_{Re} = \frac{1488 \rho_L d_H v_L}{\mu_L}, \quad (98)$$

where d_H is the hydraulic pipe diameter ($4A/\text{wetted perimeter}$), ft, and μ_L is the liquid viscosity, cp.

Slug Flow. The average density term for *slug flow* is expressed as

$$\bar{\rho} = \frac{w_t + \rho_L v_b A}{q_t + v_b A} + \delta \rho_L. \quad (99)$$

Eq. 99, with the exception of its last term, is equivalent to the average density term derived by Griffith and Wallis. The last term of Eq. 99 was added by Orkiszewski and contains a parameter, δ , that was correlated from oil-field data. The slip or bubble rise velocity, v_b , for slug flow was correlated by Griffith and Wallis and is given by

$$v_b = C_1 C_2 \sqrt{g d_H}. \quad (100)$$

The coefficient C_1 is the bubble-rise coefficient for bubbles rising in a static column of liquid. Values of C_1 have been determined theoretically by Dumitrescu³⁶ and experimentally by Griffith and Wallis¹⁹ as a function of bubble Reynolds number, Fig. 34.8, where

$$N_{Re_b} = \frac{1488 \rho_L d_H v_b}{\mu_L}. \quad (101)$$

The coefficient C_2 is a function of liquid velocity and, when multiplied by C_1 , represents the bubble-rise coefficient for bubbles rising in a flowing liquid. The coefficient C_2 has been determined experimentally by Griffith and Wallis¹⁹ and is correlated as a function of both bubble Reynolds number, N_{Re_b} , and liquid Reynolds number (Fig. 34.9), where

$$N_{Re} = \frac{1488 \rho_L d_H v_L}{\mu_L} \quad (102)$$

When Reynolds numbers larger than 6,000 are encountered, v_b can be evaluated from the following equations, which were developed by Orkiszewski and based on the work of Nicklin *et al.*²⁰ For bubble Reynolds numbers, N_{Re_b} , less than 3,000,

$$v_b = [0.546 + 8.74(10^{-6})N_{Re}] \sqrt{gd_H} \quad (103)$$

When bubble Reynolds number is between 3,000 and 8,000,

$$v_b = 0.5v_{bi} + 0.5 \left(v_{bi}^2 + \frac{13.59 \mu_L}{\rho_L \sqrt{d_H}} \right)^{0.5} \quad (104)$$

where

$$v_{bi} = [0.251 + 8.74(10^{-6})N_{Re}] \sqrt{gd_H} \quad (105)$$

For bubble Reynolds numbers greater than 8,000,

$$v_b = [0.35 + 8.74(10^{-6})N_{Re}] \sqrt{gd_H} \quad (106)$$

The friction loss gradient term for slug flow is the result of Orkiszewski's work and is given by

$$\tau_f = \frac{f \rho_L v_L^2}{2g_c d_H \cos \theta} \left(\frac{q_L + v_b A}{q_t + v_b A} + \delta \right) \quad (107)$$

Fig. 34.8—Bubble-rise coefficient for bubbles rising in a static liquid column vs. bubble Reynolds number.

The friction factor in Eq. 107 is a function of relative roughness and the Reynolds number given by Eq. 102.

Orkiszewski defined the parameter δ , which appears in Eqs. 99 and 107 as a liquid distribution coefficient. This coefficient implicitly accounts for the following physical phenomena.

1. Liquid is distributed not only in the slug and as a film around the gas bubble but also as entrained droplets inside the gas bubble.
2. The friction loss has essentially two contributions, one from the liquid slug and the other from the liquid film.
3. The bubble rise velocity approaches zero as mist flow is approached.

Liquid distribution coefficient, δ , was correlated as a function of liquid viscosity, hydraulic radius, and total velocity and may be evaluated by one of the following empirical equations.

Fig. 34.9—Bubble-rise coefficient accounting for bubbles rising in a flowing liquid vs. Reynolds number.

Continuous Oil Phase. When $v_t < 10$,

$$\delta = \frac{0.0127}{d_H^{1.415}} \log(\mu_L + 1) - 0.284 + 0.167 \log v_t + 0.113 \log d_H \quad (108)$$

When $v_t > 10$,

$$\delta = \frac{0.0274}{d_H^{1.371}} \log(\mu_L + 1) + 0.161 + 0.569 \log d_H - \log v_t \left[\frac{0.01}{d_H^{1.571}} \log(\mu_L + 1) + 0.397 + 0.63 \log d_H \right] \quad (109)$$

Continuous Water Phase. When $v_t < 10$,

$$\delta = \frac{0.013}{d_H^{1.38}} \log \mu_L - 0.681 + 0.232 \log v_t - 0.428 \log d_H \quad (110)$$

When $v_t > 10$,

$$\delta = \frac{0.045}{d_H^{0.799}} \log \mu_L - 0.709 - 0.162 \log v_t - 0.888 \log d_H \quad (111)$$

Eqs. 108 through 111 are constrained by the following limits, which eliminate pressure discontinuities between flow regimes. When $v_t < 10$, $\delta \geq -0.065v_t$, and when $v_t > 10$,

$$\delta \geq -\frac{v_b A(1 - \rho/\rho_t)}{q_t + v_b A}$$

Transition Flow. The Duns and Ros method for calculating average flowing density and friction loss gradient in *transition flow* is used. They evaluated $\bar{\rho}$ and τ_f by linearly weighting the values obtained from slug and mist flow with dimensionless gas velocity, v_{gD} , and the dimensionless boundaries defining transition flow, L_M and L_S . The average density term is defined as

$$\bar{\rho} = \left(\frac{L_M - v_{gD}}{L_M - L_S} \right) \bar{\rho}_S + \left(\frac{v_{gD} - L_S}{L_M - L_S} \right) \bar{\rho}_M \quad (112)$$

where subscripts M and S are mist and slug flow conditions, respectively. Similarly, the friction loss gradient is defined as

$$\tau_f = \left(\frac{L_M - v_{gD}}{L_M - L_S} \right) \tau_{fS} + \left(\frac{v_{gD} - L_S}{L_M - L_S} \right) \tau_{fM} \quad (113)$$
