Preface

The 1962 edition of the *Petroleum Production Handbook* filled a need at that time for a comprehensive compilation of practical information and data covering production equipment and reservoir engineering. This 1987 edition updates the original 48 chapters and adds 11 new ones. New technology, developed over the past 25 years, resulted in improved equipment, materials, and methods. They are described and discussed in the revised original chapters and in the new ones. The 11 new chapters are the following:

- Chapter 7—Electric Submersible Pumps
- Chapter 18—Offshore Operations
- Chapter 19—Crude-Oil Emulsions
- Chapter 45—Miscible Displacement
- Chapter 46—Thermal Recovery
- Chapter 47—Chemical Flooding
- Chapter 48—Reservoir Simulation
- Chapter 51—Acoustic Well Logging
- Chapter 52—Mud Logging
- Chapter 58—SI Metric System of Units and SPE Metric Standard
- Chapter 59—SPE Letter and Computer Symbols Standard

This 1987 edition, now called the *Petroleum Engineering Handbook*, provides a current and worthwhile addition to the industry's literature for students and experienced professionals working in the petroleum industry.

The handbook is again divided into three sections: Sec. 1, Mathematics (one chapter); Sec. 2, Production Engineering (18 chapters); and Sec. 3, Reservoir Engineering (40 chapters). There are 57 chapters written by professionals who are recognized as authorities in their fields of expertise. Chap. 58 is a revised version of the 1982 SI Metric System of Units and SPE Metric Standard, and Chap. 59 is the 1986 revision of the 1984 Standard SPE Letter and Computer Symbols for Economics, Formation Evaluation and Well Logging, Natural Gas Engineering, and Petroleum Reservoir Engineering.

The Mathematics section presents the basic tables and calculation procedures required by persons engaged in petroleum production. The Production Engineering section covers basic types of materials, methods, and tools available for use in petroleum operations, including their capabilities and proper applications. The Reservoir Engineering section treats gas, oil, condensate, and formation water properties and correlations; reservoir rocks and traps; primary, secondary, and tertiary recovery data and methods; oil and gas reserves; formation evaluation, including well logging methods; and well treating methods. The what, why, how, and now-what aspects of each topic are emphasized. Also, at the end of the appropriate chapters, key equations are presented with SI metric units.

Special acknowledgment is due the SPE staff for their immeasurable help and advice, the associate editors for their avid dedication to the technical-editing task, and all the authors who contributed much time and effort to provide the timely and excellent information included within each chapter. We are much indebted to the editor-in-chief of the 1962 edition, Thomas C. Fricke, and to the original group of authors for their arduous 3-year job of developing the original edition of the *Petroleum Production Handbook*. Special thanks are due Ed Mayer of THUMS and B.J. Dotson of Mobil Oil Corp. (now retired) for their advice and helpful discussions on the proper use of the 1986 SPE standard letter symbols throughout the handbook and for their editing of Chap. 59, the SPE Letter and Computer Symbols Standard.

Our hope is that by proper application of the updated information contained within the second edition of this handbook, the petroleum-industry professional will be led to more efficient production and use of the world's petroleum-energy resources.

Howard B. Bradley
Editor-in-Chief

Acknowledgments

The Society of Petroleum Engineers sincerely thanks the following organizations and individuals for permission to use the cited material.

Contents

Preface	iii
Acknowledgments	v
1. Mathematical Tables and Units and Systems of Weights and Measures	
Mathematical Tables	1-2
Units and Systems of Weights and Measures	1-68
2. Casing, Tubing, and Line Pipe	
Casing	2-1
Tubing	2-38
Line Pipe	2-46
Equations for Calculating Performance Properties of Casing, Tubing, and Line Pipe	2-46
API Threading Data	2-64
3. Wellhead Equipment and Flow Control Devices	
Introduction	3-1
API Flanged or Clamped Wellhead Equipment	3-1
Flow Control Devices: Safety Shut-In Systems	3-18
Other Flow-Control Devices	3-34
Corrosion	3-35
Special Application	3-36
Independent Screwed Wellhead	3-39
4. Production Packers	
Production Packers Classification and Objectives	4-1
Tubing-to-Packer Connections	4-1
Packer Utilization and Constraints	4-1
Considerations for Packer Selection	4-4
Tubing/Packer System	4-6
Tubing Response Characteristics	4-8
Combination Tubing/Packer Systems	4-11
Tubing/Packer Forces on Intermediate Packers	4-11
5. Gas Lift	
Introduction	5-1
Gas Fundamentals as Applied to Gas Lift	5-3
Gas Lift Valve Mechanics	5-12
Continuous-Flow Gas Lift	5-21
Intermittent Gas Lift	5-38
Unloading Procedures and Proper Adjustment of Injection Gas Rate	5-53
6. Hydraulic Pumping	
Introduction	6-1
Downhole Pumps	6-2
Principles of Operation—Reciprocating Pumps	6-8
Jet Pumps	6-34
Surface Equipment	6-49
Appendix A—Fluid Properties	6-66
Appendix B—Friction Relationships	6-69
7. Electric Submersible Pumps	
Introduction	7-1
ESP System	7-1
Applications	7-1
ESP System Components	7-3
Selection Data and Methods	7-9
Handling, Installation, and Operation	7-12
Troubleshooting	7-14

8. Subsurface Sucker-Rod Pumps	
Introduction	8-1
Pump Selection	8-2
Plungers	8-4
Slippage Past Plungers	8-5
Soft-Packed Plungers	8-6
Balls and Seats	8-7
Double Valves	8-7
Bottom-Discharge Valve	8-8
Three-Tube Pump	8-8
Gas Anchors	8-9
Special Pumps	8-9
Corrosion	8-9
Effect of Gases and Vapors	8-10
Conclusions	8-10
9. Sucker Rods	
Introduction	9-1
Steel Sucker Rods	9-1
Fiberglass Sucker Rods	9-10
10. Pumping Units and Prime Movers for Pumping Units: Part 1—Pumping Units	
Introduction	10-1
Pumping Units	10-1
Component Parts	10-4
Pumping Unit Loading	10-5
Counterbalance	10-6
Sizing	10-7
Installation	10-7
Lubrication	10-12
Changing the Oil	10-13
Pumping Units and Prime Movers for Pumping Units: Part 2—Prime Movers for Pumping Units	
Introduction	10-14
Internal-Combustion Engines	10-14
Electric Motors for Oilwell Pumping	10-19
11. Oil Storage	
Types of Storage Tanks	11-1
Tank Corrosion Protection	11-4
Appurtenances	11-6
Venting Atmospheric and Low-Pressure Storage Tanks	11-6
Materials of Construction	11-9
Production Equipment	11-9
Vapor Losses	11-11
Vapor Control and Gravity Conservation With Storage Tanks	11-12
Underground Storage	11-13
12. Oil and Gas Separators	
Summary	12-1
Introduction	12-1
Primary Functions of Oil and Gas Separators	12-3
Secondary Functions of Oil and Gas Separators	12-4
Special Problems in Oil and Gas Separation	12-6
Methods Used To Remove Oil From Gas in Separators	12-8
Mist Extractors Used in Oil and Gas Separators	12-11
Methods Used To Remove Gas From Oil in Separators	12-13
Estimated Quality of Separated Fluids	12-13
Classification of Oil and Gas Separators	12-16
Centrifugal Oil and Gas Separators and Gas Scrubbers	12-20
Illustrations of Oil and Gas Separators	12-21
Comparison of Oil and Gas Separators	12-21
Estimating the Sizes and Capacities of Oil and Gas Separators	12-21

Computer Sizing of Oil and Gas Separators	12-25
Capacity Curves for Vertical and Horizontal Oil and Gas Separators	12-27
Practical Considerations in Sizing Oil and Gas Separators	12-32
Stage Separation of Oil and Gas	12-32
Selection and Application of Separators and Scrubbers	12-35
Construction Codes for Oil and Gas Separators	12-38
Controls, Valves, Accessories, and Safety Features for Oil and Gas Separators	12-39
Operation and Maintenance Considerations for Oil and Gas Separators	12-40
 13. Gas Measurement and Regulation	
Introduction	13-1
Gas Measurement	13-1
Regulation	13-49
 14. Lease-Operated Hydrocarbon Recovery Systems	
Introduction	14-1
Low-Temperature Separation (LTS) Systems	14-1
Gas-Treating Systems for Removal of Water Vapor, CO ₂ , and H ₂ S	14-17
 15. Surface Facilities for Waterflooding and Saltwater Disposal	
Introduction	15-1
Piping System Design	15-1
Selecting Pumps and Drivers	15-14
Separating Suspended Solids From Heater	15-18
Treating Hydrocarbons From Water	15-21
Dissolved Gas Removal	15-28
Dissolved Solids Removal	15-29
Removing Hydrocarbons From Solids	15-30
Process Selection and Project Management	15-30
Project Control	15-32
 16. Automation of Lease Equipment	
Introduction	16-1
Automatic Production-Control Equipment	16-2
Production Safety Controls	16-4
Automatic Quantitative Measurement	16-5
Gas Measurement	16-6
Temperature Measurement	16-7
Automatic Sampler	16-7
BS&W Monitor	16-7
Net-Oil Computer	16-7
Supervisory Control and Data Acquisition (SCADA) Systems	16-8
Typical Automatic-Control Installations	16-10
Automatic Well Testing	16-12
LACT	16-12
 17. Measuring, Sampling, and Testing Crude Oil	
Introduction	17-1
Procedure for Typical Measuring, Sampling, and Testing	17-1
Abstract of API Manual	17-3
 18. Offshore Operations	
Introduction	18-1
Historical Review	18-1
Offshore Drilling	18-3
Field Operations	18-17
Special Considerations	18-20
Structures	18-22
Offshore Production Operations	18-27
Arctic	18-38
Electrical, Instrumentation and Control Systems	18-43
Control of Subsea Production Facilities	18-48

19. Crude Oil Emulsions	
Introduction	19-1
Theories of Emulsions	19-1
Sampling and Analyzing Crude Oil Emulsions	19-6
Methods Used in Treating Crude Oil Emulsions	19-6
Emulsion-Treating Equipment and Systems	19-15
Description of Equipment Used in Treating Crude Oil Emulsions	19-16
Operational Considerations for Emulsion-Treating Equipment	19-28
Economics of Treating Crude Oil Emulsions	19-32
20. Gas Properties and Correlations	
Molecular Weight	20-1
Ideal Gas	20-1
Critical Temperature and Pressure	20-2
Specific Gravity (Relative Density)	20-4
Mole Fraction and Apparent Molecular Weight of Gas Mixtures	20-4
Specific Gravity of Gas Mixtures	20-4
Dalton's Law	20-4
Amagat's Law	20-4
Real Gases	20-4
Principle of Corresponding States	20-4
Equations of State	20-6
Van der Waals' Equation	20-7
Viscosity	20-9
Viscosity Correlations	20-9
Natural Gasoline Content of Gas	20-10
Formation Volume Factor	20-11
Coefficient of Isothermal Compressibility	20-11
Vapor Pressure	20-11
Cox Chart	20-12
Calingeart and Davis Equation	20-13
Lee-Kesler	20-13
Example Problems	20-13
21. Crude Oil Properties and Condensate Properties and Correlations	
Introduction	21-1
Base of Crude Oil	21-1
Physical Properties	21-3
True-Boiling-Point Crude-Oil Analyses	21-8
Bubblepoint-Pressure Correlations	21-9
Dewpoint-Pressure Correlations	21-10
Sage and Olds' Correlation	21-11
Total Formation Volume Correlations	21-15
22. Oil System Correlations	
Introduction	22-1
Oil Density Determination	22-2
Bubblepoint-Pressure Correlations	22-5
Solution GOR for Saturated Oils	22-9
Oil FVF Correlations	22-10
Total FVF's	22-13
Oil Viscosity Correlations	22-13
Gas/Oil IFT	22-16
Glossary	22-20
23. Phase Diagrams	
Introduction	23-1
Single-Component Phase Diagrams	23-1
Phase Rule	23-2
Types of Diagrams	23-2
Calculation of Phase Compositions	23-10

24. Properties of Produced Waters	
Introduction and History	24-1
Sampling	24-3
Analysis Methods for Oilfield Waters	24-5
Chemical Properties of Oilfield Waters	24-5
Inorganic Constituents	24-9
Physical Properties of Oilfield Waters	24-12
Interpretation of Chemical Analyses	24-18
Occurrence, Origin, and Evolution of Oilfield Waters	24-19
Recovery of Minerals From Brines	24-20
25. Phase Behavior of Water/Hydrocarbon Systems	
Introduction	25-1
General Hydrocarbon/Water Phase Diagrams and Equilibrium Data Sources	25-1
Hydrate Stability Conditions	25-4
Determining the Water Content of Gas (or Hydrocarbon-Rich Liquid) in Equilibrium With Hydrates	25-10
Definition of the Saturated Water Content of Natural Gases in Equilibrium With Aqueous Phases	25-11
Quantitative Prediction of Water Content in Light Hydrocarbon Systems	25-16
Quantitative Predictions of Solute Concentrations in the Aqueous Phase	25-16
Sour Water Stripper Correlations	25-17
Oil and Gas Reservoirs That Exist in the Gas Hydrate Region	25-18
Hydrate Inhibition	25-19
26. Properties of Reservoir Rocks	
Introduction	26-1
Porosity	26-1
Permeability	26-10
Fluid Saturations	26-20
Electrical Conductivity of Fluid-Saturated Rocks	26-27
Empirical Correlation of Electrical Properties	26-29
27. Typical Core Analysis of Different Formations	
Introduction	27-1
Porosity	27-1
Permeability	27-1
Liquid Saturations	27-8
Percussion Sidewall Core Data	27-9
Data From U.S. Areas	27-9
Data From Non-U.S. Areas	27-9
28. Relative Permeability	
Introduction	28-1
Historical Background	28-2
Framework Ideas	28-2
Measurement Methodologies	28-3
Recent Literature	28-9
Critique of Recent Work	28-10
Ramifications Needing Attention	28-12
Conclusions	28-13
29. Petroleum Reservoir Traps	
Introduction	29-1
Trap Classification	29-1
Characteristics of Reservoir Rocks	29-6
Glossary	29-8
30. Bottomhole Pressures	
Introduction	30-1
BHP Instruments	30-1
Pressure Transducer Technology	30-6
Calculated BHP	30-7
Application of BHP	30-8

31. Temperature in Wells	
Introduction	31-1
Thermometers	31-1
Thermometry	31-2
Summary	31-7
32. Potential Tests of Oil Wells	
Texas Allowable Rule	32-1
Productivity Index (PI)	32-2
Specific PI	32-4
Theoretical PI	32-4
Pseudosteady-State Flow	32-5
Stock-Tank Measurement	32-6
Portable Well Testers	32-7
GOR	32-14
GOR as a Criterion of Reservoir Performance	32-15
33. Open Flow of Gas Wells	
Introduction	33-1
Pitot-Tube Gauging of Low-Pressure Wells	33-1
Backpressure Testing	33-3
Gas Well Inflow Equation, Pseudosteady State	33-5
Multipoint Test and Example	33-7
Isochronal Test and Example	33-10
Comparison of Multipoint With Isochronal Test	33-11
Gas Measurement	33-13
Calculation of Subsurface Pressures	33-13
Application of Backpressure Tests to Producing Problems	33-20
Production Rate	33-20
Causes of Deterioration in Performance	33-20
Examples of Remedial Operations	33-22
34. Wellbore Hydraulics	
Introduction	34-1
Theoretical Basis	34-1
Producing Wells	34-3
Injection Wells	34-28
Oil Wells	34-30
Multiphase Flow	34-35
Flow Through Chokes	34-45
Liquid Loading in Wells	34-46
35. Well Performance Equations	
Introduction	35-1
Diffusivity Equation	35-1
Multiphase Flow	35-2
Oil Well Performance	35-2
Gas Well Performance	35-10
Transient Well Test Analysis	35-14
36. Development Plan for Oil and Gas Reservoirs	
Introduction	36-1
Oil and Gas Differences	36-2
Characterization of the Reservoir	36-3
Prediction of Reservoir Performance	36-9
37. Solution-Gas-Drive Reservoirs	
Introduction	37-1
Definitions	37-1
Typical Performance	37-1
Types of Models Used	37-2
Basic Assumptions of Tank-Type Material Balance	37-2
Basic Data Required	37-3
Material-Balance Equation	37-5

Material Balance as Equation of Straight Line for Determination of OIP and of Gas-Cap Size	37-6
Material-Balance Calculations Using Tracy's Method	37-7
Comparison of Tarner's and Tracy's Methods	37-10
Material-Balance Calculations Using Muskat and Taylor's Method	37-10
Sensitivity of Material-Balance Results	37-13
Production Rate and Time Calculations	37-17
Insights From Simulator Studies	37-21
Volatile Oil Reservoir Performance Predictions	37-22
38. Water Drive Oil Reservoirs	
Introduction	38-1
Definitions	38-1
Mathematical Analysis	38-1
39. Gas-Condensate Reservoirs	
Introduction	39-1
Properties and Behavior of Gas-Condensate Fluids	39-1
Gas-Condensate Well Tests and Sampling	39-4
Sample Collection and Evaluation	39-6
Operation by Pressure Depletion	39-10
Operation by Pressure Maintenance or Cycling	39-15
General Operating Problems: Well Characteristics and Requirements	39-24
Economics of Gas-Condensate Reservoir Operation	39-26
40. Estimation of Oil and Gas Reserves	
Estimating Reserves	40-1
Petroleum Reserves—Definitions and Nomenclature	40-2
Glossary of Terms	40-3
Computation of Reservoir Volume	40-4
Computation of Oil or Gas in Place	40-5
Saturated Depletion-Type Oil Reservoirs—Volumetric Methods	40-8
API Estimation of Oil and Gas Reserves	40-12
Undersaturated Oil Reservoirs Without Water Drive Above the Bubblepoint—Volumetric Method	40-12
Volatile Oil Reservoirs—Volumetric Methods	40-13
Oil Reservoirs With Gas-Cap Drive—Volumetric Unit Recovery Computed by Frontal-Drive Method	40-13
Oil Reservoirs Under Gravity Drainage	40-14
Oil Reservoirs With Water Drive—Volumetric Methods	40-15
Volumetric Recovery Estimates for Nonassociated Gas Reservoirs	40-21
Production-Decline Curves	40-26
Other Performance Curves	40-32
41. Valuation of Oil and Gas Reserves	
Types of Oil and Gas Property Ownership	41-1
Valuation	41-2
Forecast of Future Rate of Production	41-9
Development and Operating Costs	41-11
Federal Taxes	41-12
Different Concepts of Valuation	41-16
Interest Tables and Deferment Factors	41-25
42. Injection Operations	
Introduction	42-1
Important Factors in the Design of Injection Operations	42-2
Analysis of a Reservoir for Injection Operations	42-3
43. Gas-Injection Pressure Maintenance in Oil Reservoirs	
Introduction	43-1
Types of Gas-Injection Operations	43-2
Optimal Time To Initiate Gas Pressure-Maintenance Operations	43-3
Efficiencies of Oil Recovery by Gas Displacement	43-3
Methods of Evaluating Unit-Displacement Efficiency	43-3
Methods of Evaluating Conformance Efficiency	43-6
Methods of Evaluating Areal Sweep Efficiency	43-7
Calculation of Gas Pressure-Maintenance Performance	43-8

Appendix A—Example Calculations of Future Performance	43-10
Appendix B—Selected References Containing Equations, Calculation Procedures, and Example Calculations Related to Gas-Injection Performance Predictions	43-16
Appendix C—Data Requirements for Engineering Analysis of Gas-Injection Operations	43-17
44. Water-Injection Pressure Maintenance and Waterflood Processes	
Introduction	44-1
Important Factors in Waterflooding or Water-Injection Pressure Maintenance	44-2
Determination of Residual Oil After Waterflooding	44-5
Predicting Water Injection Oil Recovery and Performance	44-7
Water-Injection Well Behavior	44-32
Water-Injection Case Histories	44-36
Pilot Floods	44-37
Surface-Active Agents in Waterflooding	44-39
Water Source and Requirements	44-41
Water Treating	44-43
Selection and Sizing of Waterflood Plants	44-45
45. Miscible Displacement	
Introduction	45-1
Theoretical Aspects of Miscible-Phase Displacement	45-1
Factors Affecting Displacement Efficiency	45-6
Engineering Study	45-8
Appendix—Engineering Examples	45-10
46. Thermal Recovery	
Introduction	46-1
Two Forms of Steam Injection Processes	46-1
Three Forms of In-Situ Combustion	46-1
Historical Development	46-3
Current Status	46-3
Theoretical Considerations	46-4
Analytical Models for Steam Injection	46-7
Numerical Simulation	46-11
Laboratory Experimentation	46-12
Field Projects	46-13
Project Design	46-17
Well Completion	46-19
Field Facilities	46-19
Monitoring and Coring Programs	46-20
Operational Problems and Remedies	46-21
Case Histories	46-22
Thermal Properties	46-31
47. Chemical Flooding	
Introduction	47-1
Mobility Control Processes	47-1
Low-IFT Processes	47-9
High-pH Processes	47-18
Summary	47-22
48. Reservoir Simulation	
Introduction	48-1
A Brief History	48-1
General Description of Simulation Models	48-2
Purpose of Reservoir Simulation	48-6
Considerations in Practical Application of Simulation Models	48-7
Validity of Simulation Results	48-9
Simulation Technology	48-13
49. Electrical Logging	
Fundamentals	49-1
Spontaneous Potential (SP) Log	49-7
Resistivity Logging Devices	49-11

Induction Logging	49-14
Focused-Electrode Logs	49-18
Microresistivity Devices	49-22
Uses and Interpretation of Well Logs	49-25
The Digital Age	49-36
50. Nuclear Logging Techniques	
Introduction	50-1
Nuclear Physics for Logging Applications	50-3
Nuclear Radiation Logging Devices	50-15
Interpretation of Nuclear Logs	50-23
51. Acoustic Logging	
Introduction	51-1
Elasticity	51-1
Acoustic Wave Propagation in Rocks	51-4
Acoustic Wave Propagation Methods	51-11
Methods of Recording Acoustic Data	51-14
Applications	51-28
Conclusions	51-47
Appendix—Theory of Elastic Wave Propagation in Rocks	51-49
52. Mud Logging	
Introduction	52-1
Service Types	52-1
Formation Evaluation Services	52-2
The Modern Mud Logging Unit	52-11
The Mud Log	52-11
Petroleum Engineering Services	52-16
Drilling Engineering Services	52-27
Selecting a Mud Logging Service	52-28
Standards for and Status of Services	52-30
53. Other Well Logs	
Introduction	53-1
MWD	53-1
Directional Surveys	53-3
Dipmeter Logging	53-7
Caliper Logs	53-16
Casing Inspection Logs	53-17
54. Acidizing	
Introduction	54-1
General Principles	54-1
Acid Reaction Rates	54-4
Acid Additives	54-6
Acidizing Techniques	54-8
Laboratory Testing	54-9
Acid Treatment Design	54-10
Critical Wells	54-11
Summary	54-12
55. Formation Fracturing	
Introduction	55-1
Hydraulic Fracturing Theory	55-1
Formations Fractured	55-2
Fracture Planes	55-2
Fracture Area	55-2
Reservoir-Controlled Fluids	55-2
Viscosity-Controlled Fluids	55-4
Fluid-Loss-Controlled Fluids	55-4
Stimulation Results	55-4
Fracturing Materials	55-5
Fracturing Techniques	55-8

Multiple-Zone Fracturing	55-9
Fracturing Equipment	55-9
Treatment Planning and Design	55-9
56. Remedial Cleanup, Sand Control, and Other Stimulation Treatments	
Introduction	56-1
Reperforation	56-1
Abrasive Jet Cleaning	56-1
Mud Removal	56-1
Water Blocks and Emulsions	56-2
Scale Deposits	56-2
Paraffin Removal	56-2
Large-Volume Injection Treatments	56-2
Steam Injection	56-2
General Comments	56-2
Sand Control	56-2
57. Oil and Gas Leases	
The Landowner's Interest	57-1
The Oil and Gas Lease	57-3
Assignments by the Landowner	57-6
Assignments by the Lessee	57-7
Unit Operations	57-7
Getting the Well Drilled	57-8
Lease Problems During Development	57-10
Taxation	57-11
Offshore Leasing	57-11
58. The SI Metric System of Units and SPE Metric Standard	
Preface	58-2
Part 1: SI—The International System of Units	58-2
Introduction	58-2
SI Units and Unit Symbols	58-2
Application of the Metric System	58-3
Rules for Conversion and Rounding	58-5
Special Terms and Quantities Involving Mass and Amount of Substance	58-7
Mental Guides for Using Metric Units	58-8
Appendix A—Terminology	58-8
Appendix B—SI Units	58-9
Appendix C—Style Guide for Metric Usage	58-11
Appendix D—General Conversion Factors	58-14
Appendix E—Conversion Factors for the Vara	58-20
Part 2: Discussion of Metric Unit Standards	58-21
Introduction	58-21
Review of Selected Units	58-22
Unit Standards Under Discussion	58-24
Notes for Table 2.2	58-25
Notes for Table 2.3	58-25
59. SPE Letter and Computer Symbols Standard	
Symbols in Alphabetical Order	59-2
Quantities in Alphabetical Order	59-18
Subscript Definitions in Alphabetical Order	59-52
Subscript Symbols in Alphabetical Order	59-63

Explanation of Table of Squares

This table gives the value of N^2 for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the square of a number N outside the range from 1 to 10, note that moving the decimal point one place in Column N is equivalent to moving it two places in the body of the table. For example, $(3.217)^2 = 10.35$, $(0.03217)^2 = 0.001035$, and $(3,217)^2 = 10,035,000$.

This table also can be used inversely to give square roots.

TABLE 1.1—SQUARES OF NUMBERS (continued)

Explanation of Table of Cubes

This table gives the value of N^3 for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the cube of a number N outside the range from 1 to 10, note that moving the decimal point *one* place in Column N is equivalent to moving it *three* places in the body of the table. For example, $(4.852)^3 = 114.2$, $(0.4852)^3 = 0.1142$, and $(485.2)^3 = 114,200,000$.

This table also can be used inversely to give cube roots.

Explanation of Table of Square Roots

This table gives the value of \sqrt{N} for values of N from 1 to 100, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure).

To find the square root of a number N outside the range from 1 to 100, divide the digits of the number into blocks of two (beginning with the decimal point), and note that moving the decimal point two places in N is equivalent to moving it one place in the square root of N . For example, $\sqrt{2.718} = 1.648$, $\sqrt{27.18} = 5.213$, $\sqrt{271.8} = 16.48$, $\sqrt{2,718} = 52.13$, $\sqrt{0.002718} = 0.01648$, and $\sqrt{0.002718} = 0.05213$.

Explanation of Table of Cube Roots

This table gives the value of $\sqrt[3]{N}$ for values of N from 1 to 1,000, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure).

To find the square root of a number N outside the range from 1 to 1,000, divide the digits of the number into blocks of three (beginning with the decimal point), and note that moving the decimal point *three* places in column N is equivalent to moving it *one* place in the cube root of N . For example, $\sqrt[3]{2.718} = 1.396$, $\sqrt[3]{27.18} = 3.007$, $\sqrt[3]{271.8} = 6.477$, $\sqrt[3]{2,718} = 13.96$, $\sqrt[3]{27,180} = 30.07$, $\sqrt[3]{271,800} = 64.77$, $\sqrt[3]{0.00002718} = 0.01396$, $\sqrt[3]{0.0002718} = 0.03007$, and $\sqrt[3]{0.0002718} = 0.06477$.

Explanation of Table

This table gives $N^{3/2}$ from $N = 1$ to $N = 100$. Moving the decimal point *two* places in N requires moving it *three* places in body of table. For example, $(7.23)^{3/2} = 19.44$, $(723)^{3/2} = 19,440$, $(0.0723)^{3/2} = 0.01944$, $(72.3)^{3/2} = 614.8$, $(7,230)^{3/2} = 614,800$, and $(0.723)^{3/2} = 0.6148$.

Used inversely, this table gives $M^{2/3}$ from $M = 1$ to $M = 1,000$. For example, $(0.6148)^{2/3} = 0.7230$.

**AUXILIARY TABLE OF TWO-THIRDS POWERS
AND THREE-HALVES POWERS
(to assist in locating the decimal point)**

For complete table of three-halves powers, see preceding. That table, used inversely, provides a complete table of two-thirds powers.

<i>N</i>	$N^{2/3} (= \sqrt[3]{N^2})$	$N^{3/2} (= \sqrt{N^3})$

Explanation of Table of Reciprocals

This table gives the values of $1/N$ for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the reciprocal of a number N outside the range from 1 to 10, note that moving the decimal point any number of places in either direction in Column N is equivalent to moving it the same number of places in the *opposite* direction in the body of the table. For example, $1/3.217 = 0.3109$, $1/3,217 = 0.0003109$, and $1/0.003217 = 310.9$.

Explanation of Table of Circumferences

This table gives the product of π times any number d (diameter) from 1 to 10; i.e., it is a table of multiples of π .

Moving the decimal point *one* place in Column d is equivalent to moving it *one* place in the body of the table.

Circumference = $\pi \times d = 3.141593 \times d$. Conversely, $d = 1/\pi \times \text{circumference} = 0.31831 \times \text{circumference}$.

Explanation of Table of Areas of Circles

Moving the decimal point one place in Column *d* (diameter) is equivalent to moving it two places in the body of the table. For example, area of circle = $\pi/4 \times d^2 = 0.785398 \times (d^2)$.

Conversely, diameter of circle = $\sqrt{4/\pi \times \text{area}} = 1.128379 \times \sqrt{\text{area}}$.

10	78.54	79.85	81.18	82.52	83.86	85.22	86.59	87.97	89.36	90.76	92.18
11	95.03	96.48	97.93	99.40	100.9	102.4	103.9	105.4	106.9	108.4	110.0
12	113.1	114.7	116.3	117.9	119.5	121.1	122.7	124.4	126.0	127.7	129.4
13	132.7	134.4	136.2	137.9	139.6	141.4	143.1	144.9	146.7	148.5	150.3
14	153.9	155.8	157.6	159.5	161.4	163.2	165.1	167.0	168.9	170.9	172.8

*If given diameter is not found in this table, reduce diameter to feet and decimals of a foot by aid of the following auxiliary table and use Table 1.8

From Inches and Fractions of an Inch to Decimals of a Foot**

Inches	1	2	3	4	5	6	7	8	9	10	11
Feet	0.0833	0.1667	0.2500	0.3333	0.4167	0.5000	0.5833	0.6667	0.7500	0.8333	0.9167
Inches	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$				
Feet	0.0104	0.0208	0.0313	0.0417	0.0521	0.0625	0.0729				

**For example, 5 ft $7\frac{3}{8}$ in. = 5.0 + 0.5833 + 0.0313 = 5.6146 ft

TABLE 1.11—SEGMENTS OF CIRCLES, GIVEN h/c

Explanation of Table of Segments of Circles, Given h/c

Given: h = height of segment and c = chord, to find the diameter, d , of the circle, the length of the arc, or the area of the segment, form the ratio h/c , and find from the table the value of d/c , arc/ c , or area/ hc ; then, by a simple multiplication, $d = c \times (d/c)$, arc = $c \times (\text{arc}/c)$, and area = $h \times c \times (\text{area}/hc)$.

The table also gives the angle subtended at the center, and the ratio of h to d .

TABLE 1.12—SEGMENTS OF CIRCLES, GIVEN h/d

Explanation of Table of Segments of Circles, Given h/d

Given: h = height of segment and d = diameter of circle, to find the chord, the length of arc, or the area of the segment, form the ratio h/d and find from the table the value of (c/d) , (arc/d) , or $(area/d^2)$; then by a simple multiplication, $c = d \times (c/d)$, $arc = d \times (arc/d)$, and $area = d^2 \times (area/d^2)$.

The table also gives the angle subtended at the center, the ratio of the arc of the segment to the whole circumference, and the ratio of the area of the segment to the area of the whole circle.

*Volume segment = $\frac{1}{6}\pi h^2(3d - 2h)$.

Explanation of Table of Segments of Spheres

Given: h = height of segment and d = diameter of sphere, to find the volume of the segment, form the ratio h/d and find from the table the value of (volume/ d^3): then, by a simple multiplication, volume segment = $d^3 \times$ (volume/ d^3).

The table also gives the ratio of the volume of the segment to the entire volume of the sphere. Note that the area of zone = $\pi \times h \times d$.

Explanation of Table of Volumes of Spheres

Moving the decimal point *one* place in Column *d* (diameter) is equivalent to moving it *three* places in the body of the table.

For example, volume of sphere = $\pi/6 \times (d^3) = 0.523599 \times (d^3)$. Conversely, $d = \sqrt[3]{6/\pi \times \text{volume}} = 1.240701 \times \sqrt[3]{\text{volume}}$.

TABLE 1.14—VOLUMES OF SPHERES BY HUNDREDTHS (continued)

n = number of sides,

α = $360^\circ/n$ = angle subtended at the center by one side,

L = length of one side = $R(2 \sin \alpha/2) = r(2 \tan \alpha/2)$,

R = radius of circumscribed circle = $L(1/2 \csc \alpha/2) = r(\sec \alpha/2)$,

r = radius of inscribed circle = $R(\cos \alpha/2) = L(1/2 \cot \alpha/2)$, and

area = $L^2 (1/4 n \cot \alpha/2) = R^2 (1/2 n \sin \alpha) = r^2 (n \tan \alpha/2)$.

TABLE 1.16—BINOMIAL COEFFICIENTS

$(n)_0 = 1$, $(n)_1 = n$, $(n)_2 = [n(n-1)]/(1 \times 2)$, $(n)_3 = [n(n-1)(n-2)]/(1 \times 2 \times 3)$, etc.; in general, $(n)_r = n(n-1)(n-2) \dots [n-(r-1)]/(1 \times 2 \times 3 \dots r)$. Other notations: $nCr = (n/r) = (n)_r$.

This table gives the common logarithms of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right (or left) in the number is equivalent to adding n (or $-n$) to the logarithm. Thus, $\log 0.017453 = 0.2419 - 2$, which may also be written 2.2419 or $8.2419 - 10$.

For example, $\log(ab) = \log a + \log b$, $\log(a^N) = N \log a$, $\log(a/b) = \log a - \log b$, and $\log(\sqrt[N]{a}) = 1/N \log a$.

TABLE 1.18—COMMON LOGARITHMS (continued)

This table gives the natural or Napierian logarithms (ln) of numbers between 1 and 10, correct to four places. Moving the decimal point *n* places to the right (or left) in the number is equivalent to adding *n* times 2.3026 (or *n* times 3.6974) to the logarithm. Base *e* = 2.71828 + .

*ln *x* = (2.3026) log₁₀ *x*, log₁₀ *x* = (0.4343) ln *x*, where 2.3026 = ln 10 and 0.4343 = log₁₀ *e*.

TABLE 1.26—NATURAL LOGARITHMS* (continued)

10.0	2.3026										

This table gives the natural or Napierian logarithms (ln) of numbers between 1 and 10, correct to four places. Moving the decimal point *n* places to the right (or left) in the number is equivalent to adding *n* times 2.3026 (or *n* times 3.6974) to the logarithm. Base *e* = 2.71828 + .

* $\ln x = (2.3026) \log_{10} x$, $\log_{10} x = (0.4343) \ln x$, where $2.3026 = \ln 10$ and $0.4343 = \log_{10} e$.

a = any positive quantity,
 y = number of residuals that are
numerically smaller than 1,
 r = probable error of a single
observation, and
 n = number of observations.

TABLE 1.34—COMPOUND INTEREST—AMOUNT OF A GIVEN PRINCIPAL

The amount A at the end of n years of a given principal P placed at compound interest today is $A = P \times x$ or $A = P \times y$ or $A = P \times z$, according as the interest (at the rate of i percent per annum) is compounded annually, semiannually, or quarterly; the factor x or y or z being taken from the following tables.

Values of x —Interest Compounded Annually: $A = P \times x^*$

Years	$i = 2$	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	6	7

*The formula used for this table is $v = \{[1 + (i/100)]^n - 1\} / (i/100) = (x - 1) / (i/100)$.

TABLE 1.36—PRINCIPAL AMOUNTING TO A GIVEN SUM

The principal P which, if placed at compound interest today, will amount to a given sum A at the end of n years is $P = A \times x'$ or $P = A \times y'$ or $P = A \times z'$, according as the interest (at the rate of i percent per annum) is compounded annually, semiannually, or quarterly; the factor x' or y' or z' being taken from the following tables.

Values of x' —Interest Compounded Annually: $P = A \times x'$ *

Years	$i = 2$	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	6	7

*The formula used for this table is $v' = (i/100)/[1 + (i/100)]^n - 1 = 1/v$.

TABLE 1.38—PRESENT WORTH OF AN ANNUITY

The capital C , which, if placed at interest today, will provide for a given annual payment Y for a term of n years before it is exhausted is $C = Y \times w$, where the factor w is given below. (Interest at i percent per annum, compounded annually.)

Values of w^*

Years	$i = 2$	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	6	7

* The formula used for this table is $w = \{1 - [1 + (i/100)]^{-n}\} / (i/100) = v/i$.

TABLE 1.39—ANNUITY PROVIDED FOR BY A GIVEN CAPITAL

The annual payment Y provided for for a term of n years by a given capital C placed at interest today is $Y = C \times w'$. Interest at i percent per annum, compounded annually; the fund is supposed to be exhausted at the end of the term.

Values of w'^*

Units and Systems of Weights and Measures

L.E. Barrow, U.S. Natl. Bureau of Standards

The U.S. Natl. Bureau of Standards was established by act of congress in 1901 to serve as a national scientific laboratory in the physical sciences and to provide fundamental measurement standards for science and industry. In carrying out these related functions the bureau conducts research and development in many fields of physics, mathematics, chemistry, and engineering. At the time of its founding, the bureau had custody of two primary standards—the meter bar for length and the kilogram cylinder for mass (or weight). With the phenomenal growth of science and technology over the past half century, the bureau has become a major research institution concerned not only with everyday weights and measures but also with hundreds of other scientific and engineering standards that have become necessary to the industrial progress of the U.S. Nevertheless, the U.S. still looks to the bureau for information on the units of weights and measures, particularly their definitions and equivalents.

The subject of weights and measures can be treated from several different standpoints. Scientists and engineers are interested in the methods by which precision measurements are made, general knowledge of weights and measures, the present status of units and standards, and miscellaneous facts that will be useful in their everyday professional life.

The expression “weights and measures” is used here in its basic sense of referring to measurements of length, mass, and capacity, thus excluding such topics as electrical and time measurements and thermometry. This section on units and systems of weights and measures presents some fundamental information to clarify thinking on this subject and to eliminate erroneous and misleading use of terms.

Unit and Standard Definitions

It is essential that there be established and kept in mind the distinction between the terms “units” and “standards” of weights and measures.

A *unit* is a value, quantity, or magnitude in terms of which other values, quantities, or magnitudes are expressed. In general, a unit is fixed by definition and is independent of such physical conditions as temperature. Examples include the yard, the pound, the gallon, the meter, the liter, the gram.

A *standard* is a physical embodiment of a unit. In general it is not independent of physical conditions, and it is a true embodiment of the unit only under specified conditions. For example, a yard standard has a length of one yard when at some definite temperature and supported in a certain manner. If supported in a different manner, it might have to be at a different temperature in order to have a length of 1 yard.

The Metric System

Definition, Origin, and Development

The metric system* is the international system of weights and measures based on the meter and the kilogram. The essential features of the system were embodied in a report made to the French Natl. Assembly by the Paris Academy of Sciences in 1791. The definitive action taken in 1791 was the outgrowth of recommendations along similar lines dating back to 1670. The adoption of the system in France was slow, but its desirability as an international system was recognized by geodesists and others. On May 20, 1875, an international treaty known as the Intl. Metric Convention was signed providing for an Intl. Bureau of Weights and Measures, thus ensuring “the international unification and improvement of the metric system.” The metric system is now either obligatory or permissible throughout the world.

Although the metric system is a decimal system, the words “metric” and “decimal” are not synonymous, and care should be taken not to confuse the two terms.

*See also Chap. 58

Units and Standards of the Metric System

In the metric system, the fundamental units of length and mass are the meter and the kilogram. The other units of length and mass, as well as all units of area, volume, and compound units such as density, are derived from these two fundamental units.

From 1960 to 1983, the meter was defined as the length equal to 1 650 763.73 wavelengths in vacuum of the radiation corresponding to the transition between the levels $2p_{10}$ and $5d_5$ of the krypton 86 atom. Since 1983, the meter has been defined as the length of the path travelled by light in a vacuum during a time interval of $1/299\,792\,458$ of a second. The kilogram previously defined as the mass of 1 cubic decimeter of water at the temperature of maximum density was known as the Kilogram of the Archives. It was replaced after the Intl. Metric Convention in 1875 by the Intl. Prototype Kilogram, which became the unit of mass without reference to the mass of a cubic decimeter of water or to the Kilogram of the Archives.

The liter is a unit of capacity. In 1964 the 12th General Conference on Weights and Measures redefined the liter as being 1 cubic decimeter. By its previous definition—the volume occupied, under standard conditions, by a quantity of pure water having a mass of 1 kilogram—the liter was larger than the cubic decimeter by 28 parts in 1 000 000; except for determinations of high precision, this difference is so small as to be of no consequence.

The modernized metric system includes "base" units such as units of temperature and time, as well as many "derived" units such as units of force and work. For details, see Chap. 58.

The Intl. Bureau of Weights and Measures

The Intl. Bureau of Weights and Measures was established at Sèvres, a suburb of Paris, in accordance with the Intl. Metric Convention of May 20, 1875. At the bureau are kept the Intl. Prototype kilogram, many secondary standards of all sorts, and equipment for comparing standards and making precision measurements. The Bureau, maintained by assessed contributions of the signatory governments, is truly international.

In recent years the scope of the work at the Intl. Bureau has been considerably broadened. It now carries on research in the fields of electricity and photometry in addition to its former work in weights and measures, which included such allied fields as thermometry and the measurement of barometric pressures.

Present Status of the Metric System in the U.S.

The use of the metric system in this country was legalized by act of congress in 1866, but was not made obligatory.

The speed of light in a vacuum and U.S. Prototype Kilogram No. 20 are recognized as the primary standards of length and mass for both the metric and the inch-pound (customary) systems of measurement in this country because these standards are the most precise and reliable standards available. Since 1893 in the U.S. the yard has been defined in terms of the meter and the pound in terms of the kilogram. There is in the U.S. no primary standard either of length or mass in the inch-pound system.

From 1893 until 1959, the yard was defined as being equal exactly to 3600/3937 m. In 1959 a small change was made in the definition of the yard to resolve discrepancies both in the U.S. and abroad. Since 1959, the yard is defined as being equal exactly to 0.9144 m; the new yard is shorter than the old yard by exactly two parts in a million. At the same time, it was decided that any data expressed in feet derived from geodetic surveys within the U.S. would continue to bear the relationship as defined in 1893 (1 ft equals 1200/3937 m). This foot is called the U.S. survey foot, while the foot defined in 1959 is called the international foot. Measurements expressed in statute miles, survey feet, rods, chains, links, or the squares thereof, and also acres should therefore be converted to the corresponding metric values by using pre-1959 conversion factors where more than five-significant-figure accuracy is involved.

In 1971 the Natl. Bureau of Standards completed a 3-year study of the impact of increasing worldwide metric use on the U.S. The study ended with a report to the Congress entitled *A Metric America—A Decision Whose Time Has Come*. In the last few years metric use has been increasing rapidly in the U.S., principally in the manufacturing and educational sectors. Public Law 93-380, enacted Aug. 21, 1974, states that it is the policy of the U.S. to encourage educational agencies and institutions to prepare students to use the metric system of measurement with ease and facility as a part of the regular education program. On Dec. 23, 1975, President Gerald Ford signed Public Law 94-168, the Metric Conversion Act of 1975. This act declares a national policy of coordinating the increasing use of the metric system in the U.S. It established a U.S. Metric Board, whose functions as of Oct. 1, 1982 were transferred to the Dept. of Commerce, Office of Metric Programs, to coordinate the voluntary conversion to the metric system.

British and U.S. Systems

The implication is sometimes made that the inch/pound system of weights and measures in the British Commonwealth countries and the U.S. system are identical. It is true that the U.S. and the British inch are defined identically for scientific work, that they are practically identical in commercial usage, that a similar situation exists for the U.S. and the British pound, and that many tables, such as 12 in. = 1 ft, 3 ft = 1 yd, and 1,760 yd = 1 international mile, are the same in both countries; but there are some very important differences.

First, the U.S. bushel, the U.S. gallon, and their subdivisions differ from the corresponding British units. Also, the British ton is 2,240 lbm, whereas the ton generally used in the U.S. is the short ton of 2,000 lbm. The American colonists adopted the English wine gallon of 231 cu in. The English of that period used this wine gallon, but they also had another gallon, the ale gallon of 282 cu in. In 1824 these two gallons were abandoned by the British when they adopted the British imperial gallon, which is defined as the volume of 10 lbm of water, at a temperature of 62°F, which, by calculation, is equivalent to 277.42 cu in. At the same time, the bushel was redefined as 8 gal. In the British system, the units of dry measure are the same as those of liquid measure. In the U.S. these two are not the same, the gallon and its subdivisions being

used in the measurement of liquids, while the bushel, with its subdivisions, is used in the measurement of certain dry commodities. The U.S. gallon is divided into 4 liquid quarts and the U.S. bushel into 32 dry quarts. All the units of capacity mentioned thus far are larger in the British system than in the U.S. system. But the British fluid ounce is smaller than the U.S. fluid ounce, because the British quart is divided into 40 fluid ounces, whereas the U.S. quart is divided into 32 fluid ounces.

From the foregoing it is seen that in the British system an avoirdupois ounce of water at 62°F has a volume of 1 fluid oz, because 10 lbm is equivalent to 160 avoirdupois oz, and 1 gal is equivalent to 4 quarts, or 160 fluid oz. This convenient relation does not exist in the U.S. system because a U.S. gallon of water at 62°F weighs about $8\frac{1}{8}$ lbm, or $133\frac{1}{8}$ avoirdupois oz, and the U.S. gallon is equivalent to 4×32 , or 128 fluid oz. In comparison, 1 U.S. fluid oz = 1.041 British fluid oz; 1 British fluid oz = 0.961 U.S. fluid oz; 1 U.S. gal = 0.833 British imperial gal; and 1 British imperial gal = 1.201 U.S. gal.

Subdivision of Units

In general, units are subdivided by one of three systems: (1) decimal, i.e., into tenths; (2) duodecimal, into twelfths; or (3) binary, into halves. Usually the subdivision is continued by use of the same system. Each method has advantages for certain purposes, and it cannot properly be said that any one method is "best" unless the use to which the unit and its subdivisions are to be put is known.

For example, if we are concerned only with measurements of length to moderate precision, it is convenient to measure and to express these lengths in feet, inches, and binary fractions of an inch, thus 9 ft $4\frac{3}{8}$ in. If, however, these measured lengths are to be used subsequently in calculations of area or volume, that method of subdivision at once becomes extremely inconvenient. For that reason, engineers, instead of dividing the foot into inches and binary subdivisions of the inch, divide it decimally; that is, into tenths, hundredths, and thousandths of a foot.

The method of subdivision of a unit is thus made largely on the basis of convenience to the user. The fact that units have commonly been subdivided into certain subunits for centuries does not preclude their also having another mode of subdivision in some frequently used cases where convenience indicates the value of such other method. Thus the gallon is usually subdivided into quarts and pints, but the majority of gasoline-measuring pumps of the price-computing type are graduated to show tenths of a gallon. Although the mile has for centuries been divided into rods, yards, feet, and inches, the odometer part of an automobile speedometer indicates tenths of a mile. Although our dollar is divided into 100 parts, we habitually use and speak of halves and quarters.

Standards

Length

A specified spectral line emitted by krypton 86 is the international standard on which all length measurements are based. To obtain a constant and uniform wavelength, krypton lamps are operated at the temperature of the triple point of nitrogen.

One yard is defined as 0.9144 m. The inch is therefore exactly equal to 25.4 mm.

Mass

The primary standard of mass for this country is U.S. Prototype Kilogram 20, which is a platinum-iridium cylinder kept at the Natl. Bureau of Standards. The value of this mass standard is known in terms of the Intl. Prototype Kilogram, a platinum-iridium standard, which is kept at the Intl. Bureau of Weights and Measures.

The avoirdupois pound is defined in terms of the kilogram by the relation 1 avoirdupois lbm = 0.453 592 37 kg.

Mass vs. Weight. The mass of a body is a measure of its inertial property. The *weight* of a body has in the past been used at times to designate its mass and at other times to designate a force that is related to gravitational attraction. Because these two concepts of weight are incompatible, and have therefore resulted in confusion, the term "weight" should be avoided in technical practice except under circumstances in which its meaning is completely clear. When the term is used, it is important to know whether *mass* or *force* is intended and to use SI units properly by using kilograms for mass and newtons for force. See also Chapter 58.

As weighing and measuring are important factors in our everyday lives, it is quite natural that questions arise about the use of various units and terms and about the magnitude of quantities involved.

The ton is used as a unit of measure in two distinct senses: (1) as a unit of weight, and (2) as a unit of capacity or volume.

In the weight sense the term means: (1) the *short*, or *net* ton of 2,000 lbm; (2) the *long*, *gross*, or *shipper's* ton of 2,240 lbm; (3) the *metric* ton of 1,000 kg, or 2,204.6 lbm. In the capacity sense "ton" is restricted to uses related to ships.

In the U.S. and Canada the ton (weight) most commonly used is the *short* ton, in Great Britain it is the *long* ton, and in countries using the metric system it is the *metric* ton.

Effect of Air Buoyancy. Another point to consider in the calibration and use of standards of mass is the buoyancy or lifting effect of the air. A body immersed in any fluid is buoyed up by a force equal to the force of gravity on the displaced fluid. Two bodies of equal mass, if placed one on each pan of an equal-arm balance, will balance each other in a vacuum. A comparison in a vacuum against a known mass standard gives "true mass." If compared in air, however, they will not balance each other unless they are of equal volume. If of unequal volume, the larger body will displace the greater volume of air and will be buoyed up by a greater force than will the smaller body, and the larger body will appear to be of less mass than the smaller body. The greater the difference in volume, and the greater the density of the air in which the comparison weighing is made, the greater will be the apparent difference in mass. For that reason, in assigning a precise numerical value of mass to a standard, it is necessary to base this value on definite values for the air density and the density of the mass standard of reference.

TABLE 1.41—LENGTH EQUIVALENTS

Meters	Centimeters	Inches	Feet	Yards	Chains	Kilometers	Miles
1	100	39.37	3.281	1.0936	0.04971	0.001	0.0₅6214

3.00000	5.00000	4.59517	3.51598	3.03886	1.69644		1.79335
1609	160 935	63,360	5,280	1,760	80	1.609	1
3.20665	5.20665	4.80182	3.72263	3.24551	1.90309	0.20665	

The equivalents are given in the bold-faced type. Logarithms of the equivalents are given immediately below with the characteristic of the logarithm (i.e., 1.59517 = 0.59517). In some cases, the equivalents have been rounded off, while the logarithm corresponds to the equivalent carried to a greater number of decimal places. Subscripts after any figure—0₃, 9₄—mean that that figure is to be repeated the indicated number of times.

TABLE 1.42—CONVERSION OF LENGTHS*

	Inches to Millimeters	Millimeters to Inches	Feet to Meters	Meters to Feet	Yards to Meters	Meters to Yards	Miles to Kilometers	Kilometers to Miles
1	25.40	0.03937	0.3048	3.281	0.9144	1.094	1.609	0.6214

9	228.60	0.3543	2.743	29.53	8.230	9.842	14.48	5.592

*For example, 1 in. = 25.40 mm.

The corrections furnished by the U.S. Natl. Bureau of Standards (NBS) for the more precise mass standards are given on two bases: comparison in vacuum and comparison against normal brass standards in air under standard conditions, with no correction applied for the buoyant effect of the air. By definition, brass standards have a density of 8400 kg per m³ at 0°C and a coefficient of cubical thermal expansion of 0.000 054 per °C. Standard conditions are defined as air of 1.2 kg per m³ and temperature of 20°C. The corrections to be used with precise analytical weights are ordinarily given only in terms of apparent mass against normal brass standards.

A full discussion of this topic is given in NBS Monograph 133, Mass and Mass Values, by Paul E. Pontius (Natl. Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161; COM 7450309).

Capacity

Units of capacity, being derived units, are defined in the U.S. in terms of linear units and are not represented by fundamental standards. Laboratory standards have been constructed and are maintained at NBS. These have validity only by calibration with reference either directly or indirectly to the linear standards.

The equivalents are given in the bold-faced type. Logarithms of the equivalents are given immediately below with the characteristic of the logarithm (i.e., 2.59699 = 0.059699). In some cases, the equivalents have been rounded off, while the logarithm corresponds to the equivalent carried to a greater number of decimal places. Subscripts after any figure—0₃, 9₄, etc.—mean that the figure is to be repeated the indicated number of times.

*1 hectare = 100 acres = 10 000 m².

The equivalents are given in bold-faced type. Logarithms of the equivalents are given immediately below with the characteristic of the logarithm (i.e., 1.00848 = 0.00848). In some cases, the equivalents have been rounded off, although the logarithm corresponds to the equivalent carried to a greater number of decimal places. Subscripts after any figure—0₃, 9₄, etc.—mean that the figure is to be repeated the indicated number of times.

* Calculated from the formula relative density = $(141.5)/(131.5 + \gamma_{API})$. The weights in this table are weights in air at 60°F with humidity 50% and pressure 760 mm Hg.

Relative Density and Density

The relative density of a solid or liquid is the ratio of the mass of the body to the mass of an equal volume of water at some standard temperature. At the present time, a temperature of 4°C [39°F] is commonly used by physicists, but the engineer uses 60°F. The relative density of gases is usually expressed in terms of hydrogen or air.

The density of a body is its mass per unit volume. If the gram is used as the unit of mass and the millimeter as the unit of volume, or if the kilogram is used as the unit of mass and the liter as the unit of volume, the figures representing the density are the same as the relative density of the body. The inch-pound unit is pounds per cubic foot.

The relative density of liquids is usually measured by a hydrometer, and different special arbitrary hydrometer

scales are used in various trades and industries. The most common of these are the API and Baumé. The API scale is approved by the American Petroleum Inst., the ASTM, the U.S. Bureau of Mines, and the Natl. Bureau of Standards and is recommended for exclusive use in the U.S. petroleum industry, superseding the Baumé scale for liquids lighter than water. The relation between API degrees and relative density is expressed by the following equation.

$$\gamma_{API} = (141.5)/(\rho_{60/60^{\circ}F}) - 131.5.$$

The relative densities corresponding to °API and weights per U.S. gallon are given in Table 1.65.

Chapter 2

Casing, Tubing, and Line Pipe

William O. Clinedinst, Consultant

Casing

The successful production of oil and gas depends on the proper performance of casing, which serves as a structural retainer in the well, excludes undesirable fluids, and confines and conducts oil or gas from subsurface strata to ground level. Casing must be capable of withstanding external collapsing pressure from fluid surrounding the casing, internal pressure encountered in conducting oil or gas from the producing formation, and tension loads resulting from its own suspended weight. It also must be equipped with threaded joints that can be made up easily and that provide leakproof connections.

API Casing

API developed specifications for casing that meet the major needs of the oil and gas industry and published these in API specifications and bulletins.¹⁻⁶ These provide standard dimensions, strength and performance properties, and the required thread-gauging practice to ensure complete interchangeability.

In addition to the API strength grades, the following tables include information on higher-strength casing developed to meet the needs of unusually deep wells. Tables 2.1 and 2.2 give the tensile requirements and range lengths of API casing and liner casing. Table 2.3 lists the minimum performance properties of casing. Table 2.4 lists the minimum collapse resistance under axial loads for various API casing grades. Tables 2.5 through 2.7 give the dimensions, weights, and tolerances of round-thread and buttress-thread coupling and length of upset for extreme-line API casing (see also Figs. 2.1 through 2.3). Factors for conversion of gross linear footage to net footage of API short-thread, long-thread, buttress-thread, and extreme-line casings are shown in Tables 2.8 through 2.11, respectively. Equations for calculating performance properties of casing are given in a later section.

Special Casing Joints

A number of special casing joints are available that are useful where higher strength, leak resistance, or clearance is needed than that provided by the standard API round-thread, buttress-thread, or extreme-line casing joints. These special joints obtain their improved properties by various means, such as (1) couplings or box ends with seal rings of teflon, etc.; (2) special thread profiles, such as Acme; (3) torque shoulders; (4) metal-to-metal seals; (5) internal upsets; (6) external upsets; (7) integral joints; and (8) flush joints.

API Liner Casing

Table 2.12 shows the minimum performance properties of API Grade J-55 plain-end liner casing. Table 2.13 shows the minimum collapse resistance under axial loads of API Grade J-55 liner casing.

Design of Casing Strings

Oil, Water, and Mud-Weight Factors. Table 2.14 gives the oil, water, and mud weight factors used in casing string design.

Safety factors commonly used in the design of casing strings are the following: collapse strength, 1.125; joint strength, 1.80; plain-end yield strength, 1.25; and internal yield pressure, 1.00. These safety factors will be used in the following casing string designs. However, it is the responsibility of the designer to select safety factors to suit particular needs.

Single Weight and Grade Casing String. Collapse Safety Factor. The collapse pressure for a single weight and grade casing string is determined by multiplying the height of the head of mud by the factor for the mud weight found

TABLE 2.1—API CASING AND LINER CASING
TENSILE REQUIREMENTS

Casing Grade	Yield Strength (psi)		Minimum Tensile Strength (psi)	Maximum Hardness		Minimum Elongation in 2 in. ** (%)
	Minimum	Maximum		HRC*	BHN*	
H-40	40,000	80,000	60,000			
J-55	55,000	80,000	75,000			
K-55	55,000	80,000	95,000			
C-75 [†]	75,000	90,000	95,000			
L-80	80,000	95,000	95,000	23	241	
N-80	80,000	110,000	100,000			
C-90 [†]	90,000	105,000	100,000	25.4	255	
C-95 [†]	95,000	110,000	105,000

Q-125 [‡]	125,000	150,000	135,000			
V-150 [‡]	150,000	180,000	160,000			
Liner Casing						
J-55	55,000	80,000	75,000			

*HRC is Rockwell hardness C scale; BHN is Brinell hardness.

**In customary units,

$$\Delta L = 625,000 \frac{A_s^{0.2}}{\sigma_T^{0.9}}$$

and in metric units,

$$\Delta L = 1942.57 \frac{A_s^{0.2}}{\sigma_T^{0.9}}$$

where

 ΔL = minimum elongation in 2 in. in percent to nearest 1/2%, A_s = cross-sectional area of the tensile test specimen in square inches based on specified OD or nominal specimen width and specified wall thickness rounded to the nearest 0.01 or 0.75 sq in., whichever is smaller, and σ_T = specified minimum ultimate tensile strength, psi.[†]Restricted yield strength intended for use in sour gas service.[‡]Non-API.[§]Special requirements on toughness, uniform hardness, and mill testing.

in Table 2.14. Thus the collapse pressure for an 11,000-ft head of mud with a weight of 9.625 lbm/gal is 5,500 psi (11,000 ft × 0.5 psi/ft = 5,500 psi). To meet the 1.125 collapse safety factor, a collapse resistance of at least 6,188 psi (1.125 × 5,500) is required.

In Table 2.3, the lightest weight of 7-in. casing with a collapse resistance of at least 6,188 psi is 29-lbm N-80 with a collapse resistance of 7,020 psi. (The designer should select the most economical weight and grade that meets the performance property requirements.) By dividing the 7,020-psi collapse resistance by the 5,500-psi collapse pressure, the collapse safety factor is found to be 1.276 (see Table 2.15).

Joint Strength Safety Factor. For the same string, the total load on the joint at the top of the well (ignoring buoyancy effects) is the product of the length of the string (11,000 ft) and the 29-lbm/ft weight of the casing or 319,000 lbm. Dividing the 597,000-lbm minimum joint strength of 7-in., 29-lbm, N-80 long-thread casing given in Table 2.3 on minimum performance properties by the 319,000-lbm weight of casing yields a 1.87 safety factor for joint strength.

Pipe Body Yield Safety Factor. In Table 2.3, the pipe body yield strength is found to be 676,000 lbm. The 676,000-lbm pipe body yield strength divided by the 319,000-lbm weight of the casing string yields the 2.12 safety factor.

Internal Yield Pressure Safety Factor. The bottomhole pressure (BHP) given is 5,500 psi. The internal yield pressure (pressure resistance) for 7-in., 29-lbm, N-80 long-thread casing is 8,160 psi (Table 2.3). The 8,160-psi internal yield pressure divided by the 5,500-psi BHP yields a 1.48 safety factor.

Combination Casing Strings

Collapse Safety Factors. In designing a combination casing string, first determine the casing required to resist the collapse pressure at the bottom of the well (Table 2.16). Then, determine how far this weight and grade must be run before a weight and grade with a lower collapse resistance can be used. The procedure is repeated until the weight with the lowest possible collapse resistance has been used, or until a higher-weight casing is chosen because the advantages of a lower-cost material are offset by increased identification and handling problems. The collapse resistance of casing is affected by any axial load applied to it. Only the bottom section is not affected by axial loading. Sections above the bottom section will have their collapse resistance reduced by the weight of the casing below. Because the axial load acting on the casing and the collapse pressure are both dependent on the depth at which the new casing item is introduced, the changeover point must be determined by

successive approximation or trial-and-error calculations.

When design calculations are made with a computer, the collapse resistance under axial loading can be calculated by use of the method described in the section on equations. Take the depth to which the weight and grade being considered will set with the desired safety factor without axial load as a starting point. Then decrease the depth by suitable increments (perhaps 50 ft), calculating the axial load, the collapse resistance, the collapse pressure, and the safety factor for each increment until the desired safety factor value is obtained.

When design calculations are made without a computer, collapse resistance values can be obtained from Table 2.4 (minimum collapse resistance under axial loading). This table lists collapse resistance under axial stress increments of 5,000 psi. For stresses intermediate to the 5,000-psi increments, collapse resistance can be determined by interpolation. The following collapse calculations for the design of the 7-in., 11,000-ft string were made from Table 2.4.

29-lbm N-80 Bottom-Section Collapse Safety Factor. The method for selection of 29-lbm N-80 for the bottom section and the determination of the 1.276 collapse safety factor is identical to that shown for the 11,000-ft single weight and grade string.

26-lbm N-80 Intermediate-Section Collapse Safety Factor. Determination of the length of the bottom section and the changeover point to 26 lbm, the next lower weight, is facilitated by constructing Table 2.17.

In this table, starting with the tabulated values of axial stress and the corresponding collapse resistance for 26-lbm N-80 casing, the lengths of the 29-lbm casing required to cause the stress and the corresponding collapse safety factors are calculated.

Col. 1 gives the axial stress values in 5,000-psi increments. Col. 3 gives collapse resistance under axial load for the cross-sectional area obtained from Table 2.4 for Grades L-80 and N-80. Col. 2 is the product of Col. 1 and the cross-sectional area. Col. 4 is determined by calculating the weight of casing below the section for which the length is being determined. (This is the general format of the table for use with all sections. In this case, the weight of casing below the section is zero because there is no casing below the 29-lbm N-80.) Col. 5 is the difference between Cols. 2 and 4. Col. 6 is Col. 5 divided by 29. Col. 7 is the depth to the bottom of the 26-lbm section—the changeover point—in this case 11,000 ft minus Col. 6. Col. 8 is Col. 7 multiplied by the mud factor (0.5), and Col. 9 is Col. 3 divided by Col. 8.

The 1,600-ft length of the 29-lbm section found in Col. 6 and the 1.126 safety factor for the 26-lbm section at the changeover point were determined by interpolation according to the following method. The length of the 29-lbm section found in Col. 6 was estimated by calculating

$$1,302 + [(1.125 - 1.095)/(1.238 - 1.095)]$$

$$\times (2,605 - 1,302) = 1,575 \text{ ft,}$$

which is rounded to the next 50-ft multiple to yield 1,600 ft. Cols. 1, 2, 5, 7, and 8 were back-calculated from Col. 6. For instance, the axial stress found in Col. 1 equals $(1,600 \times 29)/7.549$, which equals 6,147 psi.

TABLE 2.2—API CASING AND LINER CASING RANGE LENGTHS

Casing	16 to 25	25 to 34	34 to 48
Total range length, inclusive			
Range length for 95% or more of carload			
Permissible variation, maximum	6	5	6
Permissible length, minimum	18	28	36
Liners			
Same requirements as for casing in Ranges 2 and 3.			

The collapse resistance for the 26-lbm section that corresponds to the 6,147-psi axial stress is estimated by calculating

$$5,310 - [(6,147 - 5,000)/(10,000 - 5,000)]$$

$$\times (5,310 - 5,200) = 5,285 \text{ psi,}$$

which is rounded to the nearest 10 psi according to API procedures to yield 5,290 psi. The collapse safety factor at the 26-lbm section bottom that is shown in Col. 9 is obtained by dividing Col. 3 by Col. 8.

23-lbm N-80 Top Section Collapse Safety Factor. The length of the 26-lbm intermediate section and the changeover point to the next lower weight are calculated with Table 2.18. In Table 2.18, Cols. 5 through 9 cannot be calculated until Col. 2 exceeds Col. 4. The 2,900-ft length of the 26-lbm section that is shown in Col. 6 and the 1.120 safety factor of the 23-lbm section at the changeover point were determined by interpolation.

The length of the 26-lbm section listed in Col. 6 was estimated by calculating

$$2,055 + [(1.125 - 1.005)/(1.194 - 1.005)]$$

$$\times (3,335 - 2,055) = 2,868 \text{ ft,}$$

which is rounded to the next 50-ft multiple to yield 2,900 ft. Cols. 1, 2, 5, 7, and 8 were back-calculated from Col. 6. The collapse resistance of the 23-lbm section that corresponds to the 18,299-psi axial stress is estimated by calculating

$$3,690 - [(18,299 - 15,000)/(20,000 - 15,000)]$$

$$\times (3,690 - 3,620) = 3,644 \text{ psi,}$$

which is rounded to the nearest 10 psi according to API procedures to yield 3,640 psi. The 1.120 collapse safety factor at the 23-lbm section bottom that is listed in Col. 9 is obtained by dividing Col. 3 by Col. 8. By increasing the length of the 29-lbm intermediate section to 2,950 ft and by repeating the calculations for collapse resistance, we obtain a safety factor of 1.129.

(continued on page 32)

* Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E or E₁ plane.

‡ For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

** Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E₁ or E₂ plane.

‡ For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

**Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

†Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E or E₁ plane.

‡For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

** Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E or E₁ plane.

¹ For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

** Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E₁ or E₂ plane.

‡ For P-110 casing the next higher grade is 150Y5, a non-API steel grade having a minimum yield strength of 150,000 psi.

** Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E₁ or E₂ plane.

‡ For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

**Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E₁ or E₂ plane.

‡ For P-110 casing the next higher grade is 150YS—a non-API steel grade having a minimum yield strength of 150,000 psi.

**Some joint strengths listed in Col. 20 through 27 are greater than the corresponding pipe body yield strength listed in Col. 12.

† Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the E or E₁ plane.

‡ For P-110 casing the next higher grade is 150YS, a non-API steel grade having a minimum yield strength of 150,000 psi.

5	17.93	0.362	4.276	7,390	6,970	290
5½	19.81	0.361	4.778	6,610	6,320	321
6⅝	27.65	0.417	5.791	6,170	6,060	447

Joint Strength Safety Factor. To calculate the joint strength safety factor, the weight below each section of the string is calculated and multiplied by the safety factor (1.8 has been used in this design), the joint strength that equals or exceeds the value for the particular section selected, and the actual safety factor calculated. If the joint required is not the short or long thread, that section of the string should be evaluated to determine how much of the section requires the higher-strength joint. The weight per foot and length of each section required to meet the collapse safety factor requirements are listed in Table 2.19.

Joint Required for 23-lbm At Top of String. Table 2.19 shows that the total weight of the string is 271,450 lbm. Multiplying by 1.8 yields a required minimum joint strength of 488,610 lbm. In Table 2.3 we find that the long-thread joint with a joint strength of 442,000 lbm will not provide the required 1.8 minimum safety factor and that the buttress thread with a joint strength of 588,000 lbm is required. Dividing the 588,000-lbm strength of the buttress joint by the 271,450-lbm total weight of the casing yields a safety factor of 2.17.

Joint for the Lower Part of 23-lbm Section. The depth at which the 23-lbm round-thread joint with a strength of 442,000 lbm can be set with a safety factor of 1.8 is

$$(271,450 - 442,000 / 1.8) / 23 = 1,126 \text{ ft,}$$

which is rounded to 1,150 ft. At a depth of 1,150 ft, the weight of the string is $271,450 - 1,150 \times 23$, or 245,000 lbm. Dividing the 442,000-lbm joint strength by the 245,000-lbm load yields a safety factor of 1.804.

Joint for 26-lbm Section. Table 2.19 shows the weight acting on the top of the 26-lbm section to be 123,100 lbm. Multiplying 123,100 lbm by 1.8 requires that the joint strength be equal to or greater than 221,580 lbm. Referring to Table 2.3, we find that the long-thread joint has a strength of 519,000 lbm and can be used. Dividing the 519,000-lbm joint strength by the 221,580-lbm load at the top of the 26-lbm section yields the safety factor 2.34.

Joint for 29-lbm Section. Table 2.19 shows the weight of the string acting on the top of the 29-lbm section to be 46,400 lbm. Multiplying 46,400 lbm by the safety factor, 1.8, requires that the joint strength be equal to or greater than 83,520 lbm. Table 2.3 shows that a long-thread joint has a joint strength of 597,000 lbm and can be used. Dividing the 597,000-lbm joint strength by the 46,400-lbm load at the top of the 29-lbm section gives a safety factor of 12.87.

Pipe-Body Yield-Strength Safety Factors. Values of pipe-body yield strength are determined from Table 2.3 and the string weight at the top of each casing weight from Table 2.19. Pipe-body yield-strength safety factors are determined by dividing the pipe-body yield strengths by the casing weights at the top of the casing string sections (Table 2.20).

Internal-Yield-Pressure Safety Factors. The entire string can be subjected to an internal yield pressure equal to the BHP, which is 5,500 psi. Values of internal yield pressures for the casing joints are obtained from Tables 2.2 and 2.3. Safety factors are determined by dividing the internal yield pressures by 5,500 psi (Table 2.21).

*Buoyancy factor is for converting weight of steel in air to weight in liquid, for checking dead weight on hook. Actual load = length of string times weight per foot times buoyancy factor.

**Slurry giving 11.1 cu ft per sack of cement after setting.

Rough temperature correction (for oil): For temperatures close to 60°F, an approximate correction to 60°F may be made by deducting 1° API for each 13°F that the observed temperature is above 60°F or adding 1° API for each 13°F below.

Calculations based on 11.1 cu ft per sack of cement after setting.

Stretch in Casing When Freely Suspended in Fluid Media (Also Applicable to Tubing)

When pipe is subjected to an axial stress, either tension or compression, that does not exceed the elastic limit of the material, the stretch or contraction may be determined by use of Young's modulus of elasticity (30 million psi for steel pipe).

$$E = \frac{\sigma}{\Delta L_u} \text{ or } E = \frac{W_u/A_m}{\Delta L_t/L_p}, \dots\dots\dots (1)$$

where

- E = Young's modulus of elasticity, psi,
- σ = unit stress, psi,
- ΔL_u = unit axial stretch or contraction, in.,
- W_u = superimposed tension or compression axial load, lbm,
- A_m = cross-sectional metal area of pipe, sq in.,
- ΔL_t = total axial stretch or contraction, in., and
- L_p = length of pipe, in.

The unit tension or compression stress in pipe, when lateral deflection is prevented, is $\sigma = W_u/A_m$, unit axial stretch or contraction being $\Delta L_u = \Delta L_t/L_p$.

Fig. 2.4 gives stretch in single-weight strings of pipe of one grade, or in combination strings of more than one weight or grade. The equations from which these charts

were developed are based on a modified form of Eq. 1 with the lateral contraction of the pipe taken into consideration.

$$\Delta L_t = \Delta L_1 + \Delta L_2 + \Delta L_3 + F_1 \frac{W_2 + W_3}{W_1} + F_2 \frac{W_3}{W_2} + C_1 [L_{s1} \times L_{s2} + (L_{s1} + L_{s2}) L_{s3}] - C_2 \left(L_{s2}^2 \frac{W_1}{W_2} + L_{s3}^2 \frac{W_1 + W_2}{W_3} \right) \dots\dots\dots (2)$$

From Fig. 2.4 we get the values of ΔL_1 and F_1 (Free Stretch Factor 1) corresponding to length L_{s1} ; ΔL_2 and F_2 (Free Stretch Factor 2) from L_{s2} ; and ΔL_3 from L_{s3} .

TABLE 2.20—PIPE-BODY YIELD STRENGTH SAFETY FACTORS

Fig. 2.4—Relieving stresses in suspended casing strings.

Example Problem 1. Assume a 10,000-ft, three-weight combination string is freely suspended in salt water. The weight of the 5,000-ft, 23-lbm/ft top section is $5,000 \times 23 = 115,000$ lbm. The weight of the 3,000-ft, 26-lbm/ft middle section is $3,000 \times 26 = 78,000$ lbm. The weight of the 2,000-ft, 29-lbm/ft bottom section is $2,000 \times 29 = 58,000$ lbm. Determine the casing stretch.

Solution.

$$\begin{aligned} \Delta L_t &= 13.5 + 4.86 + 2.16 + 29 \frac{78,000 + 58,000}{115,000} \\ &+ 10.4 \frac{58,000}{78,000} + 0.000000120177[5,000 \times 3,000 \\ &+ (5,000 + 3,000)2,000] - 0.000000200294 \left[(3,000)^2 \right. \\ &\times \frac{115,000}{78,000} + (2,000)^2 \frac{115,000 + 78,000}{58,000} \left. \right] \\ &= 20.52 + 29 \times 1.183 + 10.4 \times 0.744 + 0.000000120177 \\ &\times 31,000,000 - 0.000000200294 \times 26,578,000 \\ &= 20.52 + 34.31 + 7.74 + 3.73 - 5.32 \\ &= 60.98 \text{ in.} \end{aligned}$$

To determine tension stresses in casing strings after they are set and cemented, the following equations are used.

$$W_t = C_3(w'_1 L'_1 + w'_2 L'_2 + \dots + w'_n L'_n),$$

$$L_0 = C_4 W_t (L_1/w_1 + L_2/w_2 + \dots + L_n/w_n),$$

and

$$L_s = C_5 \sigma_t L,$$

where

$$L = (L_1 + L_2 + \dots + L_n),$$

$$L_d = L_0 - L_s,$$

$$C_3 = (1 - \rho_f/\rho_s),$$

$$C_4 = 40.8/E, \text{ and}$$

$$C_5 = 12/E.$$

Fig. 2.5—Example string.

In these equations,

L_1, L_2, \dots

L_n = lengths above top of cement of single-weight Sections 1, 2, ..., n of combination string, ft,

L'_1, L'_2, \dots

L'_n = lengths below top of cement of single-weight Sections 1, 2, ..., n of combination string, ft,

w_1, w_2, \dots

w_n = weights of single-weight Sections 1, 2, ..., n of combination string above top of cement, lbm/ft,

w'_1, w'_2, \dots

w'_n = weights of single-weight Sections 1, 2, ..., n of combination strings below top of cement, lbm/ft,

C_1 = constant (for salt water, 0.000000120177; for rotary mud, 0.000000150869; and for air, zero),

C_2 = constant (for salt water, 0.000000200294; for rotary mud, 0.000000251448; and for air, zero),

C_3 = constant (for salt water, 0.8527; for rotary mud, 0.8151; for air, 1.0),*

C_4 = constant, 0.00000136,

C_5 = constant, 0.0000004,

L_d = distance to lower top of casing for a desired stress at top of cement, in.,

L_s = stretch corresponding to σ_t , in.,

L_0 = distance required to lower top of casing for zero stress at top of cement, in.,

W_t = total load below top of cement, lbm,

σ_t = tension stress desired to be left at top of cement, psi.

ρ_f = density of floatant, lbm/cu in. (for salt water, 0.041728; for rotary mud, 0.052385),* and

ρ_s = density of steel, 0.2833 lbm/cu in.

*Based on salt water and rotary mud having specific gravities of 1.155 and 1.45, respectively.

TABLE 2.22—API TUBING TENSILE REQUIREMENTS

Tubing Grade	Yield Strength, psi		Minimum Tensile Strength (psi)	Maximum Hardness		Minimum Elongation in 2 in.* (%)
	Minimum	Maximum		HRC	BHN	
H-40	40,000	80,000	60,000			
J-55	55,000	80,000	75,000			
C-75	75,000	90,000	95,000			
L-80	80,000	95,000	95,000	23	241	
N-80	80,000	110,000	100,000			
C-90	90,000	105,000	100,000	25.4	255	
P-105	105,000	135,000	120,000			

*The minimum elongation in 2 in. is determined by the equation in Table 2.1

Example Problem 2. Assume that an 11,000-ft combination string of 7-in.-OD casing is suspended freely in salt water, then cemented 4,000 ft up. The weight and length of the sections are shown in Fig. 2.5. We must find L_0 for zero stress at the top of the cement and L_d for a 5,000-lbm tension at the top of the cement.

Solution.

$$\begin{aligned}
 W_t &= C_3(w_1' L_1' + w_2' L_2') \\
 &= 0.8527[(32 \times 2,000) + (38 \times 2,000)] \\
 &= 0.8527(64,000 + 76,000) \\
 &= 0.8527 \times 140,000 \\
 &= 119,378 \text{ lbm.}
 \end{aligned}$$

$$\begin{aligned}
 L_0 &= C_4 W_t \left(\frac{L_1}{w_1} + \frac{L_2}{w_2} + \frac{L_3}{w_3} \right) \\
 &= 0.00000136 \times 119,378 \left(\frac{3,500}{26} + \frac{3,000}{29} + \frac{500}{32} \right) \\
 &= 0.16235(134.62 + 103.45 + 15.63) \\
 &= 0.16235 \times 253.70 \\
 &= 41.19 \text{ in.}
 \end{aligned}$$

$$\begin{aligned}
 L_s &= C_5 \sigma_t L \\
 &= 0.0000004 \times 5,000(3,500 + 3,000 + 500) \\
 &= 0.002 \times 7,000 \\
 &= 14 \text{ in.}
 \end{aligned}$$

$$\begin{aligned}
 L_d &= L_0 - L_s \\
 &= 41.19 - 14 \\
 &= 27.19 \text{ in.}
 \end{aligned}$$

For any variation in temperature after cementing, the corresponding expansion or contraction for the part of the string above the cement must be considered.

Single-Weight String Suspended in Rotary Mud

For a single-weight string suspended in rotary mud, the distance required to lower the top of the casing for a zero stress at the top of the cement is determined by

$$L_0 = C_6(D - L')L'$$

where

$$C_6 = C_3 C_4,$$

D = total depth of the well or length of string, ft, and

L' = length of casing below top of cement, ft.

Example Problem 3. Assume an 8,000-ft-long single-weight string of any OD and weight suspended freely in rotary mud with a specific gravity of 1.45, then cemented 2,100 ft up. Determine the amount the top of the casing has to be lowered for a zero stress at the top of the cement. For rotary mud with this specific gravity, $C_3 = 0.8151$, $D = 8,000$ ft, and $L' = 2,100$ ft.

Solution.

$$\begin{aligned}
 L_0 &= C_6(D - L')L' \\
 &= 0.8151 \times 0.00000136(8,000 - 2,100)2,100 \\
 &= 0.0000011085 \times 5,900 \times 2,100 \\
 &= 13.7 \text{ in.}
 \end{aligned}$$

Tubing

The performance of the tubing that is run inside the casing to conduct oil or gas to ground level is important. Tubing not only must withstand the same stresses to which casing is subjected, but also must resist the corrosive action of well fluids that in some areas is severe.

API has developed specifications that meet the major needs of the oil and gas industry.^{1,2,4-7} API specifications and bulletins provide standard dimensions, strength and performance properties, and the required gauging practice to ensure complete interchangeability.

Tables 2.22 and 2.23 give the tensile requirements and range lengths of API tubing. Listed in Table 2.24 are the minimum performance properties of tubing. Tables 2.25 through 2.27 give the dimensions, weights, and tolerances of nonupset and external-upset tubing, couplings, and integral-joint tubing upsets (see also Figs. 2.6 through 2.8). Multiplication factors for converting net footage to gross linear footage are given in Table 2.28. Equations for calculating performance properties of tubing are found in the section on equations.

Special Tubing Joints

A number of special tubing joints are useful when more strength, leak resistance, or clearance is needed than that provided by the standard API nonupset, upset, or integral joints. These special joints obtain their improved properties by various means, such as couplings or box ends with seal rings of teflon, etc.; special thread profiles, such as Acme or buttress; torque shoulders; metal-to-metal seals; internal upsets; external upsets; integral joints; and flush joints.

Design of Tubing Strings: Oil, Water, and Mud-Weight Factors

For information on oil, water, and mud weight factors needed in the design of tubing strings, refer to Table 2.14, which lists these factors for casing. The same table also will apply to tubing design.

Safety Factors

The following safety factors are commonly used in the design of tubing strings. These safety factors will be used

TABLE 2.24—MINIMUM PERFORMANCE PROPERTIES OF TUBING (continued)

in the example tubing string design. The designer has the responsibility to select safety factors to suit particular needs: collapse strength, 1.125; joint yield strength, 1.80; and internal yield pressure, 1.00.

Single Weight and Grade Tubing String. Table 2.29 includes design data and safety factors for an 11,000-ft single weight and grade upset tubing string with an OD of 2 $\frac{7}{8}$ in.

Selection of Nominal Weight and Grade. Formulating a table similar to Table 2.30 is convenient when the nominal weight and grade of tubing are selected to meet the adopted safety factor requirements. Table 2.30 is based on the safety factor requirements, collapse resistance, joint yield strengths, and internal yield pressures that can be found in Table 2.24.

Cols. 1 through 4 and 7 were obtained directly from Table 2.24. Grades C-95 and L-80, which have restricted yield-strength ranges, were eliminated from consid-

eration because the well conditions did not warrant the use of such premium grades of tubing. The collapse setting depths in Col. 5 were obtained by dividing collapse resistance (Col. 3) by the 0.5-psi pressure gradient and 1.125, the safety factor. The joint yield-strength setting depths (Col. 6) were obtained by dividing the joint yield-strength values in Col. 4 by the nominal weight per foot (Col. 1) and 1.80, the safety factor. Col. 7 was obtained directly from Table 2.24 and required no modification because the entire string may be subjected to an internal pressure equal to the BHP.

It is apparent from Table 2.30 that 2 $\frac{7}{8}$ -in., 6.5-lbm N-80 upset tubing will be required because it is the lowest grade that provides adequate collapse resistance, joint yield strength, and internal yield pressure strength.

Collapse Safety Factor. The collapse safety factor of 2.029 in Table 2.29 was determined by dividing the 11,160-psi collapse resistance in Col. 3 of Table 2.30 by the 0.5-psi/ft pressure gradient and the 11,000-ft length of the string.

TABLE 2.29—DESIGN SAFETY FACTORS FOR SINGLE WEIGHT AND GRADE TUBING STRING
Design data for an 11,000-ft string of 2 $\frac{7}{8}$ -in.-OD upset tubing with 9.625-lbm/gal
mud weight and 5,500-psi BHP

Nominal Weight per Foot (lbm/ft)	Grade	Type Thread	Amount (ft)	Safety Factor		
				Collapse	Joint Yield Strength	Internal Yield Pressure (psi)
6.50	6,680	API	11,000	2.029	2.03	1.92

TABLE 2.30—2 7/8-in.-OD UPSET TUBING SETTING DEPTHS IN COLLAPSE, TENSION, AND INTERNAL PRESSURE RESISTANCE, INCLUDING SAFETY FACTORS

Nominal Weight per Foot (lbm/ft)	Grade	Collapse Resistance (psi)	Joint Yield Strength (lbf)	Setting Depth (ft)		Internal Yield Pressure (psi)
				Collapse	Joint Yield Strength	
					Safety Factors	
				1.125	1.80	1.00
				6.50	H-40	5,580
6.50	J-55	7,680	99,700	13,653	8,521	7,260
6.50	N-80	11,160	145,000	19,840	12,393	10,570

Joint Yield Strength Safety Factor. The joint yield strength safety factor of 2.03 was determined by dividing the 145,000-lbm joint yield strength in Col. 4 by 6.50 lbm, the nominal weight per foot, and the 11,000-ft length of the string.

Internal Yield Pressure Safety Factor. The internal yield pressure safety factor of 1.92 was determined by dividing the 10,570-psi internal yield pressure in Col. 7 by 5,500 psi, the BHP.

Stretch in Tubing When Freely Suspended in Fluid Media

When tubing is subjected to an axial stress, either tension or compression, that does not exceed the elastic limit of the material, the stretch or contraction may be determined by Eqs. 1 and 2 for casing. These equations also are applicable to tubing.

Line Pipe

Line pipe is used by the oil and gas industry to transport oil, gas, and water. API has developed specifications for line pipe⁶⁻⁸ to meet the needs of the oil and gas industry. These provide standard dimensions, strength and performance properties, and the required thread gauging practice to ensure complete interchangeability. Tables 2.31 through 2.37 include dimensional and strength data of API line pipe.

Tables 2.31 and 2.32 give the tensile requirements and tolerances on lengths of API line pipe. Performance property data applicable to standard-weight, threaded line pipe are given in Tables 2.33 through 2.35 and Fig. 2.9. Table 2.36 gives the dimensions, weights, and test pressures of extra-strong threaded line pipe. Table 2.37 lists the dimensions, weights, and test pressures of plain-end line pipe. Equations for calculating performance properties of line pipe are found in the following section.

Equations for Calculating Performance Properties of Casing, Tubing, and Line Pipe

API developed equations for calculating the performance properties of API casing, tubing, and line pipe.⁷ These equations were used to calculate the performance properties for non-API grades of casing and tubing, except for the collapse resistance of HC-95 casing. The collapse resistance of HC-95 casing is assumed to be the same as that published by Lone Star Steel⁹ for their proprietary S-95 grade. This proprietary grade is offered by other manufacturers under various 95 designations.

Collapse Pressure Equations

The minimum collapse pressures given in API Bull. 5C2 are calculated by means of Eqs. 3, 5, 7, and 9, adopted at the API 1968 Standardization Conference and reported in API Circular PS-1360, Sept. 1968.¹⁰ Eqs. 4, 6, and 8 for the intersections between the four collapse pressure equations have been determined algebraically and are included for use in calculating the applicable d_o/e range (OD/wall thickness) for each collapse pressure equation. Factors F_A , F_B , F_C , F_F , and F_G are calculated by Eqs. 12 through 16.

The collapse pressures for Tables 2.3 and 2.4 are calculated with the specified values for d_o and e . The calculated d_o/e was rounded to two decimals. The collapse pressure calculations were carried to eight or more digits and rounded to the nearest 10 psi to produce the final values in the tables.

TABLE 2.31—TENSILE REQUIREMENTS OF LINE PIPE

Grade	Minimum Yield Strength (psi)	Minimum Ultimate Tensile Strength (psi)	Minimum Elongation in 2 in.* (%)
A25	25,000	45,000	
A	30,000	48,000	
B	35,000	60,000	
X42	42,000	60,000	
X46	46,000	63,000	
X52	52,000	66,000**	
		72,000†	
X56	56,000	71,000**	
		75,000†	
X60‡	60,000	75,000**	
		78,000†	
X65	65,000	77,000**	
		80,000†	
X70	70,000	82,000	

*The minimum elongation in 2 in. shall be that determined by the equation in Table 2.1.

**For pipe less than 20 in. OD with any wall thickness and for pipe 20 in. OD and larger with wall thickness greater than 0.375 in.

†For pipe with a 20-in. OD and larger with a wall thickness of 0.375 in. and less.

‡The minimum ultimate tensile strength for Grade X60 Electric-Resistance Welded Pipe in all sizes and wall thicknesses shall be 75,000 psi.

TABLE 2.32—TOLERANCES ON LENGTHS OF LINE PIPE*

	Shortest Length in Entire Shipment (ft)	Shortest Length in 95% of Entire Shipment (ft)	Shortest Length in 90% of Entire Shipment (ft)	Minimum Average Length Entire Shipment (ft)
Threaded-and-Coupled Pipe				
Single random lengths	16.0	8.0	—	
Double random lengths	22.0	—	—	35.0
Plain-End Pipe				
Single random lengths	9.0	—	—	17.5
Double random lengths	14.0	—	26.3	35.0
As agreed upon lengths in excess of 20 ft*	40% of average agreed upon	—	75% of average agreed upon	

*By agreement between the purchaser and the manufacturer, these tolerances shall apply to each carload.

Fig. 2.9—Line pipe and coupling. See Table 2.33 for pipe dimensions.

Yield-Strength Collapse-Pressure Equation. The yield-strength collapse pressure is not a true collapse pressure, but rather the external pressure, p_y , that generates minimum yield stress, σ_y , on the inside wall of a tube as calculated by Eq. 3.

$$p_y = 2\sigma_y \left[\frac{d_o/e - 1}{(d_o/e)^2} \right] \quad \dots \dots \dots (3)$$

Eq. 3 for yield strength collapse pressure is applicable for d_o/e values up to the value corresponding to the intersection with the plastic collapse (Eq. 5). This intersection is calculated by Eq. 4. Applicable d_o/e ratios for yield-strength collapse are shown in Table 2.38.

$$(d_o/e)_{yp} = \frac{\sqrt{(F_A - 2)^2 + 8(F_B + F_C/\sigma_y)} + (F_A - 2)}{2(F_B + F_C/\sigma_y)} \quad \dots \dots \dots (4)$$

*Grades indicated without letter designation are not API grades but are grades in use or grades being considered for use.

**The d_o/e range values were calculated from Eqs. 4 and 12 through 14 to eight or more digits.

where F_A , F_B , and F_C are equation factors established by the API task group on performance properties (Table 2.39) and σ_y is yield pressure.

Plastic Collapse-Pressure Equation. The minimum collapse pressure for the plastic range of collapse is

$$p_p = \sigma_y \left(\frac{F_A}{d_o/e} - F_B \right) - F_C \quad \dots \dots \dots (5)$$

The equation for minimum plastic collapse pressure is applicable for d_o/e values ranging from $(d_o/e)_{yp}$ (Eq. 4 for yield-point collapse pressure) to the intersection with Eq. 7 for transition collapse pressure, $(d_o/e)_{pT}$. Values for $(d_o/e)_{pT}$ are calculated by

$$(d_o/e)_{pT} = \frac{\sigma_y(F_A - F_F)}{F_C + \sigma_y(F_B - F_G)} \quad \dots \dots \dots (6)$$

*The d_o/e range values and equation factors were calculated from Eqs. 4, 6, and 12 through 16 to eight or more digits.

**Grades indicated without letter designation are not API grades but are grades in use or grades being considered for use.

where F_F and F_G are equation factors (Table 2.40), and the subscript pT denotes transition pressure.

The factors and applicable d_o/e range for the plastic collapse equation are shown in Table 2.39.

Transition Collapse-Pressure Equation. The minimum collapse pressure for the plastic to elastic transition zone is calculated with

$$p_T = \sigma_y \left(\frac{F_F}{d_o/e} - F_G \right) \quad \dots \dots \dots (7)$$

Eq. 7 for p_T is applicable for d_o/e values from $(d_o/e)_{pT}$ (Eq. 6 for plastic collapse pressure) to the intersection $(d_o/e)_{TE}$ with Eq. 9 for elastic collapse. Values for $(d_o/e)_{TE}$ are calculated with

$$(d_o/e)_{TE} = \frac{2 + F_B/F_A}{3F_B/F_A} \quad \dots \dots \dots (8)$$

where the subscript TE denotes elastic transition.

The factors and applicable d_o/e range for the transition collapse-pressure equation are shown in Table 2.40.

Elastic Collapse-Pressure Equation. The minimum collapse pressure for the elastic range of collapse is calculated with

$$p_E = \frac{46.95}{(d_o/e)[(d_o/e) - 1]^2} \quad \dots \dots \dots (9)$$

The applicable d_o/e range for elastic collapse is shown in Table 2.41.

Collapse Pressure Under Axial-Tension Stress. The collapse resistance of casing in the presence of an axial stress is calculated by modifying the yield stress to an axial stress equivalent grade according to Eq. 10.⁵

$$\sigma_{ya} = [\sqrt{1 - 0.75(\sigma_a/\sigma_y)^2} - 0.5\sigma_a/\sigma_y]\sigma_y \quad \dots \dots (10)$$

where

σ_a = axial stress (tension is positive), psi,

σ_y = minimum yield strength of pipe, psi, and

σ_{ya} = yield strength of axial-stress equivalent grade, psi.

Collapse-resistance equation factors and d_o/e ranges for the axial-stress equivalent grade are then calculated with Eqs. 4, 6, 8, and 12 through 16. With the equation factors for the axial-stress equivalent grade, collapse resistance under axial load is calculated with Eqs. 3, 5, 7, and 9, with d_o/e rounded to two decimals. The reduced collapse-pressure calculations are carried to eight digits in all intermediate steps, and the final answer is rounded to the nearest 10 psi.

Eq. 10 is based on the Hencky-von Mises maximum strain energy of distortion theory of yielding.

Example Problem 4. Calculate the collapse pressure of 7-in., 26-lbm P-110 casing with an axial stress of 11,000 psi. The wall thickness is 0.362 in.; $\sigma_a = 11,000$ psi, and $\sigma_y = 110,000$ psi.

-160	21.32 and greater
-170	20.60 and greater
-180	19.93 and greater

*Grades indicated without letter designation are not API grades but are grades in use or grades being considered for use.

**The d_o/e range values were calculated from Eqs. 8, 12, and 13 to eight or more digits.

Solution. Substitution into Eq. 10 gives

$$\sigma_{yu} = [\sqrt{1 - 0.75(11,000/110,000)^2} - 0.5(11,000/110,000)]110,000 = 104,087 \text{ psi.}$$

Substitution of σ_{yu} for σ_y in Eqs. 4, 6, 8, and 12 through 16 results in the following values.

$$\begin{aligned} F_A &= 3.158, \\ F_B &= 0.0789, \\ F_C &= 2.675, \\ F_F &= 2.051, \\ F_G &= 0.0512, \\ (d_o/e)_{yp} &= 12.59, \\ (d_o/e)_{pT} &= 20.75, \text{ and} \\ (d_o/e)_{TE} &= 27.02. \end{aligned}$$

The d_o/e range for yield collapse is 12.59 or less; for plastic collapse, 12.59 to 20.75; for transition collapse, 20.75 to 27.02; and for elastic collapse, 27.02 or greater. The d_o/e is 7/0.362, or 19.34, indicating that collapse is in the plastic range. Substitution of F_A (3.158), F_B (0.0789), and F_C (2.675) into Eq. 5 for plastic collapse yields

$$\begin{aligned} p_p &= \sigma_{yu}[F_A/(d_o/e) - F_B] - F_C \\ &= 104,087(3.158/19.34 - 0.0789) - 2.675 \\ &= 6,110 \text{ psi.} \end{aligned}$$

HC-95 Casing. The collapse resistance of casing in the presence of an axial stress is calculated with Eq. 11, which is based on the total strain energy theory of yielding.⁹

$$p_{ca} = [\sqrt{1 - 0.9324(\sigma_a/\sigma_y)^2} - 6.26(\sigma_a/\sigma_y)]p_{co}, \quad (11)$$

where p_{ca} is the minimum collapse pressure under axial stress, psi, and p_{co} is the minimum collapse pressure without axial stress, psi.

Collapse Equation Factors. Collapse equation factors for plastic and transition collapse are calculated by the following equations:

$$\begin{aligned} F_A &= 2.8762 + 0.10679 \times 10^{-5} \sigma_y \\ &\quad + 0.21301 \times 10^{-10} \sigma_y^2 - 0.53132 \times 10^{-16} \sigma_y^3, \end{aligned} \quad (12)$$

$$F_B = 0.026233 + 0.50609 \times 10^{-6} \sigma_y, \quad (13)$$

$$\begin{aligned} F_C &= -465.93 + 0.030867 \sigma_y - 0.10483 \times 10^{-7} \sigma_y^2 \\ &\quad + 0.36989 \times 10^{-13} \sigma_y^3, \end{aligned} \quad (14)$$

and

$$F_F = \frac{46.95 \times 10^6 \left(\frac{3F_B/F_A}{2 + F_B/F_A} \right)^3}{\sigma_y \left(\frac{3F_B/F_A}{2 + F_B/F_A} - F_B/F_A \right) \left(1 - \frac{3F_B/F_A}{2 + F_B/F_A} \right)^2}, \quad (15)$$

Expressed in metric units, Eqs. 12 through 15 become, respectively,

$$\begin{aligned} F_A &= 2.8762 + 1.5488 \times 10^{-4} \sigma_y + 4.4806 \times 10^{-7} \sigma_y^2 \\ &\quad - 1.6209 \times 10^{-3} \sigma_y^3, \end{aligned}$$

$$F_B = 0.026233 + 7.33995 \times 10^{-6} \sigma_y,$$

$$\begin{aligned} F_C &= -3.2126 + 0.030867 \sigma_y - 1.5204 \times 10^{-6} \sigma_y^2 \\ &\quad + 7.7804 \times 10^{-10} \sigma_y^3, \end{aligned}$$

and

$$\begin{aligned} F_F &= \frac{323.7 \times 10^3 \left(\frac{3F_B/F_A}{2 + F_B/F_A} \right)^3}{\sigma_y \left(\frac{3F_B/F_A}{2 + F_B/F_A} - F_B/F_A \right) \left(1 - \frac{3F_B/F_A}{2 + F_B/F_A} \right)^2}, \\ F_G &= \frac{F_F F_B}{F_A}. \end{aligned} \quad (16)$$

Pipe-Body Yield Strength

Pipe-body yield strength is the axial load required to yield the pipe. It is taken as the product of the cross-sectional area and the specified minimum yield strength for the particular grade of pipe.

Values for pipe-body yield strength were calculated with Eq. 17.

$$W_p = 0.7854(d_o^2 - d_i^2)\sigma_y, \quad (17)$$

where

$$\begin{aligned} W_p &= \text{pipe-body yield strength, lbf (rounded to} \\ &\quad \text{the nearest 1,000), and} \\ d_i &= \text{specified inside diameter, in.} \end{aligned}$$

Internal Pressure Resistance

Internal pressure resistance is the lowest of the internal yield pressure of the pipe, the internal yield pressure of the coupling, or the internal pressure leak resistance at the d_{p1} or d_p plane calculated with Eqs. 18, 19, and 22.

Internal Yield Pressure for Pipe. Internal yield pressure for pipe is calculated from Eq. 18. The factor 0.875 appearing in Eq. 18 allows for minimum wall.

$$p_{yi} = 0.875 \left(\frac{2\sigma_y e}{d_o} \right). \quad (18)$$

Included taper on diameter, all sizes, 0.0625 in./in.

* $L_c = L_4 - 1.125$ in. for eight round thread casing.

**For 10¾-in. Grade P-110 casing, and 20-in. Grade J-55 and K-55 casing, the hand-tight standoff "A" is four thread turns.

Internal Yield Pressure for Couplings. Internal yield pressure for threaded and coupled pipe is the same as for plain-end pipe, except where a lower pressure is required to avoid leakage because of insufficient coupling strength. The lower pressure is based on Eq. 19 and is rounded to the nearest 10 psi.

$$p_{yi} = \sigma_{yc} \left(\frac{d_{oc} - d_1}{d_{oc}} \right), \quad (19)$$

where

σ_{yc} = minimum yield strength of coupling, psi.

d_{oc} = nominal OD of coupling, rounded to the nearest 0.001, in., and

d_1 = diameter at the root of the coupling thread at the end of the pipe in the power-tight position, rounded to the nearest 0.001, in.

For round-thread casing and tubing,

$$d_1 = d_p - (L_1 + L_{so})F_T + h_{tc} - 2S_m, \quad (20)$$

where

d_p = pitch diameter at hand-tight plane (Table 2.42), in.,

L_1 = length from end of pipe to hand-tight plane (Table 2.43), in.,

L_{so} = hand-tight standoff, in. (L_{so} in API Standard 5B is given in turns),

F_T = taper, in./in. ($F_T = 0.0625$ for 4½- through 13¾-in. casing and 0.0833 for casing larger than 13¾ in.),

h_{tc} = thread height (0.08660 for 10 threads/in.; 0.10825 for 8 threads/in.), in., and

S_m = thread root truncation (0.014 for 10 threads/in.; 0.017 for 8 threads/in.), in.

For buttress-thread casing,

$$d_1 = d_p' - (L_7 + I)F_T + 0.062, \quad (21)$$

where

d_p' = pitch diameter, in.,

L_7 = length of perfect threads, in., and

I = length from the end of the coupling to the base of the triangle in the hand-tight position (Fig. 2.10), in. ($I = 0.400$ for 4½-in. casing; 0.500 for 5- through 13¾-in. casing; and 0.375 for casing larger than 13¾ in.)

Internal-Pressure Leak Resistance at Plane d_{p1} or d_p

The internal-pressure leak resistance at Plane d_{p1} or d_p is calculated with Eq. 22 and rounded to the nearest 10 psi. Eq. 22 is based on the assumption that the seal is at

Included taper on diameter: Sizes 13 $\frac{3}{8}$ in. and smaller—0.0625 in./in.
 Sizes 16 in. and larger—0.0833 in./in.

* $L_c = L_7 - 0.400$ for buttress casing. Within the L_c length, as many as 2 threads showing the original outside surface of the pipe on their crests for a circumferential distance not exceeding 25% of the pipe circumference is permissible. The remaining threads in the L_c thread length shall be full crested threads.

NOTE: At plane of perfect thread length L_7 , the basic major diameter of the pipe thread and plug gauge thread is 0.016 in. greater than nominal pipe diameter d_o for sizes 13 3/8 in. and smaller, and is equal to the nominal pipe diameter for sizes 16 in. and larger.

The interface pressure between the pin and box as a result of makeup is

$$p_{ij} = EF_T n L_{ip} (r_b^2 - r_c^2)(r_c^2 - r_i^2) / 4 r_c^2 (r_b^2 - r_i^2), \quad \dots \dots \dots (23)$$

where r_i is the pipe radius in inches.

After makeup, internal pressure, p_i , causes a change in the interface pressure by an amount Δp_{if} :

$$\Delta p_{if} = p_i r_i^2 (r_b^2 - r_c^2) / r_c^2 (r_b^2 - r_i^2). \quad \dots\dots\dots (24)$$

Because $r_b > r_c > r_i$, $\Delta p_{if} < p_i$. Therefore, when $p_{if} + \Delta p_{if} = p_i$, the connection has reached the leak resistance limit, p_H . In other words, if $p_i > p_{if} + \Delta p_{if}$, leakage would occur.

$$p_{if} + \Delta p_{if} = p_i = p_{il}, \quad \dots \dots \dots (25)$$

Substituting the appropriate values of $p_{ij} + \Delta p_{ij}$ into Eq. 25 and simplifying produces Eq. 22. Note that the dimension r_i no longer remains a variable.

Fig. 2.10B—Basic dimensions of buttress casing threads, hand-tight makeup.

Joint Strength

Round-Thread Casing Joint Strength. Round-thread casing joint strength is calculated with Eqs. 26 and 27. The lesser of the values obtained from these two equations governs. Eqs. 26 and 27 apply to both short and long threads and couplings. Eq. 26 is for minimum strength of a joint failing by fracture, and Eq. 27 is for minimum strength of a joint failing by thread jumpout or pullout.

$$W_j = 0.95 A_{ip} \sigma_{up} \quad (26)$$

and

$$W_j = 0.95 A_{ip} L_e \left(\frac{0.74 d_o^{-0.59} \sigma_{up}}{0.5 L_e + 0.141 d_o} + \frac{\sigma_y}{L_e + 0.14 d_o} \right), \quad (27)$$

where

W_j = minimum joint strength, lbf,

A_{ip} = cross-sectional area of the pipe wall under the last perfect thread,
 $0.7854[(d_o - 0.1425)^2 - d_i^2]$ for eight round threads, sq in.,

L_e = engaged thread length ($L_4 - L_{ph}$ for nominal makeup, API Standard 5B), in.,

L_{ph} = length face of coupling to hand-tight plane, Col. 10 of Table 2.42 or Col. 9 of Table 2.43,

σ_{up} = minimum ultimate strength of pipe, psi, and

σ_y = minimum yield strength of pipe, psi.

Joint strengths of round-thread casing given in API Bull. 5C2⁵ were calculated with tabulated values of diameter and thickness and API-listed values of L_4 and L_{ph} . Pipe area was calculated to three decimals, $d_o^{-0.59}$ was calculated to five digits from a seven-place logarithm table, and remaining calculations used six digits. Listed values were rounded to 1,000 lbf.

Eqs. 26 and 27 were adopted at the 1963 API Standardization Conference.¹¹ Clinedinst¹² covers the derivation of the equations. They are based on the results of an API-sponsored test program consisting of tension tests of 162 joints of round-thread casing in Grades K-55, N-80, and P-110 covering a range of wall thicknesses in 4½-, 5-, 5½-, 6¾-, 7-, 9¾-, and 10¾-in. diameters using both short and long threads where called for by the size and grade tested. Fourteen tests failed by fracture of the pipe, and 148 tests failed by pullout. Eq. 26 agrees satisfactorily with the 14 test fractures. Eq. 27 is based on analytical considerations and was adjusted to fit the data by statistical methods. The analytical procedure included coupling properties, but analysis of the current group of tests showed that the coupling was noncritical for standard coupling dimensions. Subsequent testing established that these equations are also applicable to J-55 casing.

The factor 0.95 in Eqs. 26 and 27 originates in the statistical error of a multiple-regression equation with adjustment to permit the use of minimum properties in place of average properties.

Buttress-Thread Casing Joint Strength. Buttress-thread casing joint strength is calculated from Eqs. 28 and 29. The lesser of the values obtained from the two equations governs.

For pipe thread strength,

$$W_j = 0.95 A_p \sigma_{up} [1.008 - 0.0396(1.083 - \sigma_y/\sigma_{up})d_o], \quad (28)$$

and for coupling thread strength,

$$W_j = 0.95 A_c \sigma_{uc}, \quad (29)$$

where

A_p = cross-sectional area of plain-end pipe
 $(0.7854 \text{ or } d_o^2 - d_i^2)$, sq in.,

A_c = cross-sectional area of coupling $(0.7854 \text{ or } d_{oc}^2 - d_i^2)$, sq in., and

σ_{uc} = minimum ultimate strength of coupling, psi.

Joint strengths were calculated to six-digit accuracy with cross-sectional areas of the pipe and the coupling rounded to three decimals. Final values were rounded to the nearest 1,000 lbf for listing in Table 2.3.

The equations, adopted at the June 1970 API Standardization Conference,¹³ were based on a regression analysis of 151 tests of buttress-thread casing ranging in size from 4½- to 20-in. OD and in strength levels from 40,000- to 150,000-psi minimum yield. Derivation of the equations is covered by Clinedinst.¹⁴

Extreme-Line Casing Joint Strength. Extreme-line casing joint strength is calculated from Eq. 30:

$$W_j = A_{cr} \sigma_{up}, \quad (30)$$

where

A_{cr} = critical section area of box, pin, or pipe, whichever is least $[0.7854(d_{oj}^2 - d_b^2)$ if box is critical, $0.7854(d_p^2 - d_j^2)$ if pin is critical, $0.7854(d_o^2 - d_i^2)$ if pipe is critical],

d_{oj} = nominal joint OD, made up, in.,

d_b = box critical section ID
 $(d_{bc} + 2h_{tb} - \delta_{Td} + \theta_{th})$, in.,

d_p = pin critical section OD $(d_{pp} + \delta_{Tr} - \theta_s)$, in.,

d_j = nominal joint ID, made up, in.,

h_{tb} = minimum box thread height (0.060 for 6 threads/in. and 0.080 for 5 threads/in.), in.,

δ_{Td} = taper drop in pin perfect thread length (0.253 for 6 threads/in. and 0.228 for 5 threads/in.), in.,

θ_{th} = one-half maximum thread interference
 $(d_{pp} - d_{bc})/2$, in.,

d_{pp} = maximum root diameter at last perfect pin thread, in.,

d_{bc} = minimum crest diameter of box thread at Plane H, in.,

- δ_{Tr} = taper rise between Plane H and Plane J
(0.035 for 6 threads/in. and 0.032 for 5
threads/in.), in.,
 θ_s = one-half maximum seal interference
($d_{ps} - d_{bs}$)/2, in.,
 d_{ps} = maximum diameter at pin seal tangent
point, in., and
 d_{bs} = minimum diameter at box seal tangent
point, in.

With the values listed in API standards, critical areas were calculated to three decimals, and the joint strengths were rounded to 1,000 lbf.

Tubing Joint Strength. Tubing joint strength is calculated from Eqs. 31 and 32 as the product of the specified minimum yield strength for the steel grade and the area of section under the root of the last perfect pipe thread or of the area of the pipe body, whichever is smaller. The areas of the critical sections of regular tubing couplings, special-clearance couplings, and the box of integral-joint tubing are, in all instances, greater than the governing critical areas of the pipe part of the joint and do not affect the strength of the joint.

For calculations that are based on the thread root area,

$$W_j = \sigma_y \times 0.7854[(d_o - 2h_{ij})^2 - d_i^2], \quad (31)$$

and for calculations that are based on area of the body of the pipe,

$$W_j = \sigma_y \times 0.7854(d_o^2 - d_i^2), \quad (32)$$

where

$$h_{ij} = \text{height of thread (0.05560 for 10 threads/in. and 0.07125 for 8 threads/in.)}, \text{ in.}$$

Joint strength was calculated to an accuracy of at least six digits and rounded to 100 lbf.

Joint Strength of Round-Thread Casing with Combined Bending and Internal Pressure. Joint strength of round-thread casing subjected to combined bending and internal pressure is calculated from Eqs. 33 through 39 on a total load basis and is expressed in pounds. These equations were based on Clinedinst's paper.¹⁵ Tables of joint strength of API round-thread casing with combined bending and internal pressure are given in API Bull. 5C4.¹⁶

Full Fracture Strength.

$$W_{fu} = 0.95A_{jp}\sigma_{up}, \quad (33)$$

Jumpout and Reduced Fracture Strength.

$$W_{jo} = 0.95A_{jp}L_e \left[\frac{0.74d_o^{-0.59}\sigma_{up}}{0.5L_e + 0.14d_o} + \frac{(1 + 0.5F_{sy})\sigma_y}{L + 0.14d_o} \right], \quad (34)$$

Bending Load Failure Strength. For $W_b/A_{jp} \geq \sigma_y$,

$$W_b = 0.95A_{jp} \left\{ \sigma_{up} - \left[\frac{140.5\delta d_o}{(\sigma_{up} - \sigma_y)^{0.8}} \right]^5 \right\}, \quad (35)$$

For $W_b/A_{jp} < \sigma_y$,

$$W_b = 0.95A_{jp} \left(\frac{\sigma_{up} - \sigma_y}{0.644} + \sigma_y - 218.15r_b d_o \right), \quad (36)$$

Relationship Between Total and External Load.

$$W_t = W_{ex} + W_{sh}, \quad (37)$$

where

$$W_{sh} = p_i A_{id}, \quad (38)$$

Relationship Between Bending and Curvature Radius.

$$\delta = 5730/r_{bc}, \quad (39)$$

In Eqs. 33 through 39,

A_{id} = area corresponding to ID, sq in.,

A_{jp} = cross-sectional area of the pipe wall under the last perfect thread $[0.7854 \text{ or } (d_o - 0.1425)^2 - (d_o - 2e)^2]$, sq in.,

δ = bending, degrees/100 ft,

F_{sy} = ratio of internal pressure stress to yield strength, or $p_i d_o / 2\sigma_y e$,

W_b = total tensile failure load with bending, lbf,

W_{ex} = external load, lbf,

W_{jo} = total tensile load at jumpout or reduced fracture, lbf,

W_{fu} = total tensile load at fracture, lbf,

W_{sh} = head load, lbf,

W_t = total load, the least of W_b , W_s , or W_{fu} , lbf, and

r_{bc} = bending radius of curvature, ft.

Calculations were made to six or more digits accuracy without intermediate rounding of areas. The final joint strength values were rounded to the nearest 1,000 lbf.

The equations for joint strength on a total load basis are based on a work by Clinedinst,¹⁵ who covers the development of combined loading joint strength equations and the determination of material constants and equation coefficients based on the results of an API-sponsored research project where 26 tests were made on 5½-in., 17-lbm/ft K-55 short round-thread casing.

Line-Pipe Joint Strength

The following equations for the fractured strength and the pullout or jumpout strength of API threaded line-pipe joints have been adapted from Clinedinst's¹² equations:

Minimum fracture strength is

$$W_f = 0.95A_{jp}\sigma_{up}, \quad (40)$$

TABLE 2.45—LINE-PIPE THREAD HEIGHT DIMENSIONS, in. (FIG. 2.11)

Thread Element	27 Threads Per Inch $p = 0.0370$	18 Threads Per Inch $p = 0.0556$	14 Threads Per Inch $p = 0.0714$	11½ Threads Per Inch $p = 0.0870$	8 Threads Per Inch $p = 0.1250$
$h_{tc} =$	$0.866p$	0.0321	0.0481	0.0619	0.0753
$h_{ij} = h_n =$	$0.760p$	0.0281	0.0422	0.0543	0.0661
$f_{rs} = f_{rn} =$	$0.033p$	0.0012	0.0018	0.0024	0.0029
$f_{cs} = f_{cn} =$	$0.073p$	0.0027	0.0041	0.0052	0.0063

h_{tc} = sharp thread height
 h_{ij} = thread height of pipe
 h_n = thread height of coupling
 L_{tp} = thread pitch
 f_{rs} = thread root truncation of pipe
 f_{rn} = thread root truncation of coupling
 f_{cs} = thread crest truncation of pipe
 f_{cn} = thread crest truncation of coupling

and minimum pullout strength is

$$W_{po} = 0.95 A_{jp} L_e \left[\frac{2.39(2h)^{0.59} d_o^{-0.59} \sigma_{up}}{0.5L_e + 0.14d_o} + \frac{\sigma_{yc}}{L_e + 0.14d_o} \right], \dots (41)$$

where

$$A_{jp} = 0.7854[(d_o - 2h_{ij})^2 - (d_o - 2e)^2], \text{ sq in.},$$

W_f = minimum joint fracture strength, lbf

W_{po} = minimum joint pullout strength, lbf,

h_{ij} = thread height (0.0950 for 8 threads/in.; 0.0661 for 11½ threads/in.; 0.0543 for 14 threads/in.; 0.0422 for 18 threads/in.; 0.0281 for 27 threads/in.), in.,

h = engaged height of thread or $h_{ij} - (f_{cs} + f_{cn})$ (0.0900 for 8 threads/in.; 0.0627 for 11½ threads/in.; 0.0515 for 14 threads/in.; 0.0399 for 18 threads/in.; 0.0267 for 27 threads/in.), in.,⁷

f_{cs} = crest truncation of pipe (Table 2.45), and

f_{cn} = crest truncation of coupling (Table 2.45).

Hydrostatic Test Pressures for Plain-End Pipe, Extreme-Line Casing, and Integral-Joint Tubing. The hydrostatic test pressures for plain-end pipe, extreme-line casing, and integral-joint tubing are calculated with Eq. 42 except for Grade A25 line pipe, Grades A and B line pipe in sizes less than 2½-in. OD, and threaded and coupled line pipe in sizes 6½-in. OD and less, which were determined arbitrarily.

$$p_H = \frac{2\sigma_f e}{d_o}, \dots (42)$$

where

p_H = hydrostatic test pressure rounded to the nearest 10 psi for line pipe and to the nearest 100 psi for casing and tubing, psi, and

σ_f = fiber stress corresponding to the percent of specified yield strength as given in Table 2.46, psi.

Fig. 2.11—Line pipe thread form. Buttress casing thread form and dimensions for casing sizes 4½ to 13½ in.

Hydrostatic Test Pressure for Threaded and Coupled Pipe. The hydrostatic test pressure for threaded and coupled pipe is the same as for plain-end pipe except where a lower pressure is required to avoid leakage caused by

TABLE 2.46—FACTORS FOR TEST PRESSURE EQUATIONS

Grade	Size (in.)	Fiber Stress as Percent of Specified Minimum Yield Strength		Test Pressure Rounding	Maximum Test Pressure, psi*

*Higher test pressures are permissible by agreement between purchaser and manufacturer.

**Plain-end pipe is tested to 3,000 psi maximum unless a higher pressure is agreed upon by the purchaser and manufacturer.

†No maximum test pressure, except that plain-end pipe is tested to 3,000 psi maximum unless a higher pressure is agreed upon by the purchaser and manufacturer.

insufficient internal yield pressure of the coupling or insufficient internal pressure leak resistance at Plane d_{p1} or d_p calculated with Eqs. 19 and 43, respectively.

Internal Yield Pressure for Couplings. The internal yield pressure for the coupling is calculated with Eq. 19 and rounded to the nearest 100 psi. For round-thread casing and tubing, d_1 is calculated with Eq. 20. For line pipe,

$$d_1 = d_p - (L_1 + L_{so})F_t + h_{tc} - 2f_{rn}, \quad (43)$$

where $h_{tc} = 0.0321$ for 27 threads/in.; 0.0481 for 18

threads/in.; 0.0619 for 14 threads/in.; 0.0753 for 11½ threads/in.; 0.10825 for 8 threads/in., and $f_{rn} =$ thread root truncation (Table 2.47), 0.0012 for 27 threads/in.; 0.0018 for 18 threads/in.; 0.0024 for 14 threads/in.; 0.0029 for 11½ threads/in.; and 0.0041 for 8 threads/in.

For buttress-thread casing, d_1 is calculated with Eq. 21. Eq. 19 bases the coupling hydrostatic pressure on the assumption that the coupling is stressed to 80% of minimum yield strength at the root of the coupling thread at the end of the pipe in the power-tight position. The basis of this equation was adopted at the 1968 API Standardization Conference.¹⁷

Internal-Pressure Leak Resistance at Plane d_{p1} or d_p . The internal pressure leak resistance at Plane d_{p1} or d_p is calculated with Eq. 22 and rounded to the nearest 100 psi.

API Threading Data

Dimensional data on API threads were taken from API Specification 5B for threading, gauging, and thread inspection of casing, tubing, and line-pipe threads. For information on gauges and gauging, and thread inspection equipment and inspection, refer to Ref. 6.

Fig. 2.10A shows the basic dimensions of line-pipe threads and casing and tubing round-thread hand-tight makeup. Tables 2.42, 2.43, and 2.48 give the tabulated data for casing short-thread, casing long-thread, and line-pipe thread dimensions. Fig. 2.10B shows and Table 2.44 lists the basic dimensions of buttress casing threads, hand-tight makeup. Thread dimensions of nonupset tubing,

external-upset tubing, and integral joint tubing are listed in Tables 2.49 through 2.51.

Thread height dimensions for line pipe are given in Table 2.45 and for casing and tubing in Table 2.52. The respective thread forms are shown in Figs. 2.11 and 2.12. Buttress casing thread forms and dimensions for 4 $\frac{1}{2}$ - through 12-in. sizes are shown in Fig. 2.11 and for 16-in. and larger are shown in Fig. 2.12.

Machining details for 5- through 7 $\frac{5}{8}$ -in. casing are given in Fig. 2.13 and for 8 $\frac{5}{8}$ - through 10 $\frac{3}{4}$ -in. casing in Fig. 2.14 and the tabulated data are given in Tables 2.47 and 2.53, respectively. The box and pin entrance threads are given in Figs. 2.15 and 2.16. Also, the product thread form for 5- through 7 $\frac{5}{8}$ -in. sizes, 6 threads/in., 1 $\frac{1}{2}$ -in. taper/ft on diameter is shown in Fig. 2.17, and for 8 $\frac{5}{8}$ - through 10 $\frac{3}{4}$ -in. sizes, 5 threads/in., 1 $\frac{1}{4}$ -in. taper/ft on diameter is shown in Fig. 2.18.

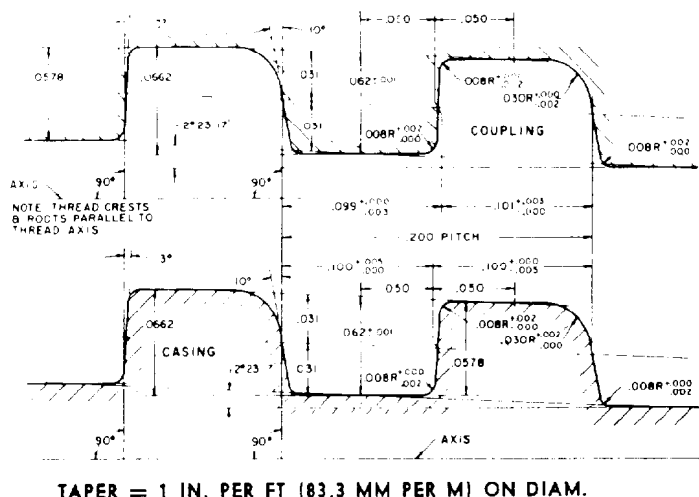

Fig. 2.12—Casing and tubing round-thread form. Buttress casing thread form and dimensions for sizes 16 in. and larger.

Nomenclature

A_c = cross-sectional area of coupling, sq in.
 A_{cr} = critical section area of box, pin, or pipe, whichever is least, sq in.
 A_{id} = area corresponding to ID, sq in.
 A_{jp} = cross-sectional area of the pipe wall under the last perfect thread, sq in.
 A_m = cross-sectional metal area of pipe, sq in.
 A_p = cross-sectional area of plain-end pipe, sq in.
 b = width of bearing face, in.
 C_3 = constant (0.8527 for salt water; 0.8151 for rotary mud; and 1.0 for air)
 C_4 = constant, 0.00000136
 C_5 = constant, 0.0000004
 d_b = box critical section ID, in.
 d_{bc} = minimum crest diameter of box thread at Plane H, in.
 $(d_{bf})_{\max}$ = maximum bearing face diameter bevel, in.
 d_{bs} = minimum diameter at box seal tangent point, in.
 d_c = diameter of chamfer, in.
 d_{cr} = diameter of coupling recess, in.
 d_i = inside diameter, in.
 d_j = nominal joint ID made up, in.
 d_o = OD, in.
 d_{ob} = integral joint OD of box, in.
 $(d_o/e)_{yp}$ = d_o/e intersection between yield-strength collapse and plastic collapse
 $(d_o/e)_{pT}$ = d_o/e intersection between plastic collapse and transition collapse
 $(d_o/e)_{TE}$ = d_o/e intersection between transition collapse and elastic collapse
 d_{oc} = coupling OD, in.
 d_{ocs} = coupling OD, special clearance, in.
 d_{oj} = nominal joint OD made up, in.
 d_p = pitch diameter at hand-tight plane, in.
 d_{p1} = pitch diameter at hand-tight plane for round threads, in.
 d_{ps} = maximum diameter at pin seal tangent point, in.
 d_r = diameter of recess, in.
 d_{rp} = maximum root diameter at last perfect pin thread, in.
 d_1 = diameter at the root of the coupling thread at the end of the pipe in the power tight position, in.
 D_{cr} = depth of coupling recess, in.
 e = wall thickness, in.
 E = Young's modulus of elasticity, psi
 f_{ch} = crest truncation of coupling (Table 2.45)
 f_{cs} = crest truncation of pipe (Table 2.45)
 f_m = thread root truncation of coupling (Table 2.45)
 $F_A, F_B, F_C,$
 F_F, F_6 = equation factors for calculating collapse pressure

F_{sy} = ratio of internal pressure stress to yield strength
 F_T = taper
 F_1 = free stretch factor corresponding to L_{s1}
 F_2 = free stretch factor corresponding to L_{s2}
 h = engaged height of thread, in.
 h_{so} = hand-tight standoff, thread turns
 h_{tb} = minimum box thread height, in.
 h_{tc} = thread height of coupling, in.
 h_{ij} = height of thread, in.
 I = length from end of coupling to base of triangle in hand-tight position (Fig. 2.2), in.
 L_c = minimum length, full crest threads, from end of pipe, in.
 L_d = distance to lower top of casing for desired stress at top of cement, in.
 L_e = engaged thread length, in.
 L_{cut} = length of external upset taper, in.
 L_{fh} = length face of coupling to hand-tight plane, in.
 L_{hc} = end of pipe to center of coupling, hand-tight makeup, in.
 L_{iut} = length of internal upset taper, in.
 L_{\min} = minimum length, in.
 L_p = length of pipe, in.
 L_{pc} = length from end of pipe to center of coupling, power-lift makeup, in.
 L_{ps} = length from end of pipe to triangle stamp, in.
 L_s = stretch, in.
 L_{so} = hand-tight standoff, in.
 ΔL_t = total axial stretch or contraction, in.
 L_{ti} = length from face of coupling to plane of perfect thread, in.
 L_{tp} = thread pitch, in.
 ΔL_u = unit axial stretch or contraction, in.
 L_0 = distance required to lower top of casing for zero stress at top of cement, in.
 L_1 = length from end of pipe to hand-tight plane, in.
 $L_1, L_2 \dots$
 L_n = lengths above top of cement on single-weight Sections 1, 2... n of combination string, ft
 L_4 = total thread length
 L_7 = length of perfect threads, in.
 $L'_1, L'_2 \dots$
 L'_n = lengths below top of cement of single-weight Sections 1, 2... n of combination string, ft
 n = number of thread turns makeup
 p = pressure, psi
 p_{ca} = minimum collapse pressure under axial stress, psi
 p_{co} = minimum collapse pressure without axial stress, psi
 p_E = minimum collapse pressure for elastic range of collapse, psi

- p_H = hydrostatic test pressure, psi
 p_i = internal pressure, psi
 p_{if} = interface pressure, psi
 Δp_{if} = change in interface pressure, psi
 p_{il} = internal-pressure leak resistance, psi
 p_p = minimum collapse pressure for plastic range of collapse, psi
 p_T = minimum collapse pressure for plastic to elastic transition zone, psi
 p_y = yield-strength collapse pressure, psi
 p_{yi} = internal yield pressure, psi
 r_b = external box radius, in.
 r_{bc} = bending radius of curvature
 r_c = contact radius, in.
 r_i = pipe internal radius, in.
 $w_1, w_2 \dots$
 w_n = weights of single-weight Sections 1, 2... n of combination string above cement, lbm/ft
 $w'_1, w'_2 \dots$
 w'_n = weights of single-weight Sections 1, 2... n of combination string below top of cement, lbm/ft
 W_a = superimposed tension or compression, axial load, lbf
 W_b = total tensile failure load with bending, lbf
 W_f = minimum joint fracture strength, lbf
 W_{fu} = total tensile load at fracture, lbf
 W_{fo} = total tensile load at jumpout or reduced fracture strength, lbf
 W_j = minimum joint strength, lbf
 W_p = pipe-body yield strength, lbf
 W_{po} = minimum joint pullout strength, lbf
 W_t = total load below the top of cement, lbf
 γ_m = specific gravity of rotary mud
 γ_w = specific gravity of water
 δ = bending, degrees/100 ft
 δ_{Td} = taper drop in pin perfect thread length, in.
 δ_{Tr} = taper rise between Planes H and J, in.
 θ_s = one-half maximum seal interference, in.
 θ_{th} = one-half maximum thread interference, in.
 σ = unit stress, psi
 σ_a = axial stress, psi
 σ_f = fiber stress corresponding to the percent of specified yield strength given in Table 2.46, psi
 σ_i = tension stress desired to be left at top of cement, psi
 σ_{uc} = minimum ultimate strength of coupling, psi
 σ_{up} = minimum ultimate strength of pipe, psi
 σ_y = minimum yield stress or strength of pipe, psi
 σ_{ya} = yield strength of axial stress equivalent grade, psi
 σ_{yc} = minimum yield strength of coupling, psi

Key Equations in SI Metric Units

$$p_E = \frac{323.7 \times 10^3}{(d_o/e)[(d_o/e) - 1]^2}, \dots \dots \dots (9)$$

where p_E is in kPa.

$$d_1 = d'_p - (L_7 + I)F_T + 1.578, \dots \dots \dots (21)$$

where d_1 , d'_p , and L_7 are in cm.

$$W_j = 0.95 A_{ip} L_e \left(\frac{5d_o^{-0.59} \sigma_{up}}{0.5L_e + 0.14d_o} + \frac{\sigma_y}{L_e + 0.14d_o} \right), \dots \dots \dots (27)$$

Chapter 3

Wellhead Equipment and Flow Control Devices

James H. Foster, Foster Oil Field Equipment Co.*

John Beson, Foster Oil Field Equipment Co.

W.G. Boyle, Otis Engineering Corp.**

Introduction

Wellhead equipment is a general term used to describe equipment attached to the top of the tubular goods used in a well—to support the tubular strings, provide seals between strings, and control production from the well.

Since the American Petroleum Inst. (API) is an active organization set up to establish standards in sizes, grades, designs, dimensions, and quality, to provide safe interchangeable equipment for the industry, this section is confined to equipment covered by API Spec. 6A for wellhead equipment.¹

API Flanged or Clamped Wellhead Equipment

Fig. 3.1 shows a typical wellhead assembly.

Working- and Test-Pressure Terminology

The maximum working pressure is the maximum operating pressure at which the equipment should be used. The hydrostatic test pressure is the static-body test pressure for ensuring a margin of safety above the rated working pressure. It is the test pressure imposed by the manufacturer to prove adequacy in design, materials, and workmanship of the body or shell member and should not be applied as a differential pressure across internal hanger-packer mechanisms or closure mechanisms.

Occasionally wellhead equipment and valves are accidentally or purposely subjected to pressures in excess of design working pressures during high-pressure remedial work. Although the equipment often withstands the mistreatment, such practices should be avoided.

All manufacturers build safety factors into their product based on sound engineering and past experience, but stresses caused by vibration, impact loads, and temperature variations are impossible to predict. Equipment should never be subjected to pressures above the recommended working pressure. If, for any reason, the equipment is to be used at unusually high or extreme working pressure, manufacturers will insist that a disclaimer clause be written and properly worded to relieve them of legal responsibility. The disclaimer should state possible results that are expected because of equipment failure.

Table 3.1 shows the standard API working pressure ratings and their respective body test pressures.

Thread Limitation

In view of the complex mechanics involved in sealing high-pressure threaded connections, it is recommended that field installations be adequately supervised and that API RP 5C1 be followed with regard to lubricants, makeup, etc., of API threads.²

The working pressure of a properly assembled threaded connection joining a wellhead or flowline component and a tubular member often is determined by the rating of the tubular element. In such a case, the maximum working pressure rating of the connection is taken as the internal yield pressure at minimum yield as stipulated in API Bull. 5C2 for the particular size and type of thread and weight and grade of tubing or casing, reduced by a suitable factor of safety.³ However, this pressure rating shall not exceed the maximum working pressure rating shown in Table 3.2. In-plant hydrostatic test pressures of components using tubing or casing threads are shown in Table 3.1

*James H. Foster wrote the original chapter on this topic in the 1962 edition.

**W.G. Boyle is author of the Safety Shut-In Systems section of this chapter.

Fig. 3.1—Typical wellhead assembly.

When line pipe threads are used as end or outlet connections of wellhead or flowline components, the maximum working pressure rating of the assembled joint is stipulated in Table 3.2. The in-plant hydrostatic test pressure of components using line pipe threads is shown in Table 3.1.

In many cases the OD of these female threaded members will be greater than API-tabulated coupling or joint diameter to ensure that the structural integrity of the threaded member will not be less than that of the compatible mating API male tubular member.

In addition to the API threads listed in Specs. 5A and 5L, there are a number of proprietary threads available in the same sizes as the API tubing and casing threads.^{4,5} Some of the proprietary threads offer advantages over the API threads, such as maximum clearance for multiple completions, special corrosion protection from internal fluids, low torque requirements, superior internal and external pressure integrity, and high joint strength.

Physical Properties

API body and bonnet members are made from steel with properties equal to or exceeding these specified in Tables 3.3 and 3.4.

Lowermost Casing Heads

The lowermost casing head is a unit or housing attached to the top end of the surface pipe to provide a means for supporting the other strings of pipe, and sealing the annular space between the two strings of casing. It is composed of a casing-hanger bowl to receive the casing hanger necessary to support the next string of casing, a top flange for attaching blowout preventers (BOP's), other intermediate casing heads or tubing heads, and a lower connection.

TABLE 3.1—TEST PRESSURE

*Working pressure of thread.

**When threads are used as end or outlet connections of wellhead or flowline components, the maximum working pressure of the assembled joint shall be stipulated in Table 3.2 and the test pressure shall be as tabulated in Table 3.1.

**TABLE 3.2—API MAXIMUM WORKING PRESSURE RATINGS
FOR WELLHEAD MEMBERS HAVING FEMALE THREADED END
OR OUTLET CONNECTIONS**

Thread Type	Size		Maximum Working Pressure Rating	
	(in.)	[mm]	(psi)	(bar)
Line Pipe (nominal sizes)	1/2	12.7	10,000	690
	3/4 to 2	19.1 to 50.8	5,000	345
	2 1/2 to 6	63.5 to 152.4	3,000	207
Tubing, nonupset and external upset (API round thread)	1,050 to 4 1/2	26.7 to 114.3	5,000	345
Casing (eight round, buttress and extreme line)	4 1/2 to 10 3/4	114.3 to 273.1	5,000	345
	11 3/4 to 13 3/8	298.5 to 339.7	3,000	207
	16 to 20	406.4 to 508.0	1,500	103

The lower connection may be a female or male thread or a slip-on socket for welding. Most common is the female-threaded lower connection, although the slip-on socket connection provides the strongest joint unless the surface casing is of such composition that welding causes serious weakening. The male lower thread is the weakest of the three connections because of the thin cross section necessary to provide full opening. It is used in most cases only to prevent removing the coupling on the surface pipe. The welded connection is most frequently used on deep wells to give the additional strength needed to suspend heavy casing loads without overstressing the threads on the surface pipe.

A landing base is sometimes used with the lowermost casing head to provide additional support for extremely heavy casing strings. The landing base is a separate unit welded to the lowermost casing head and to the surface pipe with a lower flange or skirt to transfer part of the weight to conductor strings, pilings, or a concrete foundation.

The lower connection is usually the weakest vertical load-supporting connection in an API wellhead assembly. The body-wall thickness of the lowest-working-pressure lowermost casing head is sufficient to support the most extreme casing loads. Therefore, it is not necessary to increase the working pressure of the head because heavy casing loads are anticipated.

Most lowermost casing heads are furnished with two 2-in. line-pipe threaded side outlets, although studded or extended flanged outlets are sometimes used to provide additional strength for attaching valves. Internal valve-removal threads should be included in the studded or extended flanged outlets to provide a means for seating a valve-removal plug to seal the outlet while installing or removing a valve under pressure.

In the event a valve on the side outlet of a casing head cuts out or it is desirable to install or remove a valve under pressure, after the well is completed a special tool can be attached to the outlet or the valve and a valve-removal plug can be inserted into the valve-removal thread to seal the pressure while necessary adjustments are made. A full-opening valve must be used for this application to provide clearance for the plug.

In case threaded outlets are used, a valve-removal nipple may be used to provide the same facility. Internal threads inside the valve-removal nipple provide a receptacle to seat the plug for removing, installing, or replacing the valve.

Lowermost casing heads are available with or without lock screws in the top flange. Lock screws usually are used only to hold the casing hanger down against pressures that may occur during nipple-up operations or when casing-string weights are too light to effect an automatic seal and require a lockscrew to effect the seal.

TABLE 3.3—PHYSICAL AND CHEMICAL PROPERTIES*

	Type 1	Type 2	Type 3	Type 4**

Sulfur, maximum, %	†	†	†	0.05
Phosphorus, maximum, %	†	†	†	0.05

* The designation Type 1, Type 2, Type 3, and Type 4 is a nomenclature selected by the API Committee on Standardization of Valves and Wellhead Equipment to identify material falling within the ranges of tensile requirements listed above.

** Flanges made from Type 4 steel are recognized as readily weldable; however, experience indicates that a moderate preheating is desirable under all conditions and is necessary if welding is done at ambient temperatures below 40°F (4°C).

† Chemical analyses of Types 1, 2, and 3 materials are purposely omitted from this specification in order to provide the manufacturer with complete freedom to develop steels most suitable for the multiplicity of requirements encountered in this critical service.

*Providing end connections are Type 2 and welding is done according to generally accepted welding practices.

The bowl surface can be protected by the use of a bowl protector during the drilling operations. The bowl protector is then removed before the hanger is set.

Sizes and Working Pressures. Lowermost casing heads range in size from 7¹/₁₆ in. to nominal 21 ¹/₄ in. to support casing in sizes from 4 ¹/₂ to 16 in. (Table 3.5). Table 3.5 shows the various casinghead sizes needed for common surface, intermediate, and production string sizes. The sizes of lowermost casing heads are designated by the nominal size of the API flanged-end connection and the nominal size of the lower connection.

Since the wellhead equipment attached above tubular materials should be full-opening to pass full-sized downhole tools, the bore of the tubular materials below an equipment component determines the minimum nominal size of the flange providing access to that tube.

A wellhead component must have a minimum internal diameter approximately ¹/₃₂ in. larger than the drift diameter of the tube over which it is used in order to be considered full-opening. Tables 3.6 and 3.7 give the minimum nominal flange size to give full-opening access to each standard tube size.

Because of the problems encountered in sealing large threaded connections at high pressures in field makeup, Table 3.2 gives the maximum recommended thread pressure ratings for various pipe sizes.

Selection. In selecting a lowermost casing head for a particular application, the following factors should be considered.

Design. The casing head should be designed to receive a casing hanger that will not damage the casing string to be suspended when supporting a full-joint-strength cas-

*Generally nonstock size.

**Beginning with the eleventh edition of API Spec. 6A, the traditional 6B flange nominal size designation was changed to a through-bore designation. "Old" nominal sizes will be retained for information until industry becomes accustomed to the new through-bore designations. New nominal sizes 1³/₁₆ in. [46.0 mm] through 11 in. [279.4 mm] replace "old" nominal sizes 1¹/₂ in. through 10 in. The 5,000 psi (345 bar) flanges in the larger sizes are 6BX flanges, and the new 6B flange designations for the larger sizes apply only to 2,000 and 3,000 psi (138 and 207 bar) 6B flanges. The new 20³/₄-in. [527.1-mm] designation applies only to 3,000 psi (207 bar) 6B flanges, and the new 21¹/₄-in. [539.8-mm] designation applies only to 2,000-psi (138-bar) 6B flanges.

†This 6B flange is limited to a maximum working-pressure rating of 3,000 psi (207 bar) when used over 11³/₄-in. [298.5-mm] and 13³/₈-in. [339.7-mm] casing.

‡Type 6BX flanges are required for 5,000-psi (345-bar) maximum working pressure in these sizes.

ing load with a packoff pressure equal to the minimum yield of the supported casing or the working pressure of the casing head, whichever is smaller.

Working Pressure. The minimum working pressure should be at least equal to the anticipated formation breakdown pressure at the bottom of the surface pipe, or equal to or greater than the internal pressure rating of the surface pipe. Maximum working pressure should be at least equal to the formation pressure at the bottom of the next smaller casing string.

Lock Screws. Lock screws in the casinghead flange may be used as an added safety precaution if the annulus pressures are expected during nipple-up or if a very light casing load is to be suspended.

Size. Nominal flange size should normally be the smallest permissible size to provide full-opening access to the surface pipe (Tables 3.6 and 3.7) and should fit a standard out-of-stock intermediate head or tubing head and BOP. It should have the necessary size and type of lower connection to fit the surface pipe.

Casing Hangers

A casing hanger is a device that seats in the bowl of a lowermost casing head or an intermediate casing head to suspend the next smaller casing string securely and provide a seal between the suspended casing and the casinghead bowl.

TABLE 3.7—MATCHING TUBULAR GOODS SIZES FOR USE WITH 10,000-, 15,000-, AND 20,000-psi FLANGES AND 10,000-psi CLAMP-TYPE CONNECTORS

*This flange is inactive; available on special order only.

**Available in 10,000 and 15,000-psi (690- and 1,035-bar) rated flanges only.

†Available in 10,000-psi (690-bar) rated flanges only.

Sizes and Sizing. The size of a casing hanger is determined by the nominal OD, which is the same as the nominal size of the mating casinghead flange. The nominal inside diameter is the same as the nominal outside diameter of the casing it is designed to suspend. Sizes range from nominal $7\frac{1}{16}$ through $21\frac{1}{4}$ in. to support $4\frac{1}{2}$ - through 16-in. casing. Popular sizes are nominal 9 in. for $4\frac{1}{2}$ - through $5\frac{1}{2}$ -in. casing; nominal 11 in. for $4\frac{1}{2}$ - through $7\frac{3}{8}$ -in. casing; nominal $13\frac{3}{8}$ in. for $5\frac{1}{2}$ - through $9\frac{3}{8}$ -in. casing, as indicated in Table 3.5.

Casing hangers are generally available for all casing sizes in the following types.

Automatic (most popular type). The automatic casing hanger is a unitized assembly composed of a set of slips and a sealing mechanism. It can be latched around the casing and dropped through the BOP's to set and seal automatically when the casing is slacked off to set. This type is normally used when annulus pressures are expected during nipple-up operations.

Manual. The manual casing hanger is normally used in preference to the automatic type only as a matter of economics when pressure is not expected in the annulus during nipple-up. It is composed of a set of slips and a separate packoff element. The slips can usually be latched around the casing and dropped through the BOP's, but the packoff is installed after the preventers have been removed and the casing cut off.

Slip-Weld. The slip-weld hanger usually is composed of a set of slips to support the casing weight and a spider or ring that can be welded to the casing to seal the hanger to the casing. The hanger usually is sealed in the head by a resilient compression-type seal. The hanger can be dropped through the BOP's to support casing weight, but the final seal is made by welding after the preventers have been removed and the casing cut off. Particular care must be taken in preheating the casing and the casing head to ensure an adequate weld. Some casing is permanently damaged by improper welding.

Boll-Weevil. The boll-weevil casing hanger is a simple mandrel-type hanger which screws onto the casing to be supported and seats in the casinghead bowl. This type of hanger is not recommended if there is any question about getting the casing to bottom and obtaining the accurate spacing required.

Casing hangers are rated by their capacity to support casing weight rather than by working pressure. Some manufacturers furnish actual pull curves showing the deformation that can be expected in the slip area, for any casing load, up to joint strength, for all standard casing sizes, weights, and grades. Fig. 3.2 shows acceptable pull curves for a heavy-duty casing hanger with a 5,000-psi pressure on the packoff.

Selection. In selecting a casing hanger, after establishing which type of hanger is most practical, the following factors should be considered.

1. The hanger should be capable of hanging the full joint strength of the casing to be used without sufficient reduction in diameter to obstruct full-sized downhole tools.

2. The packoff or primary seal should be of such construction that well pressure, flange test pressure, or fracture pressure cannot force the packoff down and reduce the casing-hanger capacity.

3. The hanger should be of the proper design and size to fit the mating casinghead bowl, and properly sized to support the casing to be used.

Intermediate Casing Heads

An intermediate casing head is a spool-type unit or housing attached to the top flange of the underlying casing head to provide a means of supporting the next smaller casing string and sealing the annular space between the two casing strings. It is composed of a lower flange, one or two side outlets, and a top flange with an internal casing-hanger bowl.

The lower flange of an intermediate casing head is counterbored with a recess to accommodate a removable bit guide, or a bit guide and secondary-seal assembly. The purpose of the bit guide is to protect the top end of the intermediate casing string from damage by bits and tools going into the hole. The counterbore is usually constructed to provide a fixed internal bit guide for the largest-sized intermediate casing string that can be suspended beneath that particular flange size. A removable bit guide must be used to protect smaller-sized intermediate casing.

A removable bit guide and secondary-seal assembly may also be used in place of a removable bit guide to seal the annular space between the intermediate casing and the lower flange of the intermediate casing head. By using a secondary seal, well fluids are confined to the body of the intermediate casing head and not allowed to contact the ring gasket or the packoff on the casing hanger below. If the well fluids are corrosive, use of a dependable secondary seal is particularly important to protect the ring gasket.

Use of a secondary seal and confining well fluids to a diameter approximately equal to the intermediate casing OD greatly reduces piston load or thrust on the flanges and flange studs. This permits use of an intermediate casing head with a top flange one working pressure rating higher than the lower flange. Of course, the body, the top flange, and the outlets must be sized for the higher pressure rating.

Available secondary seals are generally of three types: (1) unitized pressure-energized, (2) plastic-packed, and (3) externally adjustable. The externally adjustable type offers the advantage of being adjustable to stop a leak at any time during the life of a well. A leak in the pressure-energized type or the plastic-packed type may be sealed by injecting a plugging material into the seal under pressure or by replacement.

Intermediate casing heads are available with one or two side outlets, which may be threaded, studded, or extended flanged, depending on the working pressure and particular application. The side outlets should be equipped with valve-removal provisions as discussed in connection with the lowermost casing heads. Like a lowermost casing head, the top flange of an intermediate casing head may be equipped with lock screws if needed because of expected annulus pressures during nipple-up or very light suspended casing loads.

Fig. 3.2—Casing-hanger pull curves.

The design features for an intermediate casinghead bowl are identical to those discussed for a lowermost casinghead bowl. The bowl should be designed to receive a casing hanger which will suspend the next smaller casing string without damage to the pipe. When a relatively short intermediate casing string is used, it is sometimes desirable to use a less-expensive casing hanger with a lower load capacity for support, but a high-capacity casing hanger may be required to suspend the next smaller casing string.

Sizes and Working Pressures. The lower and upper flanges on intermediate casing heads may range in size from nominal 7 1/4 in. to nominal 21 1/4 in. to support casing in sizes from 4 1/2 to 13 3/8 in. Table 3.5 shows the various intermediate head sizes required for standard casing sizes. Tables 3.6 and 3.7 give the minimum nominal flange size to give full-opening access to standard casing.

Intermediate casing heads are available in working pressures of 1,000, 2,000, 3,000, 5,000, and 10,000 psi. Generally, the minimum working pressure of the intermediate head should be equal to or greater than the

maximum surface pressure required to break down the formation at the bottom of the intermediate casing string suspended below the intermediate casing head. The maximum working pressure should at least equal the shut-in formation pressure at the bottom of the casing string to be suspended in the intermediate casing head.

Selection. In selecting an intermediate casing head, the following factors should be considered.

1. Lower flange must be of the proper size and working pressure to fit the uppermost flange on the casing head below, or the crossover flange attached to the casinghead flange if one is used (Tables 3.5 through 3.7).
2. It must have a properly sized bit guide, or bit guide and secondary-seal assembly, to fit the casing suspended beneath it.
3. Top flange must be of the proper size and working pressure to suspend the next smaller casing string and fit the mating flange to be installed above (see working-pressure discussion and Tables 3.5 through 3.7).
4. It should have the proper size, type, and working pressure side outlets.

5. It must include a casing-hanger bowl designed to receive a casing hanger with an effective packoff mechanism that will support joint strength of the casing to be suspended without damage to the casing.

Intermediate Casing Hangers

Intermediate casing hangers are identical in every respect to casing hangers used in lowermost casing heads and are used to suspend the next smaller casing string in the intermediate casing head. These hangers are selected on the same basis as casing hangers used in lowermost casing heads, as previously discussed. Sizes are specified by the nominal diameter of the flange in which the hanger is to be used and the nominal size of the casing to be supported.

Tubing Heads

A tubing head is a spool-type unit or housing attached to the top flange of the uppermost casing head to provide a support for the tubing string and to seal the annular space between the tubing string and production casing string. It also provides access to the casing/tubing annulus through side outlets. It is composed of a lower flange, one or two side outlets, and a top flange with an internal tubing hanger bowl.

Tubing heads are generally of two types: (1) a unit with flanged top and bottom and (2) one with flanged top and threaded bottom. The unit with the threaded bottom is usually screwed directly on the production casing string, and the top flange is used for the same purpose as the double-flanged head. The lower flange, on the double-flanged type, is constructed in much the same way as the lower flange on an intermediate casing head in that a recess is provided to accommodate a bit guide or a bit guide and secondary seal. The design, purpose, types, and application of bit guides and secondary seals are explained in the discussion of the intermediate casing head. Lock screws normally are included in the top flange to hold the tubing hanger in place and/or to compress the tubing hanger seal, which seals the annular space between the tubing and the casing.

Tubing heads are available with one or two side outlets, which may be threaded, studded, or extended flanged. Usually studded-side outlets are used on units with a body working pressure of 3,000 psi and higher. Threaded side outlets are commonly used on units of 2,000-psi working pressure and lower. Extended flanged outlets are used when large-size side outlets are desired. All outlets should be equipped for valve-removal service, as explained in the discussion of the lowermost casing head. The top flange of a tubing head must be equipped with an internal bowl of the proper design to receive the required tubing hanger.

Most available tubing heads will receive any of the various types of single-completion tubing hangers of the same manufacturer. If multiple tubing strings are to be installed, a tubing head with a special bowl may be required. This subject is explained in greater detail under the discussion on multiple completion.

Sizes and Working Pressures. The lower flange on a tubing head may range in size from a nominal $7\frac{1}{16}$ in. to 13 $\frac{3}{4}$ in. The upper flange may vary from nominal $7\frac{1}{16}$

in. to 11 in. for installation over production strings varying in size from $4\frac{1}{2}$ to $9\frac{5}{8}$ in. Table 3.5 gives the various standard tubing-head sizes used over common casing sizes.

Tubing heads are available in working pressures of 1,000, 2,000, 3,000, 5,000, 10,000, 15,000, and 20,000 psi. By using a secondary seal in the lower flange to reduce the piston area exposed to well pressure, a top flange may be used with a working pressure one rating above the lower flange, provided the body and outlet dimensions also correspond to the higher rating.

The working pressure of a tubing head for particular application should be at least equal to the anticipated surface shut-in pressure of the well. In most cases, it is considered more economical to install a tubing head with a working pressure equal to the formation breakdown rather than to replace the tubing head with higher-pressure equipment during high-pressure treatment.

A standard tubing head with a $7\frac{1}{16}$ -in. top flange has a minimum bore of approximately $6\frac{1}{16}$ in., which is considered full-opening for a 7-in. or smaller production string. If a $7\frac{1}{8}$ -in. production string is used, special care should be taken to select a full-opening tubing head for $7\frac{1}{8}$ -in. casing. Special tubing heads are available for this purpose.

Backpressure Valves

Selection. In selecting a tubing head, the following factors should be considered to maintain positive control over the well at all times.

1. The lower flange must be of the proper size and working pressure to fit the uppermost flange on the casing head below or the crossover flange attached to the casinghead flange, if one is used (Table 3.5).

2. The bit guide, or bit guide and secondary-seal assembly, must be sized to fit the production casing string.

3. The size outlets must be of the proper design, size, and working pressure.

4. The working pressure of the unit must be equal to or greater than the anticipated shut-in surface pressure.

5. The top flange must be sized to receive the required tubing hanger, and of the correct working pressure to fit the adapter flange on the Christmas-tree assembly. Lock screws should also be included in the top flange.

6. The tubing head should be full-opening to provide full-sized access to the production casing string below and be adaptable to future remedial operations as well as to artificial lift.

Tubing Hangers

A tubing hanger is a device used to provide a seal between the tubing and the tubing head, or to support the tubing and to seal between the tubing and tubing head.

Types. Several types of tubing hangers are available, and each has a particular application. A brief discussion of the most popular types follows.

Wrap-Around. The popular wrap-around hanger is composed of two hinged halves, which include a resilient sealing element between two steel mandrels or plates. The hanger can be latched around the tubing, dropped into the tubing-head bowl, and secured in place

by the tubing-head lock screws. The lock screws force the top steel mandrel or plate down to compress the sealing element and form a seal between the tubing and tubing head. Full tubing weight can be temporarily supported on the tubing hanger, but permanent support is provided by threading the top tubing thread into the adapter flange on top of the tubing head. The hanger then acts as a seal only.

The tubing can be stripped through the hanger, between upsets, under pressure. After the Christmas-tree assembly has been attached to the adapter flange, the well can be circulated and a packer set under full control. This type of hanger is frequently used as a BOP when running tubing in a low-pressure well loaded with mud. If the well kicks, the tubing hanger can be latched around the tubing and lowered into the tubing-head bowl. A seal is made by tubing weight and by use of the lock screws. After circulation, it can be lifted out of the bowl with the first upset below the hanger.

Polished-Joint. This type of hanger is slipped over or assembled around the top tubing joint, and the internal seals are adjusted to provide a seal on the tubing body. The hanger is sealed against the tubing head with a resilient seal. After the hanger is set, the Christmas tree can be attached to the top tubing thread and the well circulated under full control. The top tubing joint can be stripped through the hanger, between upsets, under pressure.

Boll-Weevil. This is a doughnut- or mandrel-type hanger attached to the top tubing thread and supported in the tubing-head bowl. A seal between the mandrel and tubing head is provided by hydraulic packing or O rings. It is the only hanger designed to support the tubing weight permanently.

Stripper Rubber. A stripper rubber is a pressure-actuated sealing element used to control annulus pressures while running or pulling tubing in a low-pressure well. Tubing weight is supported by the adapter flange, a boll-weevil hanger, or slips located above the stripper rubber. In most cases, the stripper rubber should be used in conjunction with a BOP and is not intended to replace the BOP.

Selection. In selecting a tubing hanger, the particular application should dictate the type required. In general, the hanger should provide an adequate seal between the tubing and tubing head and should be of standard size suitable for lowering through full-opening drilling equipment.

A backpressure valve is a check valve that is installed in the vertical run of the Christmas tree, usually in the tubing hanger or tubing head adapter. A backpressure valve serves two main purposes: (1) to seal the bore of the tubing when removing the BOP and installing the Christmas tree when completing a well and (2) to seal the bore of the tubing when removing the Christmas tree or doing remedial work on the lower master valve. For the backpressure to pass through the Christmas tree the valves and other vertical-run fittings must be full-opening.

Available backpressure valves are generally of two types. One type is secured in place with threads, the other is secured in place with an expanding-lock mechanism.

Adapter

An adapter is a unit used to join connections of different dimensions. The adapter may be used to connect two flanges of different dimensions or connect a flange to a thread. An adapter used to connect two flanges with different dimensions may be studded and grooved on one side for a certain flange size, and studded and grooved on the other side for a different flange size. A unit of this type is called a "double-studded adapter."

Crossover Flange

A crossover flange is an intermediate flange used to connect flanges of different working pressures. Crossover flanges are usually available in two types.

1. A double-studded crossover flange is studded and grooved on one side for one working pressure, and studded and grooved on the other side for the next higher working-pressure rating. The flange must also include a seal around the inner string of pipe to prevent pressure from the higher-working-pressure side reaching the lower-working-pressure side. The seal may be of the resilient type, plastic-packed type, or welded type.

2. Another type of crossover flange includes a restricted-ring groove in the top side of the flange to fit a corresponding restricted-ring groove in the mating head. The restricted-ring groove and the seal between the flange and the inner casing string act to restrict the pressure to a smaller area, thereby allowing a higher pressure rating.

Christmas-Tree Assembly

A Christmas tree is an assembly of valves and fittings used to control production and provide access to the producing tubing string. It includes all equipment above the tubing-head top flange. A typical Christmas tree is shown in Fig. 3.3. Many variations in arrangement of wellhead and Christmas-tree assemblies are available to satisfy the needs of any particular application. Fig. 3.4 shows several typical assemblies.

Tubing-Head Adapter Flange

The tubing-head adapter flange is an intermediate flange used to connect the top tubing-head flange to the master valve and provide a support for the tubing. Standard adapter flanges of the following three types are available.

Studded Type. This unit consists of a lower flange with a ring groove and bolt holes to fit the top tubing-head flange, an internal thread in the bottom of the flange to receive and support the tubing weight, and a studded top connection to accommodate a flanged master valve.

Spool Type. This type is similar to the studded type except that the top connection is a flange to accommodate the master valve, and a top internal thread may be provided to act as a tubing landing or lift thread. It is also available with internal provisions for a backpressure-valve mandrel.

Threaded Adapter Flange. This type of adapter flange is used to connect the top tubing-head flange to a threaded master valve. It is composed of a lower flange with a

Fig. 3.3—Typical Christmas tree.

Fig. 3.4—Typical Christmas tree assemblies.

ring groove and bolt holes to fit the top tubing-head flange, an internal thread in the bottom to support the tubing string, and a male thread on top to connect the threaded master valve. The top male thread is usually an upset thread to give added strength.

A tubing-head adapter flange is described by specifying the lower flange size and working pressure, the bottom internal thread size and type, and the top-connection type, size, and working pressure. The lower flange must be of the same size and working pressure as the tubing-head top flange. The top connection must be of the same size and working pressure as the master valve. The top

flange on the adapter and the vertical run of the Christmas tree must be sized to provide full-opening access to the tubing. Tables 3.6 and 3.7 show the flange sizes that will provide full-opening bores for tubular goods.

Valves

API valves, like API wellhead equipment, are made of high-strength alloy steels to give safe dependable service. ASA valves are made of carbon steel and should not be used for wellhead service. Valves used on wellheads are basically of two types—gate valves and plug valves.

*345 bar.

**Maximum through bores of 3 3/16, 4 1/4, and 7 1/8 in. [81.0, 108.0, and 181.0 mm] are permissible for nominal sizes 3 1/8, 4 1/16, and 7 1/16 in. [79.4, 103.2, and 179.4 mm]—flanged and connections only.

Both are available with flanged end connections. Gate valves can be divided into lubricated and nonlubricated, wedging and nonwedging types.

Full-opening valves must be used in the vertical run of the Christmas-tree assembly to provide access to the tubing. Full-opening valves must also be used on tubing-head outlets and casing-head outlets equipped for valve-removal service. Restricted-opening valves are sometimes used as wing valves, without loss of efficiency or utility, to effect an economic saving.

Threaded valves are available in sizes from 1 1/4 to 4 in., with working pressures from 1,000 through 5,000 psi. Upset tubing threads are usually used on valves in the vertical run of a Christmas tree to provide maximum strength. Valves with line-pipe threads are used on tubing wings, threaded tubing-head side outlets, and threaded casinghead side outlets. Most users prefer flanged valves on applications of 3,000-psi working pressure and above. Flanged valves are available in sizes from 1 1/16 through 7 1/16 in. with working pressure ratings from 2,000 to 20,000 psi as shown in Tables 3.8 through 3.14.

Christmas-Tree Fittings

Other Christmas-tree fittings include tees, crosses, and other connections necessary to provide the most desirable arrangement for the particular application.

The size of the vertical run may vary from 2 1/16 to 4 1/16 in. but must be consistent with the master-valve and tubing-head adapter-flange size to give full-opening access to the tubing for wireline tools and instruments. The outlet on the tee or cross and wing assembly must be of sufficient size to handle the production requirements without undue restriction. Outlets vary in size from 1 1/16 to 4 1/16 in., although the 2 1/16-in. size is normally adequate and is most commonly used in the U.S.

All Christmas-tree assemblies should be assembled, pressure-tested to hydrostatic test pressure, and checked with a drift mandrel to ensure full opening before installation. Table 3.15 shows the through-bores and drift diameter for each standard tubing size.

Bottomhole Test Adapter

A bottomhole test adapter is a device attached to the top of a Christmas-tree assembly to provide fast and safe adaptation of a lubricator for swabbing or testing. It may also include an internal thread to act as a lift thread for

*690 bar.

setting or raising the Christmas tree and tubing. It is available in sizes from 2 1/16 to 4 1/16 in. and in working pressures from 1,000 to 20,000 psi.

Multiple-Completion Equipment

Multiple completions or multiple-tubing-string completions require the same lowermost casing head, intermediate casing head, and tubing-head equipment as single-tubing-string completions with one exception. The tubing-head bowl must be designed and sized to accommodate the required size and number of tubing strings and provide a means for properly orienting the tubing strings. Fig. 3.4 illustrates two types of dual parallel-string installations, and Tables 3.16 and 3.17 give a listing of common multiple-string applications and specifications. The following equations, used with Fig. 3.5, may be used to determine the minimum casing size necessary for any combination of multiple-parallel-tubing-string completions.

Duals and quadruples:

$$d_{c(min)} = A + d_t \quad \dots \dots \dots (1)$$

Triples:

$$d_{c(min)} = 2 \left(L + \frac{d_t}{2} \right), \quad \dots \dots \dots (2)$$

where

$d_{c(min)}$ = minimum casing size,

d_t = tubing diameter,

L = distance (A, B, or C, whichever is greatest, see Fig. 3.5).

Tubing Heads. In selecting a tubing head for multiple parallel-tubing-string service, the same factors should be considered as previously suggested for selecting a single-completion tubing head, with the following additions. The tubing-head bowl should (1) be of the required size and internal design to receive the desired tubing hanger, (2) have the necessary nonrestrictive positioning or indexing devices to orient the tubing hanger accurately, (3) be designed to receive an available tubing hanger, which will suspend the desired number of tubing strings or a single tubing string, and (4) be so designed that removal of the BOP's is not necessary until all tubing strings have been landed and sealed.

Tubing Hangers. Multiple-completion tubing hangers perform the same function as single-completion tubing hangers, and as many types and variations in design are available. A brief description of common available types and designs follows.

Multiple-Bore Mandrel. This type of hanger consists of a large mandrel or doughnut with a separate bore for each tubing string. The individual tubing strings are landed in the large mandrel on landing collars. Backpressure valves can be installed in the individual

*Basic end connection size is determined by the size of tubing-head top connection, which suspends the several tubing strings. If an adapter flange is used, a smaller valve end flange is sometimes permitted.

**Center distances based on 2 1/16 [52.4 mm] OD tubing.

†CAUTION: Due to the permissible tolerance on the OD immediately behind the tubing upset, the user is cautioned that difficulties may occur. It is recommended that the user select the joint of tubing to be installed at the top of the tubing string.

Note: Drift size for the 1 1/16 in. [42.9 mm] nominal size is 1 1/32 in. [42.1 mm].

*138 bar.

**These sizes available on special order only.

Notes: Maximum through bores of 3 1/16 in. [81.0 mm], 4 1/8 in. [108.0 mm], and 7 1/8 in. [181.0 mm] are permissible for nominal sizes 3 1/8, 4 1/8, and 7 1/8 in. [79.4, 103.2, and 179.4 mm], respectively.

Flanged end connections of some casing and tubing heads may have entry bevel recesses and/or counterbores greater than "B" maximum to receive a packer mechanism. The sizes and shapes of these bevels, recesses, and/or counterbores are proprietary and are not covered by this specification.

landing collars. This is the most simple and easily installed hanger but is limited to applications where gas-lift valves or tubing accessories with external diameters greater than tubing-joint diameters are not needed.

Multiple-Segment. This type of hanger is composed of an individual hanger segment for each tubing string. Each segment seats in and occupies a part of the bowl when landed. Gas-lift valves and other tubing accessories may be installed on the tubing string. Each hanger segment may be equipped with provisions for backpressure valves.

Combination Mandrel and Boll-Weevil. This type of hanger is similar to the multiple-bore mandrel hanger except that one string of tubing is supported by threading into the large mandrel.

Tension-Type. This type of hanger is constructed similar to the multiple-bore mandrel hanger and consists of a landing collar for each individual tubing string. The individual landing collars may be lowered through and lifted back up into the hanger mandrel, enabling the tubing strings to be set in tension through the BOP's. Backpressure valves may be installed in the landing collars.

Selection. In selecting a multiple-completion tubing hanger, the following factors should be considered.

1. Seals on the individual hangers should not be exposed to damage by successive running of remaining tubing strings.

THREADED FLANGE

WELD NECK
LINE PIPE FLANGE

REQUIREMENTS FOR TABLE 3.18

- The contour of the flange face outside the d_N diameter is optional with the manufacturer unless raised or full face is specified on the purchase order.
- Ring-groove radius r_{fg} shall be $1/32$ in. [0.79 mm] for groove widths $1/32$ [8.73 mm] and $1/16$ [11.91 mm]; $1/16$ in. [1.59 mm] for width $1/32$ [13.49 mm].
- The bore d_B of welding-neck flanges shall be as specified on the purchase order.
NOTE: Bore diameter should be the same as ID of pipe to be used; but, because these flanges are constructed of Type 4 material, the bore shall not exceed values of d_B .
- The wall thickness of welding-neck flanges shall be not less than 87½% of the nominal wall thickness of the pipe to which the flange is to be attached.
- The welding end of welding-neck flanges shall be cylindrical or shall have a maximum draft of 7°. The length shall be sufficient to ensure a sound weld, but in no case shall be less than ¼ in. [6.4 mm].

2. Positive packoff elements or seals should be provided.

3. Design should allow passage of gas-lift valves if needed.

4. Center lines should be provided to suspend tubing in the casing without spreading at the top.

5. The hanger should be constructed to accommodate positive seating of backpressure valves that do not require an oversize vertical run.

6. The hanger should be constructed for accurate, dependable pressure testing after tubing strings have been landed and sealed.

Christmas-Tree Assembly. The Christmas-tree assembly for a multiple-parallel-string wellhead includes

all fittings above the tubing-head top flange. Threaded, welded, independently flanged, and integrally flanged Christmas-tree assemblies are available for the installation of multiple tubing strings.

Threaded, welded, and independently flanged assemblies are furnished in working pressures of 2,000 and 3,000 psi, although threaded assemblies are rarely recommended for 3,000-psi applications. Welded assemblies are recommended for 3,000-psi service only on noncorrosive applications when pressures are expected to decline rapidly and economy is of great importance. Integrally flanged assemblies are available in 2,000-, 3,000-, 5,000-, and 10,000-psi working pressures. These assemblies are preferred on severe or corrosive 2,000- and 3,000-psi service, and recommended for 5,000- and 10,000-psi applications.

Nomenclature for Tables 3.18 through 3.29

b_f	= width of flat of octagonal ring, in.
b_g	= width of groove, in.
b_r	= width of ring, in.
d_{bc}	= diameter of bolt circle, in.
d_{bh}	= diameter of bolt holes, in.
$d_{b(max)}$	= maximum bore of welding-neck flange, in.
d_f	= diameter of flat, in.
d_g	= pitch diameter of groove, in.
d_h	= hole size, in.
d_H	= diameter of hub, in.
d_{Hl}	= large diameter of hub, in.
d_{Hs}	= small diameter of hub, in.
d_N	= neck diameter of welding-neck line-pipe flange, in.
d_o	= OD of flange, in.
d_{og}	= groove OD, in.
d_r	= OD of ring, in.
d_{rf}	= diameter of raised face, in.
d_{rg}	= pitch diameter of ring and groove, in.
D_g	= depth of groove, in.
h_o	= height of outside bevel, in., or basic thickness of flange, in.
h_r	= height of ring, in.
h_t	= total thickness of flange, in.
L_C	= hub length of threaded casing flange, in.
L_H	= length of hub, in.
L_L	= hub length of threaded line-pipe flange, in.
L_N	= hub length of welding-neck line-pipe flange, in.
L_{sb}	= length of stud bolts, in.
L_T	= hub length of tubing flange, in.
r_g	= radius in groove, in.
r_H	= radius of hub or radius at hub, in.
r_r	= radius in octagonal ring, in.

Flange Data

Tables 3.18 through 3.26 show API standard flanges and are reproduced with permission of API. These tables cover working pressures of 2,000 to 20,000 psi. API is

presently standardizing flanges for 30,000-psi working pressure. API has recently standardized a line of clamp-type connectors in sizes 2¹/₁₆ through 21¹/₄ in. in the 5,000 and 10,000-psi working pressure ranges. The design criteria and detailed dimensional data for these clamp-type connectors are given in API Spec. 6A.¹ Details for API ring-joint gaskets for API flanges and clamp-type connectors are shown in Tables 3.27 through 3.29.¹

Flow Control Devices: Safety Shut-In Systems

Since the consequences of uncontrolled well flow are so severe, especially offshore, automatic well shut-in safety systems are important enough that they are sometimes mandated by law.⁶ Safety systems must be failsafe. Failure of the energy source or any component must cause the system to go to the safe mode. Usually safe mode means the wells are shut in at one or more points.

Safety systems sense conditions on the lease or platform and shut in the well or wells when conditions deviate from the preset limits. Shutting in the well averts further danger due to (1) uncontrolled flow from ruptured pressure vessels, (2) fueling any fire that has started or may start, or (3) overfilling vessels with fluid and/or pressure.

The systems consist of fail-safe valves (safety valves), sensors, logic control valving and indicators, and a power source. Some systems may be contained in a single valve or they may be very large multiwell, multivalve, multiparameter, multilogic systems integrated into a production control system with telemetry. Severity of consequences usually dictates how elaborate the safety system should be.

Safety valves may be located in the tubing string [sub-surface safety valve (SSSV)], on the Christmas tree, or downstream of the well in the process train (surface safety valve) (Figs. 3.6 and 3.7). Most safety valves are controlled with externally applied fluid pressure. Release of the control pressure allows the valve to close.

REQUIREMENTS FOR TABLE 3.19

- 1, 3, 4, and 5. See Table 3.18.
2. Ring-groove radius r_g shall be 1/32 in. [0.79 mm] for groove widths 1 1/32 and 1 5/32 [8.73 and 11.91 mm] and 1/16 in. [1.59 mm] for widths 2 1/32 and 2 5/32 [16.67 and 19.84 mm].
6. Except for bore of welding neck flanges, dimensions for sizes 1 1/16 to 2 9/16 in. [46.0 to 65.1 mm], inclusive, are identical with 5,000-psi [345-bar] flanges in Table 3.20.
7. Maximum through bores of 3 1/8, 4 1/4, and 7 1/8 in. [81.0, 108.0, and 181.0 mm] are permissible for nominal sizes 3 1/8, 4 1/16, and 7 1/16 [79.4, 103.2, and 179.4 mm], respectively.
8. Flanged end connections of some casing and tubing heads may have entry bevel recesses and/or counterbores greater than d_b maximum to receive a packer mechanism. The sizes and shapes of these bevels, recesses, and/or counterbores are proprietary and are not covered by this specification.

§ See Table 3.22 for dimension details on these sizes.

REQUIREMENTS FOR TABLE 3.20

1, 3, 4, and 5 See Table 3.18

2 Ring-groove radius, $r_{1/2}$, shall be $1/32$ in [0.79 mm] for groove widths $1 1/32$ and $1 5/16$ in [8.73 and 11.91 mm], $1/16$ in [1.59 mm] for widths $1 7/8$ and $2 1/8$ in [13.49 and 16.67 mm]6 Except for bore of welding-neck flanges, dimensions for sizes $1 13/16$ in to $2 9/16$ in [46.0 to 65.1 mm], inclusive, are identical with 3,000-psi [207-bar] flanges in Table 3.19

7 and 8 See Table 3.19

Surface Safety Valves (SSV's)

An SSV on the Christmas tree is usually the second valve in the flow stream. Hence it is the second master valve, if it is in the vertical run, otherwise it is a wing valve. SSV's can be located downstream of the well in the process train at such places as (1) flowline headers, (2) suction, discharge, and bypass on a compressor (the bypass safety valve safe mode is open instead of closed), or (3) at the entrance to the sales pipeline or the pipeline leaving a platform.

Most SSV's are reverse-acting production-gate valves with piston-type actuators (Fig. 3.8). Valve-body pressure against the lower stem area moves the gate to the up/closed position. Control pressure applied to the piston pushes the gate to the down/open position. Usual-

ly a spring is used to close the valve if valve-body pressure is not present. Valve-body pressure and piston/stem area ratio determine the control pressure required.

Large-ratio pneumatic actuators are used because the larger ratio permits use of lower control pressure. Lower-pressure control-system valves can be simpler and more reliable. Compressed air or produced gas are the usual control fluids. Control pressures are generally 250 psi or less.

Low-ratio hydraulic actuators are used where the SSV is to be controlled by the same system that controls the SSSV, or where limited space is available on the Christmas tree (Fig. 3.9). Control pressures are generally slightly greater than the shut-in pressure of the well.

Fig. 3.8—Pneumatic-powered ratio-piston surface safety valve.

Fig. 3.9—Pneumatic and hydraulic surface safety valves

*690 and 1035 bar.

**This flange is inactive; available on special order only.

- Due to the difficulty of field welding API Types 2 and 3 material, from which these flanges are made, a transition piece may be shop welded to the basic flange and the weld properly heat treated. This transition piece shall be made from the same or similar material as the pipe to which it is to be welded by the customer. Transition piece ID and OD at the field welding end, and its material, shall be specified on the purchase order.
- The length of the transition piece shall be great enough that the heat from field welding will not affect the metallurgical properties of the shop weld.
- The API monogram shall be applied to the welding-neck flange (solid outline). The API monogram does not apply to the shop weld or the transition piece.
- Dimension h_p may be omitted on studded connections.

* 1380 bar.

** See Table 3.25 sketch.

† Type 6BX blind flanges must be provided with a prolong on the rear face, described by the large and small diameters and length of the hub.

SSV's usually have a stem protruding from a threaded boss on the actuator cylinder head for several reasons.

1. Stem position gives a visual position indication.
2. A position-indicator switch can be attached to provide telemetry feedback information.
3. A manually operated mechanical or hydraulic jack can be attached to open a closed safety valve where the control pressure source is downstream of the safety valve or where system failure makes control pressure unavailable.

4. A lockout cap, or heat-sensitive lockout cap, can be attached to hold the valve open while wireline work is being done through the valve or when the control system is out of service for maintenance.⁷

Special Designs. Special designs of SSV's may have various modifications.

1. Extra-strong springs for cutting wireline, should an emergency occur while wireline work is in progress. Special hardened gates are used for these valves.
2. Extra extension of the cylinder from the valve for nesting of two pneumatic actuators on a dual valve or tree where there is not enough space for the large cylinders to be mounted side-by-side.
3. Cover sleeve or cylinder over the bonnet bolting to protect the bolts from fire.
4. Integral pressure sensors to monitor flowline pressure and control the safety valve.

Selection. When ordering an SSV the entire system should be considered. The size of the valve is determined by the flowstream in which it is installed. If it is to be in the vertical run of the tree, it should be the same size as the lower master valve. Pressure, temperature, and service ratings should be the same as for the lower master valve. Actuator specifications should consider control system pressure that is available. Valve body pressure, ratio, and control pressure are related by

$$p_{cl} = \frac{2(p_{vb})}{F_{ac}}, \dots \dots \dots (3)$$

where

p_{cl} = control pressure,

p_{vb} = valve body pressure, and

F_{ac} = actuator ratio.

Materials for the actuator parts that contact flowline fluids should be consistent with the service and valve body.

Subsurface Safety Valves (SSSV's)

SSSV's are used because they are located in the wellbore and isolated from possible damage by fire, collision, or sabotage. They are designed to be operational when needed most—in catastrophies, but they are more difficult to maintain. SSSV's are recommended for use with an SSV. Control circuit logic should be designed to close the SSV for routine alarm conditions. Under catastrophic conditions both valves close. SSSV's are either subsurface- or surface-controlled (Fig. 3.10).

Selection. Various features should be considered in selecting an SSSV (Fig. 3.11).

Tubing-Retrievable vs. Wireline-Retrievable. Tubing-retrievable valves have larger bores through the valve for less flowing pressure drop and allow wireline work through the valve without having to retrieve the valve. Since the tubing-retrievable valve is a part of the tubing string and requires a workover rig for retrieval, maintenance is more expensive. Wireline-retrievable valves are located in special landing nipples that are part of the tubing string, and they can be retrieved for maintenance with lower cost wireline methods (Fig. 3.12).

Valve Type. The most common type of valves are rotating ball and flapper.

Single-Control Line vs. Balance Line. Permafrost, paraffin problems or other equipment such as centrifugal or hydraulic pumps may require setting the safety valve deep, and thus require a balance line (two-control-line system).

TOLERANCES

		(in.)	[mm]
b_r	(width of ring, see Note 3)	± 0.008	± 0.20
h_r	(height of ring)	± 1/64	± 0.39
b_f	(width of flat on octagonal ring)	± 0.008	± 0.20
D_g	(depth of groove)	+ 1/64, - 0	+ 0.39, - 0
b_g	(width of groove)	± 0.008	± 0.20
d_{rg}	(average pitch diameter of ring)	± 0.007	± 0.17
d_{rg}	(average pitch diameter of groove)	± 0.005	± 0.12
r_r	(radius in rings)	± 1/64	± 0.39
r_g	(radius in groove)	—	max
23°	(angle)	—	± 1/2°

- The 23° surfaces on both grooves and octagonal rings shall have a surface finish no rougher than 63 RMS.
- A small bead on the center of either oval or octagonal rings, located so that it will not enter the groove, is permissible.
- A plus tolerance of $3/64$ in. [1.19 mm] on ring height is permitted, provided the variation in height of any given ring does not exceed $1/64$ in. [0.39 mm] throughout the entire circumference.

Equalizing Valves. For equalizing pressure differentials across the closed valve rather than equalizing from an external source.

Soft Seat vs. Lapped-Metal Seat. Soft seats can have less minor leakage, but are more susceptible to damage, especially at higher pressure.

Subsurface-Controlled Subsurface Safety Valves (SSCSV's). These valves sense flow conditions in the well at the valve and close when the flow exceeds a preset limit. They are usually located in a landing nipple in the tubing. There are two main types.

Excess flow valves sense the pressure drop across an orifice in the valve and close the valve when the increased flow rate causes the pressure drop to increase past a preset limit.

Low-pressure valves have a stored reference pressure in the valve. The valve closes when tubing pressure at the valve draws down below the reference pressure due to restriction of the formation.

Both types of valves depend on a flow rate substantially in excess of normal maximum. The presumption is that essentially a complete structural failure (opening) of

the Christmas tree exists ahead of the choke. Caution must be exercised that the well is capable of closing the valve at the setting used.

Surface-Controlled Subsurface Safety Valves (SCSSV's). These valves are normally controlled by pressure maintained by a unit at the surface in response to a pilot system. Pressure is transmitted to the safety valve through a small-diameter parallel-tube control line in the annulus or through the tubing/casing annulus in conjunction with a packer below the safety valve (Fig. 3.10). Volumetric compression and expansion of the control fluid usually makes the small tubing system preferable to the annulus conduit even though it is not as rugged. However, the small tubing will convey higher control pressures more economically.

When the control pressure is released, a spring and well pressure on the control piston will close the valve. Since well pressure is not always assumed dependable, some valves have a second line, or balance line, to the surface, which is filled with control liquid. This provides a hydrostatic pressure to the back side of the piston for closure. Single control-line valves have depth failsafe

limitations. The limit is determined by the ability of the spring to overcome friction and the force of the hydrostatic pressure against the piston without help from well pressure. A depth limitation of the two-control-line system may be the time for closure due to control liquid expansion and flow restriction in the small-diameter long control line.

Control System

The control system is the interface system between the power source, the sensors, and the safety valves. The design of the control system depends on several factors: (1) type of power source available—compressed air, produced gas, or electricity; (2) pressure and volume requirements of the safety valves; (3) number and types of sensors (pneumatic—two- or three-way valves—or electric); (4) power requirements and limitations of the pilots; (5) number and type of indicators (position status,

pressure status, first-out sensor); (6) telemetry interface; and (7) logic required. (Will any pilot shut all the safety valves or should certain sensors close certain valves or combinations of valves?) We recommend a time delay after SSV's close before the SSSV's close, and that SSSV's open first.

Most systems are pneumatically powered because compressed air or gas is usually available. The power needed by most pilots and safety valves is pneumatic or hydraulic. Power is consumed only when a valve is being opened; most of the time the system is static. Most electrically powered sensors continuously consume power and are sensitive to short-duration power transients. Electro-hydraulic systems are well suited to cold environments.

The air or gas supply should be kept clean and dry. Electrical power should be protected from transient disruptions, especially in the sensor circuitry. Such precautions greatly enhance reliability.

* A plus tolerance of 0.008 in. for b_f and h_r is permitted, provided the variation in width or height of any ring does not exceed 0.004 in. throughout its entire circumference.

NOTE: r_r shall be 8 to 12% of the gasket h_r .

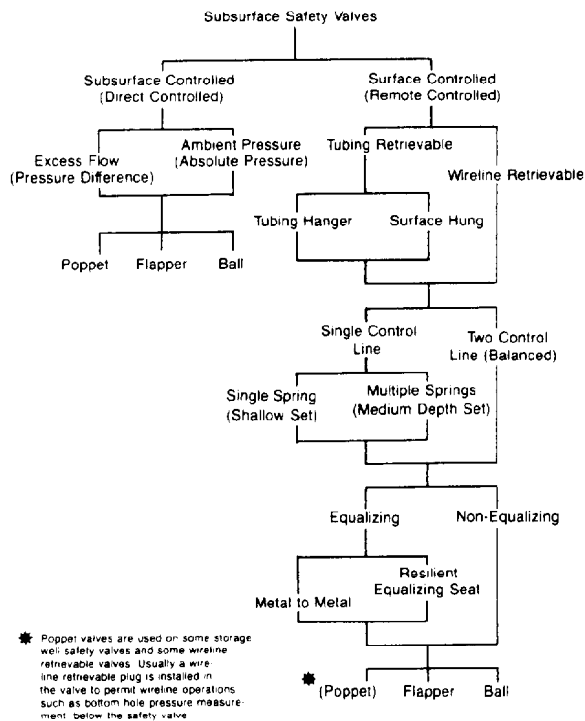

Fig. 3.11—Subsurface safety valve design options.

Hydraulically powered safety valves require a pump/control unit in the system (Fig. 3.13). The preferred type of pump is the ratio-piston pneumatic-over-hydraulic pump. These pumps have pneumatic pressure operating on a relatively large piston to push a relatively small pump plunger. Low pneumatic pressure can thus develop high hydraulic pressure. The output pressure is easily controlled by the pressure of the input power gas, which can be controlled by a simple demand-pressure regulator. Pressure maintenance is automatic and continuous. Care should be taken to select a pump that is free of continuous bleeding of gas and that will not stall in its reciprocating motion at the end of a stroke.

Valve control and system logic is performed by pneumatic/hydraulic or pneumatic/pneumatic relays. These relays permit the use of either bleed (two-way) or block and bleed (three-way) sensors (Figs. 3.14 and 3.15). Relays are reset manually to put the system back in service after a closure. This safety feature ensures that a person is present to determine that the cause for closure has been corrected and that reopening would not be hazardous.

Fig. 3.12—Tubing-retrievable and wireline-retrievable surface-controlled subsurface safety valves.

Fig 3.13—Basic hydraulic control circuit.

Circuit design determines the hierarchy of closure. All surface and subsurface safety valves should close in case of fire, collision, and manual actuation of the emergency shutdown system (ESD). Many systems close only the SSV of a single well when sensors on a single well actuate because of high liquid level, high pressure resulting from freezing or valve malfunction downstream, or low pressure resulting from flowline rupture or backpressure

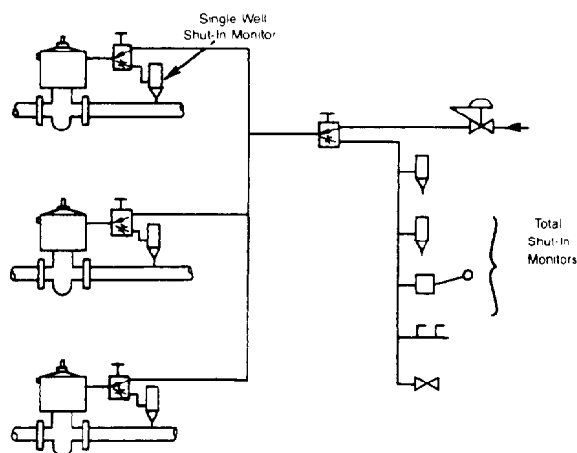

Fig. 3.14—Single branched system for two hierarchies of control (bleed-type sensors).

valve failure. Sometimes several wells on a platform or lease will be closed as a group if they are high vs. low pressure, oil vs. gas wells, etc. Every system should be designed to suit the characteristics of the wells and the severity of consequences of malfunctions.

Platforms and compact land leases may have all the control system in a cabinet or console. Communication between the cabinet and well should be with control system media. If well pressure is piped to sensors in the cabinet, the well fluids may freeze and prevent proper operation. There is also the danger of high-pressure, high-volume flow from a ruptured line and leakage of toxic or flammable fluids to an enclosed area. Electric devices and lines usually need to be explosion proof. Requirements for the designation "explosion proof" are explained in the Natl. Electrical Code.⁸ API RP14F⁹ defines which installation areas require explosion-proof equipment.

Sensors

Sensors monitor conditions that indicate production system hazards or malfunctions. The sensor then actuates an integral pilot valve or switch to activate a control valve. The pilot valve and/or control valve may

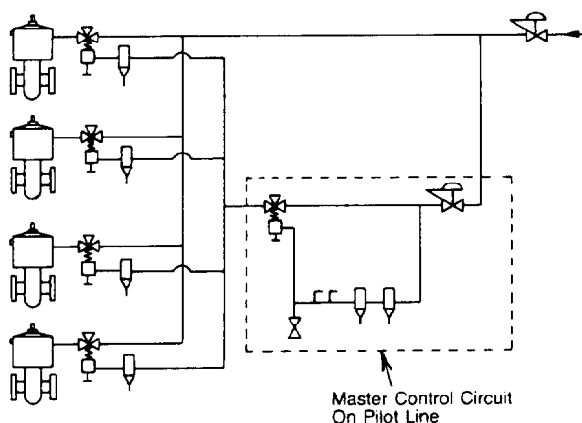

Fig. 3.15—Single branched system for two hierarchies of control (block-and-bleed-type sensors).

bleed (two-way) or block-and-bleed (three-way). Electric sensors interface with pneumatic systems with solenoid valves. Conditions that are usually monitored include (Fig. 3.16): (1) pressure—high or low because of flowline or pressure vessel blockage or rupture; (2) level—high or low in separator or storage tank resulting from control valve system malfunction; (3) fire—heat is sensed by fusible plugs or fusible control line, flames are sensed by ultraviolet detectors, and temperature is detected by infrared detectors; (4) toxic or flammable gas mixtures—detectors located at four or more locations around the perimeter or in enclosures; (5) manual control—ESD system valves at boat landings, living quarters, and other critical locations.

Pressure sensors should be located at any point in the production system where sections of the system can be isolated by a check valve or block valve, or where there is a change in pressure due to a choke or pressure reducing valve.¹⁰ Pressure sensors may have a moving-seal sensing element or an elastic element such as a Bourdon tube. Moving-seal sensors have poorer repeatability but are considerably less susceptible to damage by abuse and overpressure.

Regulations

Governmental regulations control the design and operation of some safety shut-in systems. For example, the Minerals Management Service of the U.S. government controls installations in the outer continental shelf (OCS) waters of the U.S. The rules are published in the OCS Order No. 5.⁶ The OCS orders require that safety valves installed in or on wells in the federally controlled waters be made according to the ANSI/ASME SPPE-1¹¹ specification and API Specs. 14A¹² and 14D.⁷ ANSI/ASME SPPE-1 is an extensive quality-assurance specification. API Specs. 14A and 14D are performance and design specifications for SSSV's and SSV's.

Other Flow-Control Devices

Most flow-control functions are described in this chapter in the sections on Wellheads and Safety Shut-In Systems, and in Chaps. 11 through 16. Some valves and controls are discussed in Chaps. 4 (Production Packers) and 5 (Gas Lift). Other flow-control devices are discussed in the following.

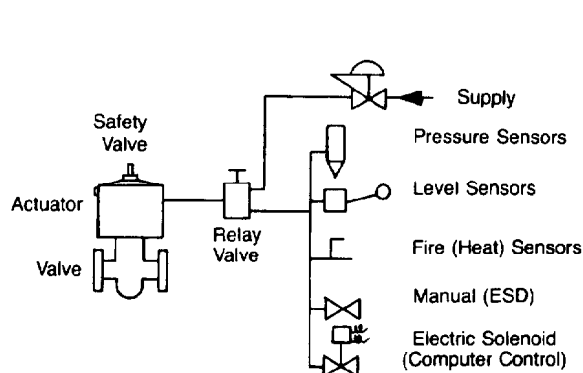

Fig. 3.16—Remote controlled SSV system.

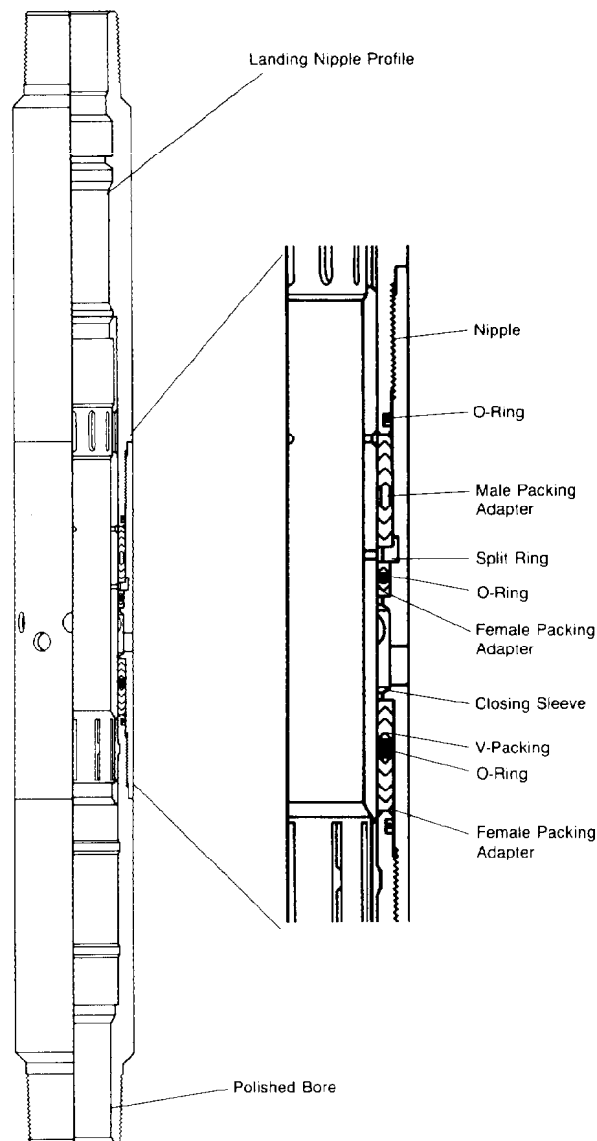

Fig. 3.17—Sliding sleeve valve.

Input Safety Valves (ISV's)

Injection wells can be protected by the safety shut-in systems discussed earlier in this chapter. The ISV is a lower-cost safety valve that can be used for wells where there is only flow downward into the well. It is basically a check valve mounted on a wireline-retrievable mandrel located in a landing nipple. Upward flow closes the valve.

Circulating Devices

Circulating devices are wireline-operable valves or devices used to permit selective communication between the tubing and the tubing/casing annulus. Variations include (1) sliding-sleeve valve (Fig. 3.17), (2) side-pocket mandrel and inserted "dummy" valve (Fig. 3.18), and (3) ported nipple and lock mandrel.

Sliding-sleeve valves and side-pocket mandrels permit wireline operations to be performed through them, and

Fig. 3.18—Side pocket mandrel.

they do not obstruct flow up through the tubing. Side-pocket-mandrel valves can be removed by wireline for redressing the seals, which are subject to damage when the circulation path is first opened. Sliding-sleeve valves can be provided with landing-nipple profiles for isolation with a wireline lock mandrel in case of sealing failure. Sliding-sleeve valves can be incorporated in safety-valve nipples to isolate the control line when the safety valve is removed.

Tubing Plug

The tubing should be plugged to prevent flow or loss of control when the tree and/or master valve is to be removed. Plugs are available for landing nipples in the wellhead and for nipples in the tubing string. Tubing plugs are set and retrieved with wireline methods.

Chemical Injection Valves

Some wells require frequent or continuous injection of small quantities of chemicals, such as methanol, for protection from freezing or as inhibitors for corrosion control. The chemicals can be injected down through a small-diameter parallel tubing or through the tubing/casing annulus. Chemical injection valves can be installed in a circulating device to better control the injection rate and to provide backflow protection.

Corrosion

Wellhead Corrosion Aspects

Corrosion has often been defined as the destruction of a metal by reactions with its environment. The attack may be internal or external and may result from chemical or electrochemical action.

Internal attack usually results from weight loss corrosion ("sweet corrosion") caused by the presence of CO₂ and organic acids, or sulfide or chloride stress cracking

corrosion ("sour corrosion") caused by the presence of H_2S , chlorides, or a combination of these elements. External attack usually results from "oxygen corrosion" caused by exposure to atmospheric oxygen, "electrochemical corrosion" caused by the flow of electric currents, or a combination of the two.

One or more methods may be employed to control corrosion in wellhead equipment, depending on the type of corrosion present and the economics involved: (1) use of special corrosion-resistant alloys, (2) injection of an effective inhibitor, (3) application of effective coatings, and/or (4) properly applied and maintained cathodic protection. Although a detailed discussion of corrosion is not the purpose of this section, it is necessary to describe briefly the various types of corrosion encountered in wellhead equipment to explain the various methods of control. Internal and external corrosion are controlled differently and are discussed separately.

Internal Corrosion

Weight Loss Corrosion. Weight loss corrosion is usually defined as corrosion occurring in oil or gas wells where no iron sulfide corrosion product or H_2S odor exists. Corrosion of this type in gas-condensate wells is often attributed to CO_2 and organic acids. Although noncorrosive in the absence of moisture, when moisture is present, CO_2 dissolves and forms carbonic acid. Carbonic acid with the organic acids contributes to corrosion. The quantity of CO_2 dissolved in the corroding fluid determines the severity of corrosion.

Generally, corrosion can be expected when the partial pressure of the CO_2 , at bottomhole conditions, exceeds 30 psi. The partial pressure of CO_2 can be easily determined: partial pressure equals (total pressure) times (percent CO_2).

Wellhead Protection Methods. Wellhead protection methods for weight loss corrosion may take two forms.

1. An effective inhibitor, protective coatings, or special-alloy equipment is generally required when the CO_2 partial pressure, at bottomhole conditions, exceeds 30 psi.

2. Special-alloy equipment is generally required when the CO_2 partial pressure, at bottomhole conditions, exceeds 100 psi.

Sulfide or Chloride Stress Cracking Corrosion. Sulfide or chloride stress cracking corrosion is defined as corrosion occurring in oil or gas wells when hydrogen sulfide or chlorides are present. Iron sulfide appears as a black powder or scale. Hydrogen sulfide, like CO_2 , is not corrosive in the absence of moisture. If moisture is present, the gas becomes corrosive. If CO_2 is also present, the gas is more severely corrosive.

Attack by H_2S causes the formation of iron sulfide, and the adherence of the iron sulfide to steel surfaces creates an electrolytic cell. The iron sulfide is cathodic to the steel and accelerates local corrosion. Hydrogen sulfide also causes hydrogen embrittlement by releasing hydrogen into the steel grain structure to reduce ductility and cause extreme brittleness.

Wellhead Protection Methods for Sulfide or Chloride Stress Cracking. These protection methods take three forms.

1. Special alloy equipment is generally required when pressures exceed 65 psia and the partial pressure of H_2S exceeds 0.05 psia.

2. Proper injection of an effective inhibitor.

3. Carbon and low alloy steels that should not exceed a hardness level of HRC 22.

Extreme Sour Service. This is sometimes referred to as critical service. An extreme sour condition exists when both CO_2 and H_2S are present in the well fluids. In this case, protection is required for both sulfide stress cracking and metal loss. In general, stainless steel, Monel®, or other nonferrous materials are used for this service. API Spec. 6A refers to NACE Standard MR-01-75 as the governing standard for materials to resist sulfide stress cracking.¹³

External Corrosion

Oxygen Corrosion. Oxygen corrosion is caused by the oxidation or rusting of steel due to exposure to atmospheric oxygen or a corrosive atmosphere. The severity of corrosion depends on temperature, erosion of the metal surface, property of corrosion product, surface films, and the availability and type of electrolyte. Salt water causes a very rapid increase in corrosion rate.

On offshore installations, wellhead equipment is often subjected to one or more of three zones of attack: (1) the underwater or submerged zone, (2) the splash zone (most severe), and (3) the spray zone.

Wellhead Protection Methods for Oxygen Corrosion.

The protection methods for oxygen corrosion include (1) use of special-alloy equipment, (2) application of effective external protective coatings of metallic or nonmetallic materials, and (3) use of cathodic protection for the underwater zone.

Electrochemical Corrosion. There are two major types of electrochemical corrosion. One type is somewhat of a reverse plating reaction caused by stray direct electric currents flowing from the steel anode to a cathode. Another type of electrochemical corrosion occurs when pipe or a wellhead is exposed to certain types of moist soil.

Bimetallic corrosion, another form of electrochemical corrosion aggravated by use of dissimilar metals, is often called galvanic corrosion.

Wellhead Protection Methods for Electrochemical Corrosion.

There are four protection methods for electrochemical corrosion: (1) use of properly applied and maintained cathodic protection, (2) application of effective external surface coatings, (3) avoiding use of dissimilar metals, and (4) use of electrical insulation of surface lines from wellhead assembly.

Material Selection

Table 3.30 shows the general accepted materials for various wellhead services.

Special Application

High Pressure Seals

Flange connections for pressures through 20,000 psi have been standardized by API and the specifications for these flanges are given in API Spec. 6A.¹ However, other pressure-sealing elements in wellhead equipment

2.95	75	12.5	17	8.5	12
1.97	50	10.0	14	7.0	9
0.98	25	5.0	7	3.5	5

NOTE: Purchasers are cautioned that the energy values tabulated above have been selected to cover a broad range of possible physical properties, and care should be exercised in energy value interpretations for the higher strength Types 2 and 3 materials where minimum energy values have not been clearly established.

such as valve seat, valve stem, fittings, hanger-packer, casing secondary seals, lockscrews, etc., have not been standardized and are subject to agreement between purchaser and manufacturer.

Seals other than flange seals for 20,000 psi and higher working pressures require special consideration because of the difficulty in sealing these high pressures, which are usually encountered in combination with hostile fluids and are subject to agreement between purchaser and manufacturer.

Low- and High-Temperature Application

Unless otherwise specified, API Spec. 6A for wellhead equipment is designed to operate in temperatures from -20 to 250°F .

Low Temperature. API Spec. 6A also provides specifications for materials to operate in temperatures below -20°F . Materials operating in extremely low temperatures become brittle and have low impact resistance. API Spec. 6A specifies minimum impact values at -25°F , -50°F , and -75°F test temperatures. The specified impact values are shown in Table 3.31.

High Temperature. As the temperature rises, the strength of steel decreases. Table 3.32 shows the working pressure-temperature relationship of wellhead steel pressure containing parts at temperatures from -20 to 650°F .

There are some applications where valves with fire-resistance capability are required, particularly on offshore platforms where a fire on one well endangers the other wells. API provides API RP 6F, a recommended

practice fire test for valves.¹⁴ The fire test is conducted in a flame with a temperature of $1,400$ to $1,600^{\circ}\text{F}$ for a 30-minute test period.

Subsea Applications

Although subsea wellhead and Christmas-tree equipment has been available for a number of years and a number of installations have been made, most of the installations have been made in relatively shallow water. Equipment is now being designed for use in water depths of several thousand feet. Various methods for installing, operating, repairing, or replacing subsea equipment are being utilized such as by remote operation, the use of divers, or the use of submarines or robots.

At this time, subsea equipment is proprietary, with each manufacturer providing his own design. Subsea installations are designed for specific projects and are agreed on by the manufacturer and the customer.

Offshore wells can be broadly classified as those drilled from a fixed or bottom-supported platform or from a floating platform. Floating platforms are either of the semisubmersible or floating-ship type.

Fixed Platform Drilling. Offshore wells drilled from a fixed platform normally are drilled with the wellhead and the BOP's on the platform. The well is completed with the Christmas tree attached to the wellhead on the platform. Wells drilled using a bottom-supported drilling rig (jackup rig) normally utilize mudline-suspension wellheads. The wellhead is installed on the ocean floor, with riser pipe extending from the wellhead to the rig floor. The well is drilled with BOP's attached to the riser

TABLE 3.32—PRESSURE/TEMPERATURE RATINGS OF STEEL PARTS

600	316	1540	106.2	2310	159.3	3850	265.5
650	343	1430	98.6	2145	147.9	3575	246.5

pipe and the completion is made at the top of the riser pipe, above water, usually on a fixed platform that is installed for the completion.

Floating Drilling Vessels. Wells drilled utilizing floating drilling vessels normally utilize remote subsea equipment. The wellhead equipment is installed on the ocean floor. The BOP's are installed on the wellhead on the ocean floor. Riser pipes connect the equipment on the ocean floor with the vessel. Guidelines extending from the wellhead to the vessel are used for guiding equipment to the wellhead. For water depths too deep to utilize guidelines, guidelineless drilling systems are available. The guidelineless systems are normally used with dynamically positioned vessels. Guidance is accomplished by the use of acoustics, sonar, or TV.

The completion (installation of the Christmas tree) on remote subsea equipment can be made either on the ocean floor or on a platform by utilizing tieback equipment.

A variety of completion systems can be utilized for the production of oil and gas in various subsea environments. Some of these include single-well (diver-assisted or diverless) satellite, platform, template, production riser, caisson or capsule (wet or dry), or combinations of the various basic systems.

SPPE/OCS Equipment. The U.S. Geological Survey (USGS), in cooperation with API and ASME, has established rules and regulations for safety and pollution prevention equipment (SPPE) used in offshore oil and gas operations.¹¹

As described under Surface Safety Valve, the USGS rules and regulations require an SSV on each Christmas tree installed in federal offshore waters. The specification governing SSV's is API Spec. 14D.⁷ To qualify as a manufacturer and/or an assembler of SPPE equipment, a company must become an SPPE certificate holder. To become an SPPE certificate holder, a company must be qualified by ASME to certify compliance with ANSI/ASME SPPE-1 standard on quality assurance and certification of safety and pollution prevention equipment used in offshore oil and gas operations.¹¹ An SPPE certificate holder certifies his equipment by marking it with an authorized OCS symbol.

Independent Screwed Wellhead

API Independently Screwed Wellhead Equipment

This section covers casing and tubing heads having upper-body connections other than API flanges or clamps, in 1,000- and 2,000-psi working pressures. A typical arrangement of this equipment is shown in Fig. 3.4.

Lowermost Casing Heads. Lowermost casing heads are furnished with a lower thread, which is threaded onto the surface pipe. Usually the top of the casing head is equipped with an external thread to receive a threaded cap used to compress the packing to make a seal and hold the slips down. The top thread can also be used to support a companion flange with an API ring groove and bolt holes for attaching standard BOP's.

Casing Hanger. The casing-hanger slip segments are wrap-around type with a lower capacity than API casing hangers. The slips can be dropped through the BOP's to support the casing, but the seal must be placed around the suspended casing after the cutoff has been made.

Intermediate Casing Heads. Intermediate casing heads in this class are identical in design to lowermost casing heads. If an intermediate-casing string is used, it is usually suspended in the lower-casing head with a thread positioned just above the lower-casing head to permit easy installation of the intermediate-casing head. If proper spacing is impractical, the intermediate casing may be cut off a few inches above the lower-casing head and a socket-type nipple with a top thread welded to the intermediate casing. Then the intermediate casing head can be attached to the thread.

Tubing Heads. A tubing head threads onto the top thread of the production string to support and seal the tubing string. The tubing may be supported with a set of slips and sealed with a sealing element compressed with a cap screwed down on top of the tubing head. Maximum capacity of the slip-type tubing hanger is about 125,000 lbm of tubing weight. A mandrel or doughnut tubing hanger may be used to support the tubing if desirable. Maximum weight-supporting capacity of this type of tubing hanger is limited only to the weight-supporting strength of the tubing head.

A BOP can be attached to the tubing head with a companion flange for protection while running tubing.

A stripper rubber may also be used to strip the tubing in or out of the hole under pressure, if needed. If a stripper rubber is used, it can be placed in the tubing-head bowl and a separate bowl can be attached to the tubing head to support the slip assembly or mandrel hanger.

Casing heads are available in all standard sizes with working pressures of 1,000 psi and lower. Tubing heads are available in working pressures of 1,000 and 2,000 psi. Both units are usually furnished with two 2-in. line-pipe outlets, although 3-in. outlets are available.

Christmas-Tree Assembly. Christmas-tree assemblies for this type of equipment are usually very simple. If the well is expected to flow, a master valve is screwed onto the top tubing thread, a nipple and tee are screwed into the master valve, and a wing valve and choke are screwed into the tee.

Selection. In selecting this class of equipment, the following factors should be considered.

1. Casinghead and tubing-head components should be constructed of cast steel or forged steel and should be full-opening.

2. Casing-hanger slips should be of drop-through type.

3. Caps used to hold down the suspension members and provide a seal should have hammer lugs for easy effective installation.

4. Both casing heads and tubing heads should be easily adaptable, with a full-opening adapter, to a standard BOP.

Chapter 4

Production Packers

L. Douglas Patton, L.D. Patton & Assocs.*

Production Packers Classification and Objectives

Production packers generally are classified as either retrievable or permanent types. Packer innovations include the retrievable seal nipple packers or semipermanent type.

The packer isolates and aids in the control of producing fluids and pressures to protect the casing and other formations above or below the producing zone. All packers will attain one or more of the following objectives when they are functioning properly.

1. Isolate well fluids and pressures.
2. Keep gas mixed with liquids, by using gas energy for natural flow.
3. Separate producing zones, preventing fluid and pressure contamination.
4. Aid in forming the annular volume (casing/tubing/packer) required for gas lift or subsurface hydraulic pumping systems.
5. Limit well control to the tubing at the surface, for safety purposes.
6. Hold well servicing fluids (kill fluids, packer fluids) in casing annulus.

Once a tubing-packer system has been selected, designed, and installed in a well there are four modes of operation: shut-in, producing, injection, and treating. These operational modes with their respective temperature and pressure profiles have considerable impact on the length and force changes on the tubing-to-packer connections.

Tubing-To-Packer Connections

There are three methods of connecting a packer and a tubing string, and the tubing can be set in tension, compression, or left in neutral (no load on the packer, tension nor compression).

1. Tubing is latched or fixed on the packer, allowing no movement (retrievable packers). Tubing can be set either in tension, compression, or neutral.

2. Tubing is landed with a seal assembly and locator sub that allows limited movement (permanent or semipermanent packers only). Tubing can be set only in compression or neutral.

3. Tubing is stung into the packer with a long seal assembly that allows essentially unlimited movement (permanent packers only). Tubing is left in neutral and it cannot be set in tension or compression.

A retrievable packer is run and pulled on the tubing string on which it was installed. No special tubing trips are required. It has only one method of connection to the tubing — latched or fixed. The tubing can be set in tension, compression, or left in neutral. Tubing-length changes will result in force changes on the packer and tubing. In deep or high-temperature wells the rubber element may “vulcanize” and take on a permanent set, making release very difficult.

Permanent and semipermanent packers can be run on wireline or tubing. They have three methods of tubing connection: latched (fixed), landed (limited movement), or stung in with a long seal assembly (free movement). Special tools plus milling are needed to recover it from the well. When left for long periods of time without movement, the seal assembly and polished bore (in the packer) may stick together.

Packer Utilization And Constraints

Understanding uses and constraints of the different types of packers will clarify the factors to consider before selecting the best packer and will illustrate how they achieve their specific objectives.

*Author of the chapter on this topic in the 1962 edition was W.B. Bleakley.

Fig. 4.1—Solid-head retrievable compression packer.

Fig. 4.2—Solid-head retrievable tension packer.

Retrievable Packers

Solid-Head Compression Packer. Retrievable compression (weight-set solid-head) packers are applied when annulus pressure above the packer exceeds pressure below the packer, as in a producing well with a full annulus. This situation precludes gas lift. Fig. 4.1 shows this type of packer.¹

The constraints of a solid-head compression packer are:

1. Packer release can be hampered by high differential pressure across packer.
2. Packer may unseat if a change in the operational mode results in a tubing temperature decrease (tubing shortens).
3. Tubing may corkscrew permanently if a change in the operational mode results in a tubing temperature increase (tubing lengthens).

Solid-Head Tension Packer. Retrievable tension packers generally are used when pressure below the packer is greater than the annulus pressure above the packer, such as in an injection well or low-pressure and -volume treating (Fig. 4.2). These packers also are used in shallow wells where the tubing weight is insufficient to set a compression packer properly.

Constraints of the solid-head retrievable tension packer are:

1. Release is difficult with high differential pressure across the packer.
2. Tubing could part if a change in the operational mode results in a temperature decrease.
3. Packer could release if a change in the operational mode results in a temperature increase.

Isolation Packer. A retrievable isolation packer (Fig. 4.3)

is used when two mechanically set packers are to be set simultaneously. It requires anchor pipe on the plugged back depth below it to use tubing weight to shear the pins that hold the packer in the unset mode. It can be used to isolate old perforations or a damaged spot in the casing temporarily. This packer is for temporary use only and should be retrieved as soon as its purpose is accomplished.

Control-Head Compression Packer. The control-head retrievable compression packer (Fig. 4.4) has a bypass valve to alleviate the packer release problem resulting from excessive differential pressure. The valve is on top of the packer. It is opened, equalizing the pressure across the packer, by picking up the tubing without moving the packer. As with the solid-head packer, using tubing weight, this packer holds pressure from above only. It is not suitable for injection wells or low-volume and -pressure treating.

Constraints are: (1) the bypass or equalizing valve could open if an operational mode change results in a tubing temperature decrease, and (2) tubing could corkscrew permanently if an operational mode change results in a tubing temperature increase.

A control-head retrievable compression packer run with an anchor is basically a treating packer. It holds pressure from below without tubing weight because the anchor holds the packer and constrains its movement. Pressure across the packer is equalized through a valve operated by picking up on the tubing (Fig. 4.5). Temperature changes have the same effect as they have with the control-head compression packer without an anchor.

Control-Head Tension Packer. The control-head retrievable tension packer is released easily even if high

Fig. 4.3—Isolation packer is held in place with shear pins.

Fig. 4.4—Control-head compression packer employs a top equalizing valve.

differential pressure exists across the packer during normal operations. This pressure is equalized by a valve on top of the packer that is opened by lowering the tubing without moving the packer. This type packer holds pressure from below only, with tubing in tension, and is not suitable for wells with well servicing fluid in the annulus.

Constraints of a control-head tension packer are: (1) premature bypass valve opening could occur with a tubing temperature increase as the tubing elongates, and (2) tubing could part with a tubing temperature decrease as the tubing contracts.

Mechanically Set Packer. Mechanically set retrievable packers (Fig. 4.6) have slips above and below the seal element and can be set with either tension, compression, or rotation. Once the packer is set, the tubing can be left in tension, compression, or neutral mode. How the tubing is left is dictated by future operations to be performed. Careful planning of these subsequent operations is needed to neutralize temperature and pressure effects on the tubing and the equalizing valve.

The mechanically set retrievable packer is suitable for almost universal application, the only constraint being found in deep deviated wells where transmitting tubing movement will be a problem.

Hydraulic-Set Packer. The retrievable hydraulic-set packer (Fig. 4.7) also has slips above and below the packing element. It is set by applying the hydraulic pressure in the tubing to some preset level above hydrostatic pressure. Once the packer is set, the tubing may be put in limited tension, compression, or left neutral. The packer generally is released with tension-actuated shear pins. It is universally applicable, the only constraint being its high cost.

Common Constraint — All Latched Packers. Severe tubing length changes resulting from changing temperatures can develop sufficient forces to move the packer in the casing. This can happen in old corroded casing or in the harder grades of new casing such as P-110. The teeth on the slips “shave” the pipe, thus loosening their grip.

Permanent Packers

The polished sealbore packer (Fig. 4.8) is a permanent-type or semipermanent packer that can be set with precision depth control on conductor wireline. It also can be set mechanically or hydraulically on the tubing. A locator sub and seal assembly is attached to the bottom of the tubing and is stung into the polished bore receptacle of the packer. Isolation is achieved by the fit of the seals inside the polished bore.

This packer allows all three connection methods—fixed, limited movement, or free movement—that subsequent operations will dictate. It is ideal for wells subject to frequent workover because the tubing is retrieved easily.

Permanent packers are especially useful where tubing temperature may vary widely because the seals slide up and down in the polished bore. They can be retrieved by using a special tool on the end of the tubing in place of the seal assembly, but a round trip with the tubing is required.

There is one important constraint with this packer—if the tubing remains in a place for a long time at the same temperature and no movement occurs between the seals and the polished bore, the seals may stick to the polished bore surface, creating a tubing-retrieval problem.

The seal assembly length (Fig. 4.8) should allow sufficient free upward tubing movement during stimulation treatments and permit tubing weight slackoff to eliminate seal movements during the producing life of the well.

Fig. 4.5—Treating compression packer is held by an anchor containing piston slips.

Fig. 4.6—Mechanically set dual-slip packer has slips above and below rubber element.

Considerations For Packer Selection

Packer selection requires an analysis of packer objectives for the anticipated well operations, such as initial completions, production stimulation, and workover procedures. Considering both current and future well conditions, the packer with the minimum overall cost that will accomplish the objectives should be selected. Initial investment and installation costs should not be the only criteria. Overall packer cost is related directly not only to retrievability and failure rate but to such diverse factors as formation damage during subsequent well operations or replacement of corkscrewed tubing.

Retrievability will be enhanced greatly by using oil or solid-free water rather than mud for the packer fluid. Frequency of packer failures may be minimized by using the proper packer for the well condition and by anticipating future conditions when setting the packer. Permanent packers are by far the most reliable and, when properly equipped and set, are excellent for resisting the high pressure differentials imposed during stimulation. They are used widely when reservoir pressures vary significantly between zones in multiple completions.

Weight-set tension types of retrievable packers will perform satisfactorily when the force on the packer is in one direction only and is not excessive.

Surface/Downhole Equipment Coordination

Setting a packer always requires surface action and in most cases either vertical or rotational movement of the tubing. Selection of the packer must be related to wellhead equipment. The well completion must be considered as a coordinated operation. The surface and downhole equipment must be selected to work together as a system to ensure a safe completion. This is especially true in high-pressure well applications.

Packer Mechanics

The end result of most packer setting mechanisms is to (1) drive a cone behind a tapered slip to force the slip into the casing wall and prevent packer movement, and (2) compress a packing element to effect a seal. Although the end result is relatively simple, the means of accomplishing it and subsequent packer retrieval varies markedly between the several types of packers.

Some packers involve two or more round trips, some require wireline time, and some eliminate trips by hydraulic setting. The time cost should be examined carefully, especially on deep wells using high cost rigs. In some cases higher initial packer costs may be more than offset by the saving in rig time, especially offshore.

Corrosive Well Fluids

Materials used in the packer construction must be considered where well fluids contain CO_2 or H_2S in the presence of water or water vapor.

Sour Corrosion (Sulfide or Chloride Stress Cracking Corrosion). Even small amounts of H_2S with water produce iron sulfide corrosion and hydrogen embrittlement. The Natl. Assn. of Corrosion Engineers specifies that materials for H_2S conditions be heat-treated to only a maximum hardness of 22 Rockwell C to alleviate embrittlement. Hardness has no effect on iron sulfide corrosion, however. For critical parts where high strength is required, K-Monel® is resistant to both embrittlement and iron sulfide corrosion. Corrosion inhibitors may be required to protect exposed surfaces.

Sweet Corrosion ("Weight Loss" Corrosion). CO_2 and water cause iron carbonate corrosion, resulting in deep pitting. For ferrous materials, low-strength steels or cast

Fig. 4.7—Hydraulic packer is set by tubing pressure.

Fig. 4.8—Retrievable, permanent-type packer is made with polished sealbore.

iron are desirable to resist stress concentrations from pitting. Critical parts of production equipment can be made of stainless steel with 9% or higher chromium. Corrosion inhibitors may be required to protect exposed surfaces.

Bimetallic or galvanic corrosion resulting from contact of dissimilar metals should be considered. Usually this is not a problem, since steel is the anode, or sacrificial member, and the resulting damage is negligible because of the massive area of the steel compared with the less-active stainless or K-Monel.

Sealing Element

The ability of a seal to hold differential pressure is a function of the elastomer pressure, or stress developed in the seal. The seal stress must be greater than the differential pressure. In a packer sealing element, the stress developed depends on the packer setting force and the backup provided to limit seal extrusion.

The sealing element may consist of one piece or may be composed of multiple elements of different hardnesses. In a three-element packer, for example, the upper and lowermost elements are usually harder (abrasion resistant) than the center element. The center element seals off against imperfections in the casing, while the harder outside elements restrict extrusion and seal with high temperature and pressure differentials. Many packers also include metallic backup rings to limit extrusion.

Where H_2S or CO_2 is present, seal materials and temperature and pressure conditions must be considered carefully. Teflon® resists H_2S or chemical attack up to 450°F; but Teflon seal extrusion can be a problem. With controlled clearance and suitable metallic backup to prevent extrusion, glass-filled Teflon has performed satisfac-

torily to 450°F with a 15,000-psi differential pressure. Because of seal rigidity it may not perform well below 300°F. With temperatures below 250°F, Nitrile® rubber can be used with metallic backup for static seals. The performance of Viton® seals becomes marginal at 300°F. A tubing-to-packer seal consisting of vee-type rings of Kalrez®, Teflon®, and Rylon® in sequence with metallic backup have been satisfactory (under limited movement) up to 300°F and 10,000-psi differential pressure.

Retrievability

Consideration of retrievability must combine several factors, relative to packer design and use. Retrievable packers are released by either straight pull or rotation. In a deviated hole, applied torque usually can develop more downhole releasing force than pull, although sometimes it also is necessary to manipulate the tubing up and down to transmit the torque to bottom.

The packer sealing element should prevent solids from settling around the slips. Usually the bypass on a control-head packer opens before the seal is released; this allows circulation to remove sand or foreign material.

High setting force is needed to provide a reliable seal under high differential pressures, but it should be recognized that the resulting seal extrusion can contribute to the retrieval problem. A jar stroke between release and pickup positions is an aid in packer removal.

The method of retracting and retaining slip segments is a factor in retrievability. Bypass area around the packer is also important. Where external clearance is minimized to promote sealing, the internal bypass area must be sufficiently large to prevent swabbing by the sealing element when pulling out of the hole.

Fishing Characteristics

A permanent packer must be drilled out to effect removal. This usually presents little problem because all material is millable. Some expensive variations of permanent packers provide for retrieval but retain the removable seal tube feature. Removal of stuck retrievable packers usually results in an expensive fishing operation because components are nondrillable and require washover milling. When selecting packers, consider the volume and type of metal that must be removed if drilled and the presence of rings or hold-down buttons that may act as ball bearings to milling tools.

Through-Tubing Operations

Packers with internal diameters equal to that of the tubing should be used to facilitate through-tubing operations. Also, tubing should be set to minimize or alleviate buckling where through-tubing operations are anticipated.

Purchase Price

Table 4.1 presents a range of packer cost indices. The most economical types are weight-set and tension packers. However, inclusion of a hydraulic hold-down with a compression packer will increase the initial cost from 20 to 100%. Multistring hydraulic-set packers are usually the most expensive and also require many accessories.

Tubing/Packer System

Advantages

By using a properly selected packer, well operations will be more efficient. Wireline pressure and logging operations will proceed faster and smoother. Longer flowing life will be achieved with the use of a packer through the optimal use of the gas energy.

The use of a packer in a gas well, with a tailpipe run below the perforations, will alleviate the problem of gas wells heading, loading up with water, and dying prematurely. (The water is produced continuously as a mist and is not allowed to build up over the perforations.)

This use of a packer and tail pipe will not control the natural water influx, but will keep the water moving along until such time as the available pressure is less than the pressure required to flow.

Where Packers Are Not Used

Packers are not run in rod-pumped wells, unless extraordinary circumstances such as dual completion call for one. Electric submersible pumped wells would not have a packer, except when used with uphole subsurface safety valves required by government safety regulations for off-shore wells. Many naturally flowing, high-volume, sweet-crude wells are produced up the annulus without packers; a small tubing string is run to be used to kill (circulate) the well or for running certain logs or pressure gauges. Dry, sweet-gas wells often are produced up both the tubing and the annulus and have no packers.

Operational Well Modes

There are four modes of operation that any given well might experience: (1) shut-in; (2) producing (either liquids, gas, or a combination); (3) injecting (hot or cold

TABLE 4.1—COST COMPARISON OF PRODUCTION PACKERS

Packer Type	Tubing-Casing size (in.)	Typical Cost Index**
Compression	2 × 5½	1.00
Tension set	2 × 5½	0.925
Mechanical set	2 × 5½	1.54
Hydraulic set	2 × 5½	2.30
Dual	2 × 2 × 7	5.85
Permanent*	2 × 5½	1.85
Semipermanent*	2 × 5½	2.30

*Electric-line setting charge not included.

**Cost of simple compression packer = 1.00.

liquids, or gases); or (4) treating (high, low, or intermediate pressures and volumes).

The usual mode of operation is only one of the factors that need to be considered when selecting a particular type of packer to be used in a well. Subsequent operations and their pressures and temperature changes are likely to be extremely important to packer utilization success.^{2,3} Typical temperature-vs.-depth profiles are illustrated in Fig. 4.9. These profiles are similar to those measured in wells operating in one of four modes: shut-in, production, injection, or treatment.

Fig. 4.9a depicts a typical geothermal gradient, with the temperature increasing with depth to the bottomhole temperature (BHT). Every time a well is shut in, the operating temperature profile will begin to move toward the shape of the natural geothermal profile.

Producing well temperature profiles for both gas and oil are shown in Fig. 4.9b. The wellhead temperature of an oil well will be somewhat less than BHT. The amount of cooling as crude flows to the surface will depend on several factors: (1) the relative amount of oil and water, (2) the specific heats of the oil and water, (3) the flow rate, (4) the gas/liquid ratio, and (5) the vertical flow pressure drop that controls gas liberated and attendant cooling effect.

The temperature profile of a gas well may have a wellhead temperature lower than ambient. In any case the wellhead temperature of a gas well will depend on the BHT, the flow rate, the pressure drop in the tubing, the specific heat of the gas, and other factors.

Injection temperature profiles can be quite varied (Fig. 4.9c). The profile will depend on such factors as the nature of the injection fluid (liquid or gas), the rate of injection, and the injected fluid temperature (cold liquid or gas, hot gas or liquid, or even steam). The liquids injected will tend to have little heat loss down the tubing, while the gas injected will tend to pick up or lose heat to approach the BHT.

While treating is simply a special case of the injection mode, and it is temporary in nature, it is considered important enough to be discussed separately. As with the liquid injection profile, the treating liquid will not pick up any appreciable amount of heat as it moves down the tubing and the treating temperature profile is essentially vertical (Fig. 4.9d).

As illustrated in some examples later, the important thing about these profiles is not their shape but how much the shape and temperature change from one operational

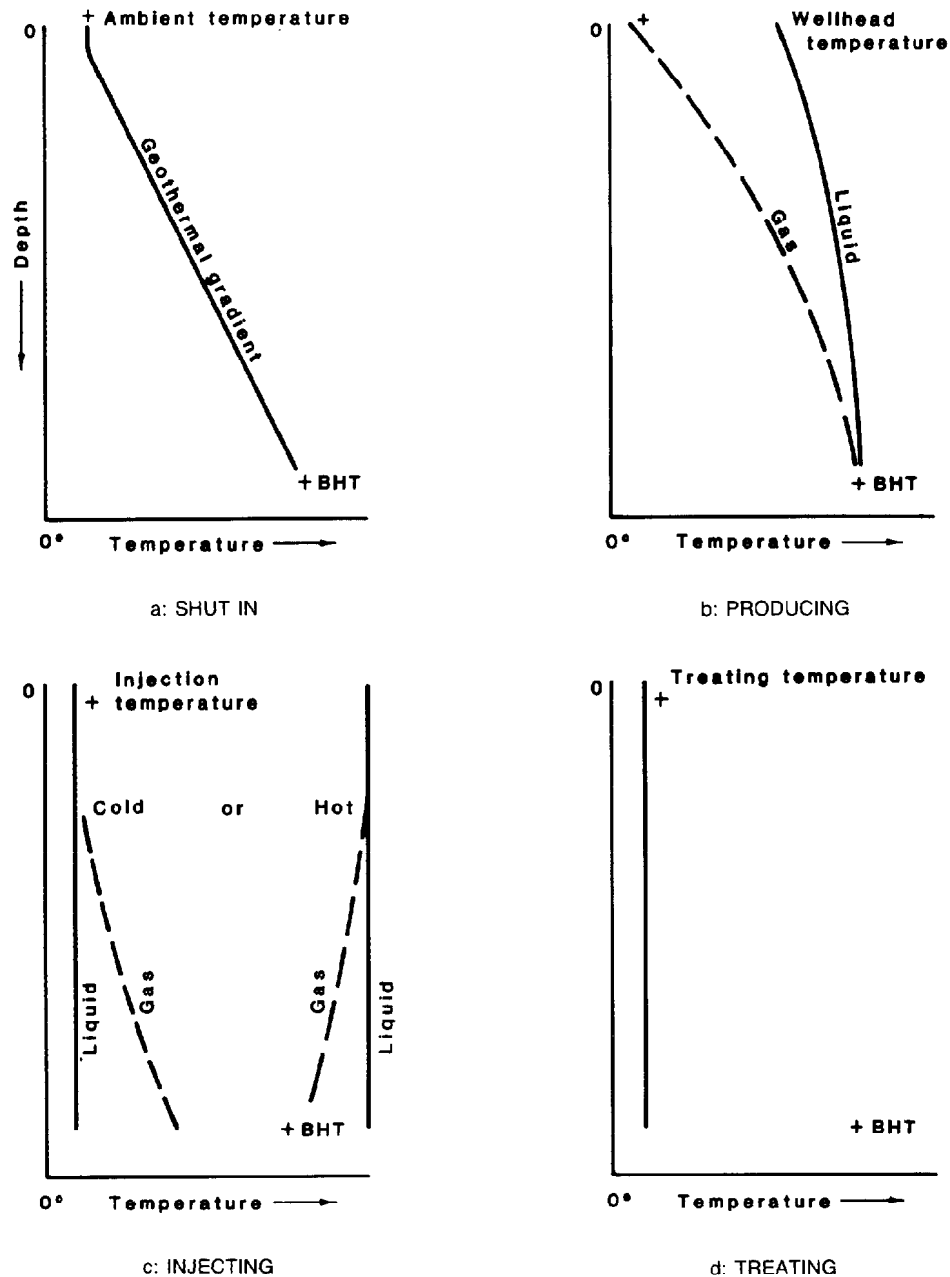

Fig. 4.9—Temperature profiles for four possible modes of oil and gas wells: a. Shut-in, b. Producing, c. Injecting, d. Treating.

mode to another, and how those temperature changes affect the tubing and packer system. It is strongly recommended that anticipated temperature profiles of each operational mode be drawn accurately when planning various steps of any completion or major workover.

Fig. 4.10 shows the pressure profiles of the four modes of well operation. Fig. 4.10a illustrates a typical shut-in well with well servicing fluid in the wellbore. The slope of the profile and the height to which the fluid level rises on the depth scale (and in the wellbore) will depend on the average reservoir pressure, \bar{p}_R , and the gradient of the well servicing fluid. Fig. 4.10b shows the profiles of typical producing oil and gas wells. A liquid injection pro-

file (Fig. 4.10c) is similar to the shut-in profile, the difference being that the bottomhole injection pressure, $(p_i)_{bh}$, is greater than the average reservoir pressure, \bar{p}_R . The wellhead pressure, p_{wh} , can have any value, from a vacuum to several thousand psi. The gas injection profile may have a reverse slope on it or may have a normal but steep slope, depending on the rate, tubing size, and bottomhole injection pressure.

The treating pressure (Fig. 4.10d) is a special temporary case of the injection profile. The bottomhole treating pressure, $(p_t)_{bh}$, often will be greater than the injection pressure, especially in a fracturing job. The surface pressure will be constrained by the burst strength of the

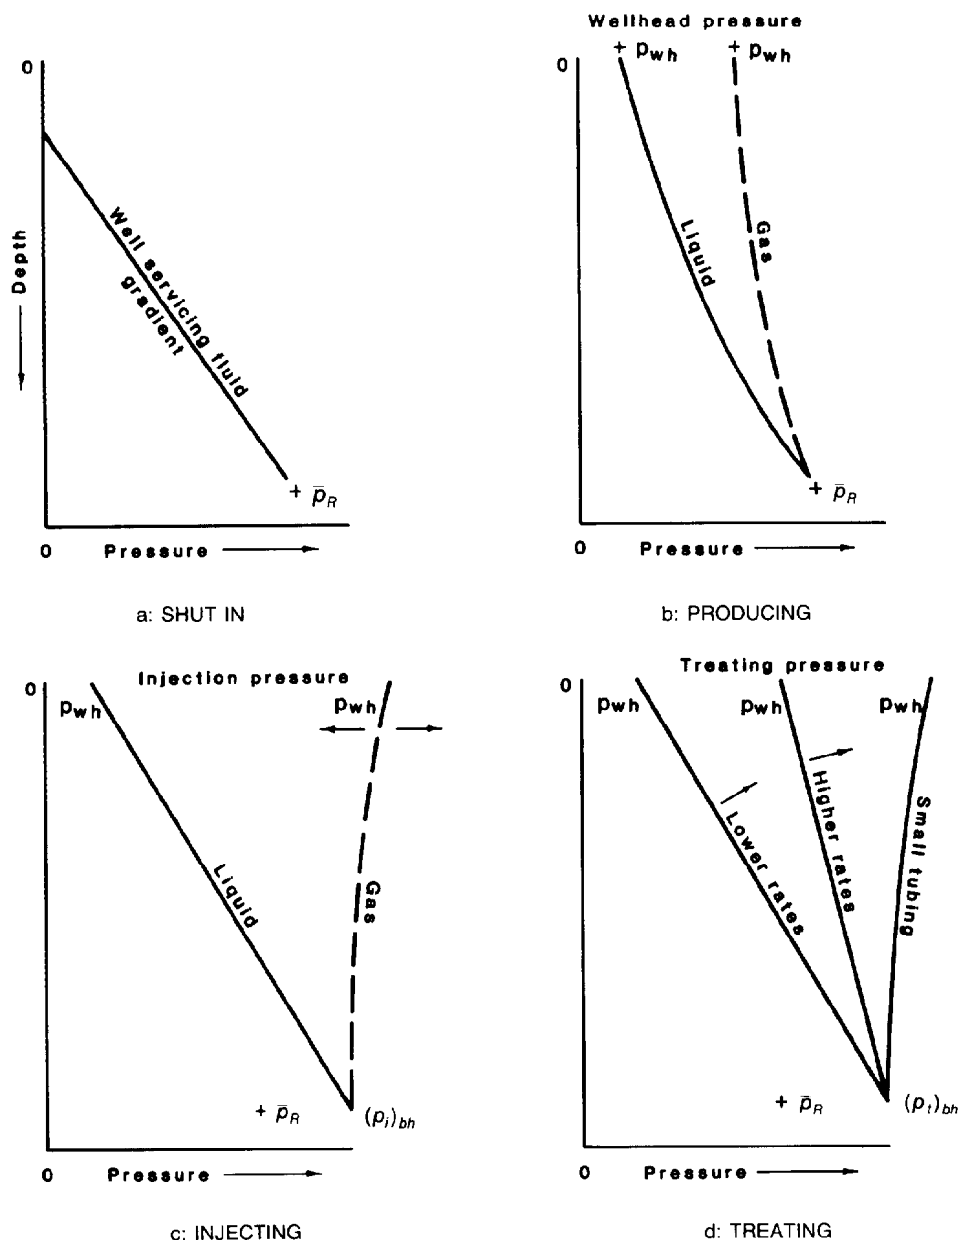

Fig. 4.10—Pressure profiles for four possible operational modes of oil and gas wells: a. Shut-in b. Producing c. Injecting d. Treating.

tubing and casing, and safety considerations. The slope of the pressure profile will depend on the tubing size, the treating rates, and the treating pressure downhole, $(p_t)_{bh}$.

It is recommended that pressure profiles of each operational mode be drawn for each step of a completion or major workover. As the examples will point out, the importance of pressure changes from one well mode to another and their effects on the tubing and packer system cannot be overemphasized.

Tubing Response Characteristics

Changing the mode of a well (producer, injector, shut-in) causes changes in temperature and pressures inside and outside the tubing. Depending on (1) how the tubing

is connected to the packer, (2) the type of packer, and (3) how the packer is set, temperature and pressure changes will effect the following.

1. Length variation in the tubing string will result if the seals are permitted to move inside a permanent polished seal-bore packer.

2. Tensile or compressive forces will be induced in the tubing and packer system if tubing motion is not permitted (latched connection).

3. A permanent packer will be unsealed if motion is permitted (tubing contraction) and the seal assembly section is not long enough.

4. Unseating of a solid-head tension (or compression) packer will occur if it is not set with sufficient strain (or weight) to compensate for tubing movement.

5. The equalizing valve will open prematurely on control-head packers (tension or compression).

The net result of any of these five events could reduce the effectiveness of the downhole tools and/or damage the tubing, casing, or even the formations open to the well. Failure to consider length and force changes may result in costly failures of such operations as squeeze cementing, acidizing, fracturing, and other remedial operations. Formation damage may result. In addition, the tubing string could be corkscrewed or parted.

Potential length changes under extreme conditions determine the length of seals necessary to remain packed-off with a polished seal-bore packer. Potential induced forces need to be calculated to prevent tubing damage, unseating packers, or opening equalizing valves.

The two major factors that tend to lengthen or shorten the string (movement permitted) are^{4,5} (1) temperature effect and (2) pressure effects—piston, ballooning, and buckling effects.

Buckling will only shorten the tubing string. The other factors may shorten or lengthen the tubing string. If motion is prevented, tension or compression forces are induced. It is important to understand and remember the direction of action of the length and force changes. It is equally important to remember that a string of tubing landed in any packer is initially in a neutral condition, except for any subsequent mechanical strain or set-down weight applied by the rig operator. After the tubing is landed, the factors that cause changes in length or force are always the result of a change in temperature and pressure.

Temperature Effect

Thermal expansion or contraction causes the major length change in the tubing.

$$\Delta L_t = 8.28 \times 10^{-5} \times L_t \times \Delta \bar{T}, \quad \dots \dots \dots (1)$$

where

$$\begin{aligned} \Delta L_t &= \text{change in tubing length, ft,} \\ L_t &= \text{tubing length, ft, and} \\ \Delta \bar{T} &= \text{change in average temperature, } ^\circ\text{F.} \end{aligned}$$

Length changes are calculated readily if the average temperature of the tubing can be determined for the initial condition and then again for the next operation and the next, etc. The average string temperature in any given operating mode is one-half the sum of the temperatures at the top and at the bottom of the tubing. The $\Delta \bar{T}$ is the difference between the average temperatures of any two subsequent operating modes.

If the motion is constrained, forces will be induced as a result of the temperature change. The temperature-induced force is

$$F = 207 \times A_{tw} \times \Delta \bar{T}, \quad \dots \dots \dots (2)$$

where

$$\begin{aligned} F &= \text{force (tensile or compressive, depending on} \\ &\quad \text{direction of } T), \text{ lbf, and} \\ A_{tw} &= \text{cross-sectional area of the tubing wall,} \\ &\quad \text{sq in.} \end{aligned}$$

Fig. 4.11—Tubing and packer systems, illustrating various areas and pressures necessary for movement or force calculations.

In most cases, the temperature effect provides the major length or force change when changing from one operational mode to another.

Piston Effect

The length change or force induced by the piston effect is caused by pressure changes inside the annulus and tubing at the packer, acting on different areas (Fig. 4.11). The force and length changes can be calculated as follows.

$$F = \Delta p_t (A_{pi} - A_{ti}) - \Delta p_{an} (A_{pi} - A_{to}) \quad \dots \dots \dots (3)$$

(tubing) (annulus)

and

$$\Delta L_t = \frac{12L_t}{EA_{tw}} [\Delta p_t (A_{pi} - A_{ti}) - \Delta p_{an} (A_{pi} - A_{to})], \quad \dots \dots (4)$$

(pressure acting on differential area)

where

$$\begin{aligned} E &= \text{modulus of elasticity, psi (30} \times 10^6 \text{ for} \\ &\quad \text{steel),} \\ A_{pi} &= \text{area of packer ID, sq in.,} \\ A_{ti} &= \text{area of tubing ID, sq in.,} \\ A_{to} &= \text{area of tubing OD, sq in.,} \\ \Delta p_t &= \text{change in tubing pressure at packer, psi,} \\ &\quad \text{and} \\ \Delta p_{an} &= \text{change in annulus pressure at packer, psi.} \end{aligned}$$

Note that the length change, ΔL_t , is a product of L/EA_{tw} and the piston force (Eq. 3). The piston force is the sum of two pressures acting on two areas—one for the tubing and one for the annulus. Fig. 4.11a shows that for a large bore packer, annulus pressure causes downward force while tubing pressure causes an upward force. For a small bore packer this situation is reversed (Fig. 4.11b). The force greatest in magnitude will determine the resulting direction of action. An accurate schematic of the tubing and packer bore for each case should be made for proper determination of areas, forces, and the resulting direction of action.

**TABLE 4.2—TUBING CONSTANTS FOR USE IN DETERMINING
BUCKLING MOVEMENT CAUSED BY PRESSURE
DIFFERENTIALS**

**lbm/cu ft.

Ballooning and Reverse Ballooning

Internal pressure swells or balloons the tubing and causes it to shorten. Likewise, pressure in the annulus squeezes the tubing, causing it to elongate. This effect is called "reverse ballooning." The ballooning and reverse ballooning length change and force are given by

$$\Delta L_t = 2.4 \times 10^{-7} \times L_t \frac{\Delta p_t - F_{oi}^2 \Delta p_{an}}{F_{oi}^2 - 1} \quad (5)$$

and

$$F = 0.6(\Delta \bar{p}_t A_{ti} - \Delta \bar{p}_{an} A_{to}), \quad (6)$$

where

$\Delta \bar{p}_t$ = change in average tubing pressure from one mode to another, psi,

$\Delta \bar{p}_{an}$ = change in average annulus pressure from one mode to another, psi, and

F_{oi} = ratio of tubing OD to ID (Ref. 5 uses R).

Buckling Effects

Tubing strings tend to buckle only when p_t is greater than p_{an} . The result is a shortening of the tubing; the force exerted is negligible. The tubing length change is calculated using

$$\Delta L_t = \frac{r^2 A_{pi}^2 (\Delta p_t - \Delta p_{an})^2}{8EI(W_t + W_{ft} - W_{fd})}, \quad (7)$$

where

r = radial clearance between tubing OD, d_{to} , and casing ID, d_{ci} , $= (d_{ci} - d_{to})/2$, in.,

I = movement of inertia of tubing about its diameter $= \pi/64(d_{to}^4 - d_{ti}^4)$, in.⁴,

W_t = weight of tubing, lbm/in.,

W_{ft} = weight of fluid in tubing, lbm/in., and

W_{fd} = weight of displaced fluid, lbm/in.

Buckling only shortens the tubing and in most wells it will be the smallest constraint. For use with the radial and inertia calculations, values for A_{to} , A_{ti} , A_{tw} , I , F_{oi} , and $(W_t + W_{ft} - W_{fd})$ can be found, for most tubing sizes, in Table 4.2.

The net or overall length change (or force) is the sum of the length change (or forces) caused by the piston, ballooning, and temperature effects. The direction of the length change for each effect (or action of the force) must be considered when summing them. It follows that for a change in conditions, the motion (or force) created by one effect can be offset, or enhanced, by the motion (or force) developed by some other effect.

Moseley⁶ presented a method for graphically determining the length and force changes (Eqs. 5 through 7). This method is particularly useful on a fieldwide basis where wells have the same size tubing, casing and packers.

When planning the sequential steps of a completion or workover, care should be taken to consider the temperatures and pressures in each step, once the tubing

and packer system becomes involved. By careful selection of packer bore and use of annulus pressures, one or a combination of pressure effects could be employed to offset the adverse length or force change of another effect.

Combination Tubing/Packer Systems

Uniform completions have been discussed previously (i.e., a single tubing and casing size). Hammerlindl⁷ presented a method for solving problems with combination completions. His paper in particular covered two items not covered by Lubinski *et al.*⁴ He includes a direct mathematical method for calculating forces in uniform completions where tubing movement is not permitted and a method for handling hydraulic packers set with the wellhead in place. A combination completion consists of (1) more than one size of tubing, (2) more than one size of casing, (3) two or more fluids in the tubing and/or annulus, or (4) one or more of these.

Tubing/Packer Forces on Intermediate Packers

Intermediate packers are an integral part of the tubing string. Examples are dual packers in the long string or selective completion packers. The packer-to-tubing force on the intermediate packer is needed so that wells can be treated through the completion system. Without proper design, it is possible to shear the release mechanism in the intermediate packer(s), which could result in an expensive failure of the completion or workover.

Hammerlindl⁸ wrote an extension on his⁷ and Lubinski's⁴ earlier works that developed a theory required to solve for the intermediate packer-to-tubing forces. The calculation procedure regarding pressure effects requires working the problem from the lowest packer to the surface in stages. The first stage is the tubing between the bottom and second packer. The second stage is the tubing between the second and third packer (or the surface, if there are only two packers). The procedures are the standard ones for uniform completions. The only changes are those to determine the changes in length as a result of applied forces on the intermediate packers; also the actual and fictitious force calculation procedure is modified. Interested readers are referred to Hammerlindl's 1980 paper⁹ for additional information on the nebulous fictitious force of Lubinski *et al.*⁴

Key Equations in SI Metric Units

$$\Delta L_t = 1.4935 \times 10^{-5} L_t \times \Delta \bar{T} \quad \dots \dots \dots (1)$$

$$F = 741.934 A_{pw} \times \Delta \bar{T} \quad \dots \dots \dots (2)$$

$$\Delta L_t = \frac{3.6576 L_t}{E A_{pw}} [\Delta \bar{p}_t (A_{pi} - A_{ti}) - \Delta p_{an} (A_{pi} - A_{to})] \quad \dots \dots \dots (4)$$

$$\Delta L_t = 7.3 \times 10^{-8} \times L_t \frac{\Delta \bar{p}_t - F_{oi}^2 \Delta \bar{p}_{an}}{F_{oi}^2 - 1} \quad \dots \dots \dots (5)$$

Since Table 4.2 is not available in SI metric units, Eq. 7 is solved in English units (inches) and the result is converted to SI metric units (meters).

Chapter 5

Gas Lift

Herald W. Winkler, consultant *

Introduction

Description of Gas Lift Operations

Gas lift is the method of artificial lift that uses an external source of high-pressure gas for supplementing formation gas to lift the well fluids. The primary consideration in the selection of a gas-lift system to lift a well, a group of wells, or an entire field is the availability and compression cost of gas.

Continuous-flow gas lift is the only method of artificial lift that fully utilizes the energy in the formation gas production. Most wells are gas lifted by continuous flow, which can be considered an extension of natural flow by supplementing the formation gas with additional high-pressure gas from an outside source. Gas is injected continuously into the production conduit at a maximum depth on the basis of the available injection gas pressure. The injection gas mixes with the produced well fluids and decreases the flowing pressure gradient of the mixture from the point of gas injection to the surface. The lower flowing pressure gradient reduces the flowing bottomhole pressure (BHFP) to establish the drawdown required for attaining a design production rate from the well. If sufficient drawdown in the bottomhole pressure (BHP) is not possible by continuous flow, intermittent gas lift operation may be used.

Intermittent gas lift requires high instantaneous gas volumes to displace liquid slugs to the surface. The disadvantage of intermittent lift is an "on-off" need for high-pressure gas, which presents a gas handling problem at the surface and surging in the BHFP that cannot be tolerated in many wells producing sand.

Most high-pressure gas lift systems are designed to recirculate the lift gas. The low-pressure gas from the production separator is compressed and reinjected into the

well to lift the fluids from the well. This closed loop, as illustrated in Fig. 5.1, is referred to as a closed rotative gas-lift system.[†] Continuous-flow gas lift operations are preferable with a closed rotative system. Intermittent gas lift operations are particularly difficult to regulate and to operate efficiently in smaller closed rotative systems with limited gas storage capacities in the low- and high-pressure lines.

Applications

Gas lift is particularly applicable for lifting wells where high-pressure gas is available. Gas compressors may have been installed for gas injection, or high-pressure gas wells may be nearby. Since the cost of compression far exceeds the cost of downhole gas lift equipment, gas lift always should be considered when an adequate volume of high-pressure gas is available for wells requiring artificial lift. Most wells can be depleted by gas lift, which is particularly true since the implementation of reservoir pressure maintenance programs in most major oil fields.

Advantages and Limitations

The flexibility of gas lift in terms of production rates and depth of lift cannot be matched by other methods of artificial lift if adequate injection-gas pressure and volume are available. Gas lift is one of the most forgiving forms of artificial lift, since a poorly designed installation will normally gas lift some fluid. Many efficient gas lift installations with wireline-retrievable gas lift valve mandrels are designed with minimal well information for locating the mandrel depths on initial well completion.

Highly deviated wells that produce sand and have a high formation gas/liquid ratio are excellent candidates for gas lift when artificial lift is needed. Many gas lift installations are designed to increase the daily production from

*Original chapter in 1962 edition written by C.V. Kirkpatrick.

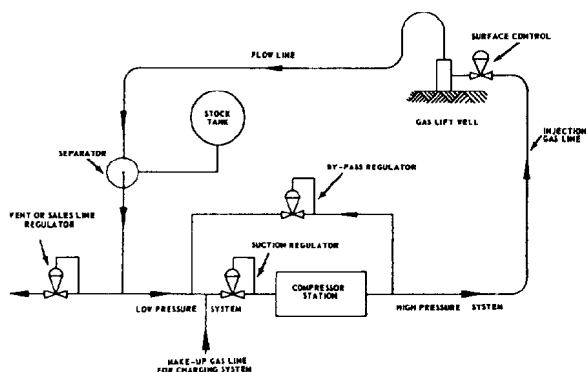

Fig. 5.1—Simplified flow diagram of a closed rotative gas lift system.

flowing wells. No other method is as ideally suited for through-flowline (TFL) ocean floor completions as a gas lift system. Maximum production is possible by gas lift from a well with small casing and high deliverability.

Wireline-retrievable gas lift valves can be replaced without killing a well or pulling the tubing. The gas lift valve is a simple device with few moving parts, and sand-laden well fluids do not have to pass through the valve to be lifted. The individual well in-hole equipment is relatively inexpensive. The surface equipment for injection gas control is simple and requires little maintenance and practically no space for installation. The reported overall reliability and operating costs for a gas lift system are lower than for other methods of lift.

The primary limitations for gas lift operations are the lack of formation gas or of an outside source of gas, wide well spacing, and available space for compressors on off-shore platforms. Generally, gas lift is not applicable to single-well installations and widely spaced wells that are not suited for a centrally located power system. Gas lift can intensify the problems associated with production of a viscous crude, a super-saturated brine, or an emulsion. Old casing, sour gas, and long, small-ID flowlines can rule out gas lift operations. Wet gas without dehydration will reduce the reliability of gas lift operations.

Conventional and Wireline-Retrieval Equipment

The early gas lift valves were the conventional type whereby the tubing mandrel that held the gas lift valve and reverse check valve was part of the tubing string. It was necessary to pull the tubing to replace a conventional gas lift valve. The first selectively retrievable gas lift valve and mandrel were introduced around 1950. The retrievable valve mandrel was designed with a pocket, or receiver, within the mandrel. A gas lift valve could be removed or installed by simple wireline operations without pulling the tubing. The wireline primary device for locating the mandrel pocket and selectively removing or installing a gas lift valve is a kickover tool. The mandrel is called a sidepocket mandrel because the pocket is offset from the centerline of the tubing. Most sidepocket-type retrievable valve mandrels have a full-bore ID equal to the tubing ID. These mandrels permit normal wireline operations, such as pressure surveys. This wireline-retrievable system for gas lift valves revolutionized the

Fig. 5.2—Conventional and wireline-retrievable gas lift valves and mandrels. (a) Conventional gas lift valve and mandrel. (b) Wireline-retrievable gas lift valve and mandrel.

application of gas lift for inaccessible wells. The newer generation of retrievable valve mandrels have orienting devices to assure successful wireline operation in highly deviated wells.

The operating principles for a given type of conventional and wireline-retrievable gas lift valves are the same. Although the performance characteristics may vary between the same type of conventional and wireline-retrievable valve, the installation design calculations outlined in this chapter do not change. The choice between conventional and wireline-retrievable equipment depends primarily on the costs associated with pulling the tubing and on whether a workover fluid may damage the deliverability of a well.

Wireline-retrievable equipment is used in most offshore wells and in wells located inaccessibly where workover operations are extremely expensive. Conventional and wireline-retrievable gas lift valves and mandrels are illustrated in Fig. 5.2.²

Open and Closed Installations

Most tubing-flow gas lift installations will include a packer to stabilize the fluid level in the casing annulus and to prevent injection gas from blowing around the lower end of

the tubing in wells with a low BHFP. A closed gas lift installation implies that the installation includes a packer and a standing valve. An installation without a standing valve may be referred to as semiclosed, which is widely used for continuous flow operations. An installation without a packer or standing valve is called an open installation. An open installation seldom is recommended unless the well has a BHFP that significantly exceeds the injection gas pressure and unless normal packer removal may be difficult or impossible because of sand, scale, etc.

A packer is required for gas lifting low-BHP wells to isolate the injection gas in the casing annulus and to allow surface control of the injection-gas volumetric rate to the well. Intermittent gas lift installations will include a packer and possibly a standing valve. Although most illustrations of an intermittent gas lift installation will show a standing valve, many actual installations do not include this valve. If the permeability of the well is very low, the need for a standing valve is questionable.

The advantages of a packer are particularly important for gas lift installations in an area where the injection gas-line pressure varies or the injection gas supply is interrupted periodically. If the installation does not include a packer, the well must be unloaded after each shutdown. More damage to gas lift valves occurs during unloading operations than during any other time in the life of a gas lift installation. If the injection gas-line pressure varies, the working fluid level changes. The result is a liquid washing action through all valves below the working fluid level, and this continuing fluid transfer can eventually fluid-cut the seat assemblies of these gas lift valves. A packer stabilizes the working fluid level and eliminates the need for unloading after a shutdown and the fluid washing action from a varying injection gas-line pressure.

Considerations for Selecting the Proper Installation and Equipment

If a well can be gas lifted by continuous flow, this form of gas lift should be used to ensure a constant injection-gas circulation rate within the closed rotative gas lift system. Continuous flow reduces the possibility of pressure surges in the BHFP, flowline, and the low- and high-pressure surface facilities that are associated with intermittent gas lift operations. Overdesign rather than underdesign of a gas lift installation always is recommended when the well data are questionable. The gas lift equipment in the wells is the least expensive portion of a closed rotative gas lift system. The larger-OD gas lift valve should be selected for lifting high-rate wells. The superior injection-gas volumetric throughput performance for the 1½-in.-OD gas lift valve as compared to the 1-in.-OD valve is an important consideration for gas lift installations requiring a high injection gas requirement.

The gas lift installation designs outlined in this chapter include several safety factors to compensate for errors in well information and to allow an increase in the injection gas pressure to open the unloading and operating gas lift valves. If an installation is properly designed, all gas lift valves above an operating gas lift valve should be closed and all valves below will be open. The installation methods presented in this chapter are based on this premise. Gas lift valve operation is discussed in detail because it is difficult to design or to analyze a gas lift installation prop-

erly without understanding the mechanics of a gas lift valve.

A large-bore seating nipple, which is designed to receive a lock, is recommended for many gas lift installations. This seating nipple should be installed at the lower end of the tubing. Applications for a seating nipple include installation of a standing valve for testing the tubing or for intermittent gas lift operation, a means to secure and to pack off a BHP gauge for conducting pressure transient tests, etc. The lock should have an equalizing valve if the tubing will be blanked off. The pressure across the lock can be equalized before the lock is disengaged from the nipple to prevent the wireline tool string from being blown up the hole.

Gas Fundamentals as Applied to Gas Lift

Introduction

Only the gas fundamentals essential to the design and analysis of gas lift installations and operations will be discussed in this section. The more important gas calculations related to gas lift wells and systems can be divided into these topics: (1) gas pressure at depth, (2) temperature effect on the confined bellows-charged dome pressure, (3) volumetric gas throughput of a choke or gas lift valve port, and (4) gas volume stored within a conduit.

All gas equations are based on pressure in pounds per square inch absolute (psia), temperature in degrees Rankine (°R), and volume or capacity in cubic feet (cu ft). An exception is pressure difference in pounds per square inch (psi), which may be a difference in gauge or absolute units since the calculated pressure difference would be the same.

Generally, field measurements of pressure are in gauge readings; therefore, the volumetric-gas-throughput and gas-pressure-at-depth charts are in units of psig. The gas lift valve equations and calculations for bellows-charge and operating pressures in this chapter use gauge pressure.

Gas Pressure at Depth

Accurate prediction of injection gas pressure at depth is essential for proper gas lift installation design and for analyzing or trouble-shooting gas lift operations. Most gas-pressure-at-depth calculations are based on a static gas column. Pressure loss because of friction from the flow of injection gas through a typical casing/tubing annulus is negligible. The gas velocity in the annulus is practically nil since the cross-sectional area of the annulus is so much larger than the port area of a gas lift valve. The maximum gas flow rate is limited by the valve port size.

Calculating Static Injection Gas Pressure at Depth. Static injection gas pressure at depth can be calculated using Eq. 1.

$$p_{ioD} = p_{io} e^{(\gamma_g D)/(53.34 T_z)}, \dots \dots \dots (1)$$

where

p_{ioD} = operating injection gas pressure at depth D ,
psia,
 p_{io} = operating injection gas pressure at surface,
psia,

Fig. 5.3—Simplified compressibility factor chart for natural gases.

e = Napierian logarithm base=2.718
 γ_g = gas specific gravity (air=1.0),
 dimensionless,
 D = true vertical depth, ft,
 T = average gas temperature, $^\circ\text{R}$, and
 \bar{z} = compressibility factor based on average
 pressure p and temperature T ,
 dimensionless.

The depth used in the equation is the true vertical depth of the gas column. Since the gas compressibility factor is a function of the average pressure and temperature, the solution to this equation is trial-and-error. A simplified compressibility chart³ is illustrated in Fig. 5.3. Generally, the average pressure and temperature are assumed to be the arithmetic mean of the wellhead and bottom-hole values. This assumption is reasonable because the increase in well temperature with depth tends to result in a constant gas density with depth. A straight-line traverse will approximate an actual static-injection-gas-pressure-at-depth traverse and is used for the design of most gas lift installations.

Example Problem 1.

Given:

1. Gas specific gravity, $\gamma_g=0.70$ (air=1.0).
2. Atmospheric pressure=14.7 psia.
3. Injection gas pressure at surface, $p_{io}=1,000$ psig=1,014.7 psia.

4. True vertical depth of gas column, $D=8,000$ ft.
5. Gas temperature at wellhead, $T_{wh}=80^\circ\text{F}$.
6. Gas temperature at depth, $T_{gD}=200^\circ\text{F}$ at 8,000 ft.

Calculate the static gas pressure at the depth of 8,000 ft.

$$1. \bar{T} = \frac{T_{wh} + T_{gD}}{2} = \frac{80 + 200}{2} = 140^\circ\text{F} + 460 = 600^\circ\text{R}.$$

$$2. \frac{\gamma_g D}{53.34 \bar{T}} = \frac{0.70(8,000)}{53.34(600)} = 0.175 \text{ (constant).}$$

3. First assumption: $p_{ioD} = p_{io} + 2.5 \times 10^{-5} (p_{io}) D$.
 $p_{ioD} = 1,000 + 2.5 \times 10^{-5} (1,000) 8,000 = 1,200$ psig at 8,000 ft.

Note: Gauge pressure can be used for approximate calculations.

$$\bar{p} = \frac{p_{io} + p_{ioD}}{2} = \frac{1,000 + 1,200}{2} = 1,100 \text{ psig,}$$

$\bar{z} = 0.865$ from Fig. 5.3 for 1,100 psig and 140°F , and

$$p_{ioD} = 1,014.7 e^{(0.175/0.865)} = 1,242.2 \text{ psia}$$

$$= 1,227.5 \text{ psig at 8,000 ft.}$$

Chart Basis:

1. Gas specific gravity (air = 1.0) = 0.65
2. Gas temperature at surface = 100°F
3. Gas temperature at depth = 70°F + 1.6°F/100 ft

Fig. 5.4—Static injection-gas pressure at depth curve.

4. Repeat Step 3 using the previously calculated p_{ioD} .

$$\bar{p} = \frac{1,000 + 1,227.5}{2} = 1,113.8 \text{ psig,}$$

$\bar{z} = 0.864$ from Fig. 5.3 for 1,114 psig and 140°F, and

$$p_{ioD} = 1,014.7e^{(0.175/0.864)} = 1,242.5 \text{ psia}$$

$$= 1,227.8 \text{ psig at 8,000 ft.}$$

Since the calculated p_{ioD} is approximately equal to the assumed p_{ioD} , let $p_{ioD} = 1,228$ psig at 8,000 ft.

The first assumption in Step 3, using a coefficient of 2.5×10^{-5} to estimate the initial gas pressure at depth, is based on a hydrocarbon gas that is primarily methane. After the initial assumption, the computations are continued as outlined in Step 4 by assuming the previously calculated p_{ioD} until the assumed and calculated values are approximately equal.

Injection-Gas-Pressure-at-Depth Curves. Since the injection gas pressure at depth is based on the injection gas gravity and the geothermal temperature at depth gradient, gas-pressure-at-depth curves should be based on the properties of the injection gas and the actual average temperature of the gas column in the well. There is no one set of gas-pressure-at-depth curves that are suited for gas lift installation design and analysis for all wells. Gas pressures at depth should be calculated on the basis of the actual field data, and should be plotted with an expanded scale for the anticipated range of kick-off and operating injection gas pressures and the well depths for the field. Static injection gas-pressure-at-depth curves are illustrated in Fig. 5.4.⁴ These curves are based on a geothermal gradient of 1.6°F/100 ft of depth and a gas gravity of 0.65. The basis for the injection gas-pressure-at-depth curves must represent actual field conditions. Indiscriminate use of just any gas-pressure-at-depth chart may result in an installation design that will not unload or in an erroneous analysis of the operation of an existing gas lift installation.

Factor for Approximating Gas Pressure at Depth. A convenient and accurate method for estimating static in-

jection gas pressure at depth is to develop a factor for gas pressure at depth on the basis of the available surface operating injection gas pressure, average well depth, the injection gas gravity, and the actual geothermal temperature gradient. The equation for calculating gas pressure at depth with the proper factor is

$$p_{ioD} = p_{io} + F_g \times 10^{-5} (p_{io})D, \quad \dots \quad (2)$$

where F_g is the gas-pressure-at-depth factor, psi/100 psi/1,000 ft.

A factor for gas pressure at depth should be calculated for a particular field on the basis of the actual operating injection gas pressure at the wellsite, the well depth, the injection gas gravity, and the geothermal temperature in the wells. Static gas pressure at true vertical depth can be calculated for the design operating surface injection gas pressure using Eq. 1. Then a gas-pressure-at-depth factor can be calculated with Eq. 3:

$$F_g = 10^5 \left[\frac{p_{ioD} - p_{io}}{p_{io}(D)} \right], \quad \dots \quad (3)$$

Eq. 3 will ensure reasonably accurate gas-pressure-at-depth calculations over the range of surface injection gas pressure associated with gas lift operations in most wells. The slope of the injection gas-pressure-at-depth curve based on Eq. 2 will increase with surface pressure, as it should.

Example Problem 2.

Given (data from previous Example Problem 1):

1. $p_{io} = 1,000$ psig at surface.
2. $p_{ioD} = 1,228$ psig at 8,000 ft.
3. $D = 8,000$ ft.

Calculate:

1. Static gas-pressure-at-depth factor from Eq. 3:

$$F_g = 10^5 \left[\frac{p_{ioD} - p_{io}}{p_{io}(D)} \right] = 10^5 \left[\frac{1,228 - 1,000}{1,000(8,000)} \right]$$

$$= 2.85 \text{ psi/100 psi/1,000 ft.}$$

2. Static gas pressure at 6,000 ft from Eq. 2:

$$p_{ioD} = p_{io} + F_g \times 10^{-5} (p_{io})D = 1,000 + 2.85 \times 10^{-5}$$

$$\times (1,000)6,000 = 1,171 \text{ psig at 6,000 ft.}$$

3. Static gas pressure at 6,000 ft from Eq. 2 for a surface pressure of 800 psig. Compare the calculated value with the chart reading for the proper gas-pressure-at-depth curve in Fig. 5.4. F_g from Fig. 5.4 is approximately 2.3 psi/100 psi/1,000 ft.

$$p_{ioD} = 800 + 2.3 \times 10^{-5} (800)6,000$$

$$= 910 \text{ psig at 6,000 ft.}$$

From Fig. 5.4, $p_{ioD} = 910$ psig at 6,000 ft.

Temperature Effect on the Confined Bellows-Charged Dome Pressure

There are more bellows-charged than spring-loaded gas lift valves in service. Most of these valves have nitrogen gas in the dome. Since it is impractical to set each gas lift valve at its operating well temperature, the test rack opening or closing pressure is set at a standard base temperature. Most manufacturers set their bellows-charged gas lift valves with the nitrogen gas charge in the dome at 60°F. Nitrogen was selected as the charge gas for these reasons: (1) the compressibility factors for nitrogen at various pressures and temperatures are known, (2) nitrogen is noncorrosive and safe to handle, and (3) nitrogen is readily available throughout the world and is inexpensive.

The temperature correction factors for nitrogen based on 60°F are given in Table 5.1. These factors are used to calculate the nitrogen-charged dome pressure at 60°F for a given valve operating temperature (T_{vD}) or unloading temperature (T_{uD}) at valve depth in a well.

$$p_b = F_T (p_{bvD}), \quad \dots \quad (4)$$

where

F_T = temperature correction factor for nitrogen from T_{vD} or T_{uD} to 60°F, dimensionless,

p_b = bellows-charged dome pressure at 60°F, psig, and

p_{bvD} = bellows-charged dome pressure at T_{vD} or T_{uD} , psig.

Although Table 5.1 is based on 60°F, a test rack opening or closing pressure can be calculated for another temperature base, or the temperature correction factors can be used to calculate the test rack opening pressure at a temperature other than 60°F when a valve has been set at 60°F.

$$p_{vos} = \frac{p_{vo}}{F_{Ts}}, \quad \dots \quad (5)$$

where

p_{vo} = test rack valve opening pressure at 60°F, psig,

p_{vos} = test rack valve opening pressure at T_{vs} , psig,

T_{vs} = test rack valve setting temperature (other than 60°F), °F, and

F_{Ts} = temperature correction factor for nitrogen at T_{vs} , dimensionless.

This is a particularly useful equation for testing or setting gas lift valves in a field where a cooler is unavailable. The most important consideration during the test rack setting procedure is that all bellows-charged gas lift valves for a given installation be set exactly at the same temperature. To ensure that the valves are at the same temperature, all gas lift valves for a given well can be stored in the same water bath. The valves remain submerged in the container of water with the exception of the short interval of time that a valve is in the tester. The tester-set tem-

$$*F_T = \frac{\text{Gas lift valve dome pressure at 60°F}}{\text{Gas lift valve dome pressure at well temperature}}$$

perature will be the temperature of the water, and the nitrogen-charged dome pressure can be calculated for any setting temperature as follows:

$$p_{bvs} = \frac{F_T(p_{bvD})}{F_{Ts}}, \dots\dots\dots (6)$$

where p_{bvs} is the bellows-charged dome pressure at T_{vs} , psig.

The reciprocal of the temperature correction factors for nitrogen in Table 5.1 is published by some companies. These factors will be greater rather than less than one. If the published factors are greater than one, simply divide instead of multiplying, or multiply rather than dividing when using Eqs. 5 and 6.

Example Problem 3.

Given:

1. Gas lift valve with ratio of valve port ball-seat contact area to effective bellows area $A_p/A_b=0.11$.
2. Valve temperature in the well, $T_{vD}=142^\circ\text{F}$.
3. Calculated bellows-charge pressure of valve at well temperature, $p_{bvD}=800$ psig at 142°F .

Refer to Table 5.2 and Eqs. 16 and 21 in the valve mechanics discussion for explanation of the port-to-bellows-area ratio terms and the equations used in the following calculations.

Calculate the test-rack valve opening pressure at 60°F .

1. $F_T=0.850$ for 142°F from Table 5.1
2. $p_b=F_T(p_{bvD})=0.850(800)=680$ psig at 60°F .

$$3. p_{vo} = \frac{p_b}{(1 - A_p/A_b)} = \frac{680}{(1 - 0.11)}$$

$$= 764 \text{ psig at } 60^\circ\text{F.}$$

Calculate the test-rack valve opening pressure at 90°F .

1. $F_{Ts} = 0.939$ for 90°F from Table 5.1.

$$2. p_{bvs} = \frac{F_T(p_{bD})}{F_{Ts}} = \frac{0.850(800)}{0.939}$$

$$= 724 \text{ psig at } 90^\circ\text{F.}$$

$$3. p_{vos} = \frac{p_{bvs}}{(1 - A_p/A_b)} = \frac{764}{(1 - 0.11)}$$

$$= 814 \text{ psig at } 90^\circ\text{F.}$$

or

$$p_{vos} = \frac{p_{vo}}{F_{Ts}} = \frac{764}{0.939} = 814 \text{ psig at } 90^\circ\text{F}$$

The previous equations using F_{Ts} are recommended when checking tester opening pressures of a string of gas lift valves at a temperature other than the base temperature of 60°F .

Volumetric Gas Throughput of a Choke or Gas Lift Valve Port

The injection gas throughput of a valve can affect the gas-lift installation design and operation. A high-rate installation will not unload if the choke or port size is too small. The volumetric gas rate required to uncover a lower valve by gas injection through the valve above is greater than the injection gas required to lift from the same lower valve for a given production rate.

The volumetric gas throughput of an orifice is calculated on the basis of an equation for flow through a converging nozzle. This equation is complex and lengthy for noncritical flow. For this reason, gas passage charts generally are used for estimating the volumetric gas rate through an orifice or valve port. One of the more widely used equations for gas throughput was published by Thornhill-Craver.⁵

Gas flow through most gas lift valves occurs in the noncritical flow range. The calculation of volumetric gas rate through a choke for noncritical flow is lengthy, as can be seen by the following basic gas flow equation.

$$q_{gsc} = \frac{155.5 C_d(A) p_1 \sqrt{2(g) \left(\frac{k}{k-1} \right) [(F_{du})^{2/k} - (F_{du})^{(k+1)/k}]} }{\sqrt{\gamma_g(T_1)}} \quad (7)$$

where

q_{gsc} = gas flow rate at standard conditions (14.7 psia and 60°F), Mscf/D,

C_d = discharge coefficient (determined experimentally), dimensionless,

A = area of opening, sq in.,

p_1 = upstream pressure, psia,

p_2 = downstream pressure, psia,

g = acceleration of gravity, ft/sec²,

k = ratio of specific heats, dimensionless,

T_1 = upstream temperature, $^\circ\text{R}$,

F_{cf} = critical flow pressure ratio = $\left(\frac{2}{k+1} \right)^{k/(k-1)}$
and

F_{du} = ratio of downstream pressure/upstream pressure, consistent units, $F_{du} = F_{cf}$ if $F_{du} < F_{cf}$ and $F_{du} = p_2/p_1 \geq F_{cf}$.

It is apparent from Eq. 7 that injection gas throughput charts are desirable for installation design and analysis purposes. The gas compressibility factor is not included in Eq. 7; therefore, most published gas passage charts do not include a gas-compressibility-factor correction. Since the compressibility factor would enter the equation as a square root term in the denominator, the chart values will be lower than actual values for most injection gas gravities and pressures.

One type of choke capacity chart is illustrated in Figs. 5.5 and 5.6. The advantages of this type of display are the number of orifice sizes on a single chart for a full range of upstream and downstream pressures, and an orifice size can be determined for a given gas throughput and the given upstream and downstream pressures. The gas throughput capacity of the different orifice sizes is based on 14.65 psia and 60°F for a gas gravity of 0.65 and an orifice discharge coefficient of 0.865. Since gas flow through a gas lift valve occurs in a gas lift installation at the well temperature at valve depth, a correction for temperature improves the prediction for the volumetric gas rate. If the actual gravity differs from 0.65, a second correction should be applied. An approximate correction for gas passage can be calculated using the following equations.

$$C_{gT} = 0.0544 \sqrt{\gamma_g(T_{gD})} \quad (8)$$

and

$$q_{ga} = \frac{q_{gc}}{C_{gT}}, \quad (9)$$

where

C_{gT} = approximate correction factor for gas gravity and temperature, dimensionless,

T_{gD} = gas temperature at valve depth, $^\circ\text{R}$,

q_{ga} = actual volumetric gas rate, Mscf/D, and

q_{gc} = chart volumetric gas rate, Mscf/D.

Although most gas lift manuals will include gas capacity charts for every conceivable gas-lift valve port and choke size, numerous charts are unnecessary. The gas capacity for any choke size can be calculated from a known gas capacity for a given choke size because the volumetric gas throughput rate is directly proportional to the area of the orifice.

$$q_{g2} = q_{g1} \left(\frac{d_2}{d_1} \right)^2, \quad (10)$$

Fig. 5.5—Gas passage chart for $\frac{1}{64}$ - through $\frac{1}{64}$ -in. orifices.

Fig. 5.6—Gas passage chart for $\frac{1}{64}$ -in. through $\frac{40}{64}$ -in. orifices.

where

q_{g1} = known volumetric gas rate, Mscf/D,

d_1 = orifice ID for known volumetric gas rate, in.,

q_{g2} = unknown volumetric gas rate, Mscf/D, and

d_2 = orifice ID for unknown volumetric gas rate, in.

Orifice sizes can be in 64ths of an inch. The denominator of the fraction for both terms must remain consistent.

Example Problem 4.

Given:

1. Injection gas gravity, $\gamma_g = 0.7$ (air = 1.0).
2. Orifice-check valve port size = $\frac{1}{4}$ in.
3. Operating injection gas pressure at valve depth (upstream pressure), $p_{iOD} = 1,100$ psig.
4. Flowing production pressure at valve depth (downstream pressure), $p_{pFD} = 900$ psig.
5. Injection gas temperature at valve depth, $T_{gD} = 140^\circ\text{F}$.

Determine the actual volumetric gas throughput of the orifice-check valve.

$$C_{gT} = 0.0544\sqrt{0.7(140+460)} = 1.115.$$

$$q_{gc} = 1,210 \text{ Mscf/D from Fig. 5.5 (chart value).}$$

$$q_{ga} = 1,210/1.115 = 1,085 \text{ Mscf/D (actual value).}$$

Calculate volumetric gas throughput of a $\frac{1}{2}$ -in. orifice ($\frac{32}{64}$ -in.) on the basis of the capacity of a $\frac{1}{4}$ -in. orifice and compare the calculated and chart values.

$$q_{gc} = 1,210 \left(\frac{0.5}{0.25} \right)^2 = 4,840 \text{ Mscf/D}$$

$$(1,210 \text{ Mscf/D for } \frac{1}{4}\text{-in. orifice}),$$

or

$$\begin{aligned} q_{gc} &= 1,210 \left(\frac{32}{16} \right)^2 \\ &= 4,840 \text{ Mscf/D, and} \end{aligned}$$

$$q_{gc} = 4,850 \text{ Mscf/D from Fig. 5.6 for } \frac{1}{2}\text{-in. orifice.}$$

Gas Volume Stored Within a Conduit

Typical applications for gas volume calculations are (1) the volume of injection gas required to fill the production conduit and to displace a liquid slug to the surface for intermittent gas lift operations; (2) the volume of injection gas available, or removed, from a casing annulus on the basis of a change in the casing pressure during an intermittent injection gas cycle—particularly important for design calculations using choke control of the injection gas; and (3) design calculations for the low- and high-pressure systems in a closed, rotative gas lift system when a minimum capacity is required for storage or retention of the injection gas within the system.

The gas capacity and volume calculations are based on an equation of state for real gases.

$$pV = znRT, \dots\dots\dots (11)$$

where

- p = pressure, psia,
- V = volume or capacity, cu ft,
- z = compressibility factor based on p and T , dimensionless,
- n = number of pound-moles, lbm-mol,
- R = gas constant = 10.73 psia-cu ft/lbm-mol-°R, and
- T = temperature, °R.

Most gas volume and capacity problems can be solved using Eq. 11 and Avogadro's principle, which states that 1 lbm-mol of any gas occupies approximately 379 scf at 14.7 psia and 60°F.

The volume of gas required to fill a conduit can be calculated with the following equation:

$$V_g = V_c \left(\frac{p T_{sc}}{z p_{sc} T} \right), \dots\dots\dots (12)$$

where

- V_g = gas volume at standard conditions, scf,
- V_c = capacity of conduit, cu ft,
- p = average gas pressure, psia,
- p_{sc} = standard pressure base, psia,
- T = average gas temperature, °R, and
- T_{sc} = standard temperature base, °R.

Also, the volume of gas can be calculated by solving for the number of pound-moles in Eq. 11 and by converting the pound-moles to standard cubic feet using Avogadro's principle. Average values for pressure and temperature based on surface and bottomhole values and the corresponding z -value must be used in the equation for inclined conduits.

A gas volume equation for pressure difference can be written as

$$V_g = \frac{V_c T_{sc}}{T p_{sc}} \left(\frac{p_1}{z_1} - \frac{p_2}{z_2} \right), \dots\dots\dots (13)$$

where Subscripts 1 and 2 refer to the high and the low average pressure and the corresponding compressibility factor, respectively, and the average temperature does not change. If the conduit is horizontal, average pressures and

temperature are the surface values in Eqs. 12 and 13. The average temperature of a gas column in the casing is assumed to be the same at the instant a gas lift valve opens or closes. Eq. 13 may be simplified by using one compressibility factor for an average of the average pressures. This assumption is particularly applicable for very little change in pressure.

Approximate estimations and questionable field data do not warrant detailed calculations. The approximate volume of gas required for a given change in pressure within a conduit can be calculated using the following equation:

$$V_{gx} = \left(\frac{\bar{p}_1 - \bar{p}_2}{p_{sc}} \right) V_c, \dots\dots\dots (14)$$

where V_{gx} is the approximate gas volume, scf.

The ratio of the standard to the average temperature, which is less than one, tends to offset the reciprocal of the compressibility factor that is greater than one. This compensation decreases the error made when not including these variables in the approximate equation.

Example Problem 5.

Given:

1. Capacity of casing annulus = 0.10 cu ft/ft (2 7/8-in.-OD tubing × 5 1/2-in.-OD casing).
2. Depth of operating valve, D_{ov} = 6,000 ft.
3. Surface closing pressure of operating valve, p_{vc} = 600 psig.
4. Surface opening pressure of operating valve, p_o = 660 psig.
5. Average temperature of gas column, T = 120°F = 580°R.
6. Standard conditions: 14.7 psia and 60°F (520°R).
7. Gas gravity γ_g = 0.65, (air = 1.0).
8. Gas-pressure-at-depth factor, F_g = 2.4 psi/100 psi/1,000 ft.
9. Atmospheric pressure = 14.7 psia.

Calculate the volume of gas stored in the casing annulus between surface pressures of 660 and 600 psig by using Eq. 13.

$$\begin{aligned} V_c &= 6,000(0.10) = 600 \text{ cu ft,} \\ \bar{p}_1 &= 660 + 2.4 \times 10^{-5} (660) 3,000 \\ &= 707.5 \text{ psig} + 14.7 = 722.2 \text{ psia,} \\ \bar{z}_1 &= 0.911 \text{ from Fig. 5.3 for } T \\ &= 120^\circ\text{F, } \gamma_g = 0.65, \text{ and } p = 707.5 \text{ psig,} \\ \bar{p}_2 &= 600 + 2.4 \times 10^{-5} (600) 3,000 \\ &= 643.2 \text{ psig} + 14.7 = 657.9 \text{ psia, and} \\ \bar{z}_2 &= 0.918 \text{ from Fig. 5.3 for } T \\ &= 120^\circ\text{F, } \gamma_g = 0.65, \text{ and } p = 643.2 \text{ psig.} \end{aligned}$$

$$\begin{aligned} V_g &= \frac{V_c T_{sc}}{T p_{sc}} \left(\frac{p_1}{z_1} - \frac{p_2}{z_2} \right) \\ &= \frac{600(520)}{580(14.7)} \left(\frac{722.2}{0.911} - \frac{657.9}{0.918} \right) \\ &= 2,784 \text{ scf at 14.7 psia and } 60^\circ\text{F.} \end{aligned}$$

Fig. 5.7—Original King unbalanced, single-element, bellows-charged, gas lift valve on a conventional tubing mandrel.

Calculate the approximate volume of gas stored in the casing annulus between average pressures of 722.2 and 657.9 psia by using Eq. 14:

$$V_{gv} = \left(\frac{p_1 - p_2}{p_{sc}} \right) V_c = \left(\frac{722.2 - 657.9}{14.7} \right) 600$$

$$= 2,624 \text{ scf at } 14.7 \text{ psia.}$$

Calculate the percentage difference between the detailed and approximate solutions:

$$\% \text{ difference} = \left(\frac{2,784 - 2,624}{2,784} \right) 100 = 5.8\%.$$

Gas Lift Valve Mechanics

Introduction

The advent of the single-element, unbalanced, bellows-charged gas lift valve (as illustrated on Sheet 1 of the King patent in Fig. 5.7) revolutionized gas lift application and installation design methods. Before the bellows-charged gas lift valve, there were differential valves and numerous types of unique devices used for gas lifting wells. These devices, or valves, were operated by rotating or vertically moving the tubing and by means of a sinker bar on a wireline.

Single-element implies that the gas lift valve consists of a bellows and dome assembly, a stem with a tip that generally is a carbide ball, and a metal seat housed in a valve body that is attached to a mandrel in the tubing string, as illustrated in Fig. 5.7. The original patent for this type of gas lift valve was filed in 1940 by W.R. King; currently, the unbalanced single-element bellows valve

remains the most widely used type of gas lift valve for gas lifting wells. The original King valve had most of the protective design features of the present gas lift valves. The bellows was protected from high hydrostatic fluid pressure by a gasket that sealed the bellows chamber from well fluids after full stem travel. A small orifice was drilled in a bellows guide tube. The orifice was designed to be an anti-chatter mechanism and the bellows guide provided bellows support.

Purposes of Gas Lift Valves

The gas lift valve is the heart of most gas lift installations and the predictable performance of this valve is essential for successful gas lift design and operations. The gas lift valve performs several functions in a typical gas lift installation.

The primary function of a string of gas lift valves is to unload a well with the available injection gas pressure to a maximum depth of lift that uses fully the energy of expansion on the basis of the injection gas pressure. Gas lift valves provide the flexibility to allow for a changing depth in the point of gas injection to compensate for a varying BHFP, water cut, daily production rate allowable, and well deliverability. The operating gas lift valve in an intermittent gas lift installation prevents an excessive injection gas pressure bleed-down following an injection gas cycle. The gas lift valve provides the means to control the injection gas volume per cycle.

Another important function of gas lift valves is the ability to maintain an excessive BHFP drawdown in a temporarily damaged well until the well cleans up. This operation is accomplished by lifting from near total depth (TD) until reservoir deliverability returns to normal. The final operating point of gas injection for the stabilized production rate in certain deep wells with a high reservoir pressure can be nearer the surface than the point of gas injection to establish initial BHP drawdown during unloading if the load fluid is salt water. Again, gas lift valves must be installed below the depth of the operating gas lift valve to clean up the well.

When the injection gas-line pressure significantly exceeds the BHFP at the maximum valve depth, freezing can occur across the surface controls for the injection gas if the operating valve is a large orifice. The orifice valve can be replaced by an injection-pressure-operated gas lift valve to transfer the pressure drop to the gas lift valve at well temperature where hydrates will not form.

The reverse check in a gas lift valve is important for valves below the working fluid level. The check prevents backflow from the tubing to the casing, which is particularly important if the well produces sand and has a packer.

Unbalanced, Single-Element Valves

The unbalanced, single-element gas lift valve is an unbalanced pressure regulator. The analogy between these two devices is apparent in Fig. 5.8. Unbalanced implies that the pressure applied over the port area exerts an opening force, whereas this same pressure has no effect on the opening pressure of a balanced backpressure or pressure-reducing regulator. The closing force for a gas lift valve can be a gas pressure charge in the bellows exerted over the effective bellows area or a spring force, or a combination of both. The closing force for the regulator or gas lift valve can be adjusted to maintain a desired

Fig. 5.8—Analogy of unbalanced, single-element, bellows-charged, gas lift valves to unbalanced pressure regulators. (a) Injection-pressure-operated gas lift valve responds to injection-gas pressure. (b) Production-pressure-(fluid)-operated gas lift valve responds to flowing production pressure.

backpressure for injection pressure operation or a design downstream pressure for production pressure operation. The regulator or valve will remain closed until this set closing force is exceeded.

Generally, the major initial opening force for a gas lift valve is the pressure exerted over the effective bellows area less the port area, and the lesser opening force is the pressure acting over the port area. In like manner, the major opening pressure is applied over an area equal to the diaphragm area less the port area for a regulator. The effect of the unbalanced opening force is far less significant for most unbalanced backpressure and pressure-reducing regulators than for gas lift valves because the ratio of the port area to the total effective bellows area of a gas lift valve is much greater than the ratio of the port area to the total diaphragm area for most regulators. The operating principle remains identical for the gas lift valve and regulator, but the pressure applied over the port area has greater effect on the initial opening pressure of most gas lift valves.

Pilot and Differential-Opening, Injection-Pressure-Operated Valves

There are numerous special-application gas lift valves available. The operation of many of these unique valves can be analyzed using the force balance equations for the simple single-element, unbalanced, gas lift valve. The many different types of gas lift valves and the variation in calculations will not be discussed in this chapter because of their limited application. Two special-purpose valves of particular importance are the pilot and the differential-opening, injection-pressure-operated gas lift valves. The construction of the differential-opening valve may vary between manufacturers but the operating principle remains the same.

The pilot-operated gas lift valve in Fig. 5.9a has operating characteristics that are ideally suited for chamber

Fig. 5.9—Pilot-operated and differential-pressure opening injection pressure-operated gas lift valves. (a) Pilot-operated gas lift valve. (b) Pressure differential opening, constant closing gas lift valve.

installations and deep intermittent gas lift operations with low injection gas pressure and large casing. The pilot valve offers a very large main port with controlled spread and a predictable constant closing pressure. This type of valve will function properly on time cycle or choke control of the injection gas. The pilot section operates in the same manner as a single-element gas lift valve, with a small choke located downstream of the valve seat. The production pressure at valve depth is exerted over the ball-seat contact area of the pilot section as an initial opening force. When the pilot section begins to open, an increase in pressure occurs between the pilot valve seat and the

750	550	150

*Based on constant closing pressure = 600 psig.

through the large main valve port. As the injection gas pressure in the casing decreases from gas passage through the large port, the pilot section begins to close. The pressure downstream of the pilot port remains equal to the injection gas pressure until the pilot port area open to flow is less than the bleed-hole area in the main valve piston. When the pressure equalizes across the piston, the spring returns the main valve to its seat. The closing pressure of a pilot valve is predictable and near the theoretical closing pressure of a single-element, unbalanced gas lift valve because the pressure upstream and downstream of the pilot port are approximately equal at the instant the pilot section closes. The spread of a pilot valve can be controlled by selecting the proper pilot port size without altering the high injection-gas throughput capacity of the large main valve port.

The differential-opening, injection-pressure-operated gas lift valve in Fig. 5.9b has operating characteristics that differ from a pilot valve. The differential-opening pressure valve has the unique feature of requiring a constant difference between the injection gas and the production pressure to open the valve when the injection gas pressure exceeds its constant closing pressure. This operating principle is illustrated for a valve with a constant closing pressure of 600 psig and a differential spring setting of 200 psi in Table 5.3.

For example, the valve will snap open when the production pressure exceeds 500 psig with an injection gas pressure of 700 psig and will close after the injection gas pressure decreases to 600 psig. The resulting spread is 100 psi for these operating conditions. The differential-opening, injection-pressure-operated valve is designed for choke control of the injection gas into the well.

The pilot valve does not operate with a constant pressure differential between the injection gas and production pressures at valve depth. The injection-gas opening pressure and spread decrease as the production pressure increases at the depth of a pilot valve. The differential-opening pressure valve cannot be opened by an increase in only the injection gas pressure, whereas the pilot valve can be opened by increasing the injection gas pressure. The similarity in these two valves is that both types have a predictable constant closing pressure and can have large ports.

Valve Specifications and Stem Travel

Gas lift valve specifications are published by each manufacturer for their valves. Some manufacturers assume a sharp-edged seat for the ball-seat contact and others arbitrarily add a small increase to the port ID to account for a slight bevel for the ball-seat contact. Since most

manufacturers use the same source for their supply of bellows and the bellows areas are relatively standard, the specifications in Table 5.2 are representative of many actual single-element, unbalanced, gas lift valves. The theoretical full-open stem travel is not included in the valve specifications published by most manufacturers.

The stem travel required to open an unbalanced, single-element, gas lift valve fully increases with the larger port sizes, as illustrated in Fig. 5.10. The curves were calculated for gas lift valves with a sharp-edged seat and a ball on the stem that is $\frac{1}{16}$ in. larger in diameter than the inside diameter of the port. The equivalent port area before a valve is full-open is based on the lateral area of the frustum of a right circular cone. The major area of the frustum is the port area, which remains constant, and the minor area decreases with an increase in stem travel as the ball moves away from its seat.

There is an important gas-lift-valve performance consideration that is not noted in the published literature and will not be discussed completely in this section. The problem needs to be recognized by operators with high-rate wells being gas lifted through large tubing or through the casing annulus. An injection gas throughput rate based on a full-open port size should not be assumed for the larger port sizes in most single-element, unbalanced, gas lift valves. For nearly all these gas lift valves with a large port area relative to the bellows area, the maximum equivalent port area open to flow of the injection gas will be less than an area based on the reported port size for an actual range in the injection gas pressure during typical gas lift operations. The necessary increase in the injection gas pressure to open fully a 1-in.-OD gas lift valve with a large port can approach 200 psi—assuming this required stem travel is possible. Maximum stem travel may be limited by a mechanical stop or bellows stacking before a full-open port area is achieved.

Gas-Lift-Valve Port Configurations

The port geometry and the maximum stem travel will affect the volumetric gas throughput of a gas lift valve. Most gas lift valves have a carbide ball silver-soldered to the stem. The valve seat can have a sharp-edged port or a taper. The chamfer may be very slight for breaking the seat line or may be of sufficient depth to assure that the ball remains in the taper for full stem travel. A sharp-edged and a tapered seat with a 45° chamfer are illustrated in Fig. 5.11. Most of the example calculations in this chapter are based on the sharp-edged seat since the majority of gas lift valves in service have a sharp-edged seat or a very shallow chamfer for breaking the seat line. The calculations are basically the same for a sharp-edged seat and a seat with a shallow taper. The calculations for an equivalent area open to the injection gas flow differ for a seat with a deep chamfer (Fig. 5.11b).

There has been no standard angle adopted for a taper of a gas-lift-valve seat. Certain manufacturers use the same tapered seat for different stem-ball sizes. The area of the port used in the port-to-bellows area ratio must be redefined for tapered seat when the ball-seat contact area is larger than the bore area through the seat, as shown in Fig. 5.11b. The port area for the ratio A_p/A_b is based on the ball-seat contact area and not on the bore area through the seat, which can be the same for more than one ball size. The specifications for the gas lift valve are

Fig. 5.11—Typical gas lift valve port configurations. (a) Sharp-edged seats have an effective A_p equal to the bore area through the seat. The A_p may be based on a diameter slightly greater than the seat bore ID if the port has a minor taper to eliminate a sharp-edged ball-seat contact. (b) Tapered seat with a 45° chamfer measured from the horizontal (90° included angle). The effective A_p in the A_p/A_b ratio is the ball-seat contact area and not the bore area through the seat.

controlled by changing the ball size and the angle of the taper, because the ball-seat contact area depends on the ball size and the angle of the chamfer for valves with a port similar to Fig. 5.11b. The selection of an angle for the taper, ball size, and the bore area through the seat can result in a ball-seat contact at the base of the taper. For this geometry, the bore area of the port would be used in the A_p/A_b term. The maximum stem travel in many gas lift valves with a deep taper is limited to prevent the ball from pulling out of the taper.

The equivalent port area open to flow for a sharp-edged seat in the throttling mode is based on the frustum of a right circular cone. A throttling mode implies that the generated area open to flow for the injection gas is less than the bore area through the valve seat. Typical curves of equivalent port area vs. stem travel for different sharp-edged port sizes are illustrated in Fig. 5.10. The calculations for an equivalent port area based on stem travel are more complex for valves with deep tapered seats. Certain types of gas lift valves with a deep tapered seat are designed to operate only in the throttling mode for continuous flow application.

Example Problem 6.

Given:

1. Seat angle = 45° (deep chamfer with ball-seat contact on taper).
2. Bore diameter through seat = 0.25 in.
3. Effective bellows area = 0.31 sq in.

Calculate the ball-seat contact diameter and area and the effective A_p/A_b ratio for a $\frac{3}{8}$ -in.-OD ball.

$$\text{Ball-seat contact ID} = (0.375) \sin 45^\circ = 0.265 \text{ in.}$$

$$\text{Ball-seat contact area} = \pi/4(0.265)^2 = 0.055 \text{ sq in.}$$

$$\text{Effective } A_p/A_b = 0.055/0.31 = 0.178.$$

Calculate the ball-seat contact diameter and area and the effective A_p/A_b ratio for a $\frac{1}{2}$ -in.-OD ball.

$$\text{Ball-seat contact ID} = (0.50) \sin 45^\circ = 0.354 \text{ in.}$$

$$\text{Ball-seat contact area} = \pi/4(0.354)^2 = 0.098 \text{ sq in.}$$

$$\text{Effective } A_p/A_b = 0.098/0.31 = 0.316.$$

Fig. 5.12—Schematic of crossover seats with and without a choke upstream of the valve port. (a) Choke upstream of port to control injection-gas volume and to ensure downstream pressure being applied to bellows area after valve opens. (b) Crossover bypass area should significantly exceed port area without choke upstream of port.

Crossover Seat

Several types of gas lift valves have a crossover seat for a particular application. The crossover seat is designed to direct the downstream pressure into the valve body, where this pressure is exerted over the area of the bellows less the port area. The upstream pressure is applied to the port area. The crossover seat in Fig. 5.12 is a schematic illustrating the principle of a crossover. An actual crossover seat will have a group of bypass openings around the main port, and the summation of these bypass areas must exceed the port area.

An example of the need for a crossover seat would be a production-pressure-operated gas lift valve in an injection-pressure-operated gas lift valve mandrel. Another application would be a casing (annulus) flow gas lift valve in a tubing flow mandrel. In both examples the gas lift valve is modified rather than the gas lift valve mandrel. For example, wireline-retrievable gas lift valve mandrels with pockets designed for injection-pressure-operated gas lift valves and tubing flow have been installed in a well. The operator desires production pressure operation. The solution is production-pressure-operated gas lift valves with a crossover seat.

Gas lift valves with a crossover seat are not recommended if the proper mandrels can be installed to utilize gas lift valves without this type of seat. The maximum port size is limited for valves with a crossover seat. This limitation can be very serious in wells requiring a high injection gas rate. Another problem with a crossover seat is the possible partial plugging of the crossover bypass area. The physical bypass area should be at least 50% greater than the valve port area because the bypass openings usually are smaller and more likely to plug than a valve port, which can be opened and closed. A production-pressure-operated gas lift valve will not close at the design closing pressure if the crossover area becomes less than the port area, because the injection gas rather than the flowing production pressure is exerted over the bellows area.

Most production-pressure-operated gas lift valves with crossover seats can be choked upstream of the ball-seat contact area. The same port size may be used in all valves,

and the volumetric injection-gas throughput for the upper unloading gas lift valves is limited by a choke size that is smaller than the port area. The small inlet chokes tend to reduce the valve closing pressure problem associated with production pressure operation.

Bellows Protection

All reputable manufacturers of gas lift valves have provided bellows protection in the design of their valves. A bellows should be protected from a high pressure differential between the bellows-charge and the well pressures and from the possibility of a resonance condition that can result in a high-frequency valve stem chatter. The bellows-charge pressure will be atmospheric pressure for a typical spring-loaded valve. The highest pressure differential will occur in most installations during initial unloading operations when the lower gas lift valves are subjected to exceedingly high hydrostatic-load fluid pressures in deep wells.

Gas lift valve bellows are protected from high hydrostatic pressures by four methods: (1) high pressure differential (hydraulically preformed), (2) support rings within the convolutions, (3) confined liquid seal with full stem travel, and (4) isolation of bellows from outside pressure with full stem travel. The primary purpose of these methods for protecting the bellows is to prevent a permanent change in the radii of the convolutions, which in turn can affect the operating pressure of a gas lift valve.

The possibility of a chatter condition is not predictable or fully understood. The evidence of valve stem chatter will be a bellows failure and a dished-out seat if the valve seat is not manufactured from an extremely hard material. Most gas lift valves will have some form of dampening mechanism, and the majority of these devices will operate hydraulically. The bellows will be partially filled with a liquid, and restricted liquid flow rate or fluid shear prevent instantaneous undamped stem movement.

Bellows-Assembly Load Rate

Bellows-assembly load rate is defined as the psi increase exerted over the bellows area per unit travel of the valve stem or unit travel per psi increase. It may be reported in either manner. The controlled pressure is applied over the entire effective bellows area, and the valve stem travel is measured by means of a depth micrometer. The bellows-assembly load rate is the slope of the pressure vs. stem travel curve and the choice of units depends on the manner in which these data are displayed. The increase in nitrogen-charged dome pressure with stem travel is generally negligible as compared with the load rate of a bellows in most bellows-charged gas lift valves. The load rate of a bellows, which is analogous to the load rate of a helical spring, is far greater than the effect of the increase in dome pressure resulting from the decrease in dome volume with the stem travel required to open a typical gas lift valve.

The measured bellows-assembly load rate is not identical for all gas lift valves with the same size of bellows. The typical three-ply monel bellows that is used in many 1½-in.-OD gas lift valves has a reported effective bellows area of 0.77 sq in. The bellows-assembly load rate for a valve with a nitrogen-charged dome will range from 400 to 500 psi/in. in the linear portion of the curve for a valve with a test-rack opening pressure between 600 and

1,000 psig. The three-ply monel bellows in the 1-in.-OD valve has a reported effective area of 0.31 sq in. and a bellows-assembly load-rate range of 1,000 to 1,200 psi/in. for a valve with a nitrogen-charged dome and a test-rack opening pressure between 600 and 1,000 psig. The bellows-assembly load rate for a spring-loaded 1-in.-OD valve can range from near 2,000 to more than 3,500 psi/in. depending on the wire size and number of free coils in the spring.

The purpose in noting the magnitude of the bellows-assembly load rate for typical gas lift valves is to emphasize the fact that a single-element, unbalanced, gas lift valve will not "snap" open. An increase in injection gas pressure, or in flowing production pressure, or a combination of an increase in both pressures, is necessary to stroke the valve stem. The larger gas lift valves should be selected for installations requiring high injection-gas rates since the smaller valves do not have the same gas throughput performance of the larger valve with the same port size. Valves with the smaller bellows assembly are not recommended for low-pressure injection gas systems that may be used to gas lift shallow wells. The low closing force and bellows stiffness can result in leaking valve seats because of poor stem seating characteristics at low injection-gas operating pressures.

Static-Force Balance Equations for Unbalanced, Single-Element, Bellows-Charged Valves

Most gas lift equipment manufacturers use a valve setting temperature based on 60°F for nitrogen-charged gas lift valves. The valve is submerged in a 60°F water bath to assure a constant nitrogen temperature in the dome of each valve during the test-rack setting procedure, whether the valve is set at test-rack opening or closing pressure. The initial tester-set opening pressure is measured with the tester pressure applied over the bellows area less the stem-seat contact area while atmospheric pressure (0 psig) is exerted over the stem-seat contact area. The valve actually is closed and begins to open from an opening force that is slightly greater than the closing force, thus allowing an extremely low tester gas leakage rate through the valve seat. Although most gas lift valves are set with an initial opening pressure, certain types of valves with very high production pressure factors and other valves with unique construction use test-rack closing pressures.

The test-rack closing pressure is obtained by bleeding the tester gas from the downstream side of the gas lift valve. This theoretical closing pressure is obtained only when the downstream and upstream tester pressures are equal at the instant the gas lift valve closes. An accurate closing pressure is more difficult to observe than an initial opening pressure and can be affected by the rate of decrease in the tester pressure during bleed-off of the tester gas. An encapsulating tester with gas capacity rather than a ring-type tester is recommended so that small leaks in the tester piping will not prevent observation of the true closing pressure. The pressure should be bled off of the downstream side of the valve through a small orifice.

The equations for initial opening pressure in a tester and well and a tester closing pressure are based on static-force balance equations and would apply to spring-loaded gas lift valves. The spring pressure effect would replace the bellows-charged pressure of the valve for the closing force. Several manufacturers with spring-loaded gas lift

Fig. 5.13—Standard ring-type gas lift valve tester. Insert sleeves are available that fit in this tester for testing smaller-OD gas lift valves.

valves report a test-rack closing pressure. The spring is adjusted until the force exerted by the spring is equal to the desired test-rack closing pressure. Since there is no nitrogen gas charge pressure in the dome, there is no need to set a spring-loaded gas lift valve at a base tester temperature. Spring-loaded valves are considered temperature insensitive. If the total closing force for a gas lift valve is a combination of a bellows-charged pressure and a spring-load, the spring-load effect must be subtracted from the total closing force to obtain the bellows-charged pressure portion of this closing force. The temperature correction factor is applied to the nitrogen-charged dome pressure before calculating the test-rack-set opening pressure of the valve. A typical ring-type tester and piping manifold are illustrated in Fig. 5.13.

The following equations for the initial gas-lift-valve opening pressures in a tester and in a well are derived for an injection-pressure-operated gas lift valve since most gas lift installations use this type of valve. The injection gas pressure and flowing production pressures are interchanged for production-pressure-(fluid)-operated gas lift valves. The flowing production pressure becomes the major opening force by being applied over the effective bellows less port area as an initial opening force.

Fig. 5.14—Illustration of nomenclature used in static-force balance equations for gas lift valves in tester and well. (a) Test-rack opening pressure (p_{vo}) obtained by flowing supply gas at a low rate into a ring-type tester with atmospheric pressure applied to the port area. (b) Test-rack closing pressure (p_{vct}) obtained by opening the gas lift valve, closing the supply valve, and slowly bleeding off the encapsulating tester pressure downstream of the port. (c) Initial valve opening pressure in well (p_{oD}) based on the flowing production pressure (p_{pFD}) at valve depth.

1. Initial opening pressure in a tester (Fig. 5.14a):
Closing force=opening force,

$$p_b(A_b) = p_{vo}(A_b - A_p).$$

Dividing by A_b ,

$$p_b = p_{vo}(1 - A_p/A_b). \quad (15)$$

Solving for test-rack initial valve opening pressure (p_{vo}) at the test-rack-setting bellows-charged pressure at 60°F,

$$p_{vo} = \frac{p_b}{(1 - A_p/A_b)}, \quad (16)$$

where

- A_b = effective bellows area, sq in.,
- A_p = valve port ball-seat contact area, sq in.,
- and
- p_b = bellows-charged dome pressure at 60°F, psig.

2. Closing pressure in a tester (Fig. 5.14b):
Closing force=opening forces,

$$p_b(A_b) = p_{vct}(A_b - A_p) + p_{vct}(A_p),$$

$$p_b(A_b) = p_{vct}(A_b).$$

Dividing by A_b ,

$$p_b = p_{vct} \text{ (when } p_o = p_{vct} = p_{pft}), \quad (17)$$

where

- p_o = initial valve opening pressure, psig,
- p_{vct} = test-rack valve closing pressure at 60°F, if, and only if, the upstream and downstream pressures across the valve port are equal at the instant the valve closes, psig, and

p_{pft} = test-rack downstream flowing production pressure, psig.

3. Initial opening pressure in a well (Fig. 5.14c):
Closing force=opening forces,

$$p_{bvD}(A_b) = p_{oD}(A_b - A_p) + p_{pFD}(A_p).$$

Dividing by A_b ,

$$p_{bvD} = p_{oD}(1 - A_p/A_b) + p_{pFD}(A_p/A_b), \quad (18)$$

where

- p_{bvD} = the bellows-charged dome pressure at well temperature, psig,
- p_{pFD} = the flowing production pressure at valve depth, psig, and
- p_{oD} = the initial valve opening pressure at valve depth, psig.

Solving for the initial injection-gas opening pressure for injection-pressure-operated gas lift valves,

$$p_{oD} = \frac{p_{bvD}}{(1 - A_p/A_b)} - p_{pFD} \left(\frac{A_p/A_b}{1 - A_p/A_b} \right), \quad (19a)$$

$$p_{oD} = p_{voD} - p_{pFD}(F_p), \quad (19b)$$

or

$$p_{oD} = \frac{p_{vo}}{F_T} - p_{pe}, \quad (19c)$$

where

- p_{voD} = initial valve opening pressure at T_{vD} when p_{pFD} equals zero, psig,
- F_p = production-pressure factor, dimensionless, and
- p_{pe} = production-pressure effect, psi.

Additional equations used in initial valve opening pressure calculations are the following:

$$F_p = \frac{A_p/A_b}{(1 - A_p/A_b)} = \frac{A_p}{A_b - A_p}, \dots (20)$$

$$p_{voD} = \frac{p_{bvD}}{(1 - A_p/A_b)}, \dots (21a)$$

OR

$$p_{voD} = \frac{p_{vo}}{F_T}, \dots (21b)$$

$$p_{pc} = F_p(p_{pfd}), \dots (22)$$

Initial Opening and Closing Pressures of a Single-Element, Unbalanced Valve

An understanding of the relationship between the initial opening and closing pressures of a single-element, unbalanced, gas lift valve is important for calculating gas lift installation designs and analyzing gas lift operations. A single-element, unbalanced, gas lift valve does not have a constant closing pressure as noted in many publications, and the valve does not "snap" full open at the initial injection-gas opening pressure. This type of gas lift valve is a simple, unbalanced, backpressure regulator. The gas lift valve opens and closes at the same injection pressure if the flowing production pressure remains constant. In like manner, an unbalanced backpressure regulator opens and closes at the same upstream pressure if the downstream pressure remains constant.

Fig. 5.15 shows a plot of the initial injection-gas opening pressure vs. the flowing production pressure for a $\frac{3}{8}$ -in.-ID sharp-edged port in a 1-in.-OD gas lift valve with an effective bellows area of 0.31 sq in. This bellows size is used by most manufacturers in the 1-in.-OD gas lift valve. A $\frac{3}{8}$ -in.-ID port is the largest port size available from several manufacturers for the 1-in.-OD, single-element, unbalanced, gas lift valve. The larger port size was selected because of the higher production pressure factor.

The closing force for a single-element, unbalanced, gas lift valve is assumed to remain constant for this analysis. The slight increase in a bellows-charged dome pressure with stem travel (or the increase in the spring force for a spring-loaded gas lift valve) is neglected in this simplified force-balance discussion. The gas lift valve actually is closed on the line that represents a balance between the opening and closing forces in Fig. 5.15. The valve is open above the line and closed below the line. The valve can be opened by (1) increasing the injection gas pressure with a constant flowing production pressure; (2) increasing the injection gas and flowing production pressures simultaneously; and (3) increasing the flowing production pressure with a constant injection-gas pressure. All three means of opening a valve are illustrated by vectors based on a 100-psi increase in the injection-gas pressure and in the flowing production pressure. The resultant vector is based on both of the other vectors. The bellows-assembly load rate for a valve and the distance from the force-balance line to the tip of the vector would control the actual stem travel. The valve in Fig. 5.15 is an injection-

Fig. 5.15—Initial injection-gas opening pressure vs. production pressure at valve depth for 1-in.-OD, unbalanced, single-element, gas lift valve with a $\frac{3}{8}$ -in. sharp-edged port and 0.31-sq-in. bellows area.

pressure-operated gas lift valve since the production-pressure factor is less than one. It is apparent from the slope of the force-balance line in Fig. 5.15 that an increase in the injection-gas pressure will result in a force and resultant stem travel greater than that from the same incremental increase in flowing production pressure because the production factor is less than one. The maximum stem travel is attained by increasing both pressures.

Production-Pressure Factor and Valve Spread

The production-pressure factor (F_p) is a relationship based on the effective bellows and port areas for an unbalanced gas lift valve. Unbalanced implies that the flowing production pressure is exerted over the entire ball-seat contact area as a portion of the initial opening force for a valve. In terms of gas lift valve operation, the production-pressure factor is the ratio of the incremental difference in the initial injection-gas opening pressure to a difference in the flowing production pressure. If the flowing production pressure increases, the initial injection-gas opening pressure decreases, and vice versa. The production-pressure factor can be obtained from the slope of the force-balance line in Fig. 5.15 or can be calculated from the specifications for the valve.

Valve spread is defined as the difference between the initial injection-gas opening and the injection-gas closing pressures of a gas lift valve. The valve spread is zero for a constant flowing production pressure because a valve initially opens and closes at the same injection-gas pressure. This concept is used in several continuous-flow installation design methods. The valve spread observed in intermittent gas lift operations results from a change in the flowing production pressure at the depth of the operating gas lift valve during an injection gas cycle. The production pressure at valve depth approaches the injection gas pressure beneath a liquid slug during gas injection, thus decreasing the valve closing pressure (also the initial opening pressure), which results in a spread between the initial opening and closing pressures of the operating valve. This can be a very important consideration for a chamber lift installation where the initial opening pressure of the operating gas lift valve will be based on a very low tubing pressure because the operating gas lift valve is located above the chamber.

Example Problem 7.

Given:

1. Effective bellows area = 0.31 sq in.
2. Port area = 0.11 sq in. (sharp-edged seat).
3. $p_{voD} = 1,000$ psig for $p_{pfD} = 0$ psig.
4. $p_{oD} = 644$ psig when $p_{pfD} = p_{oD} = 644$ psig.

Calculate the production-pressure factor on the basis of the areas in the valve specifications:

$$F_p = \frac{A_p}{A_b - A_p} = \frac{0.11}{0.31 - 0.11} = 0.55.$$

Calculate the production-pressure factor on the basis of the force-balance curve in Fig. 5.15:

$$F_p = -\left(\frac{\Delta p_{oD}}{\Delta p_{pfD}}\right) = -\left(\frac{1,000 - 644}{0 - 644}\right) = 0.55,$$

where Δp_{oD} is the difference in p_{oD} based on a change in p_{pfD} , psi, and Δp_{pfD} is the difference in p_{pfD} exerted over A_p , psi.

Calculate the initial injection-gas valve opening pressure for $p_{pfD} = 400$ psig:

$$p_{oD} = p_{voD} - F_p(p_{pfD}) = 1,000 - 0.55(400) = 780 \text{ psig}.$$

The same value for p_{oD} can be determined from Fig. 5.15. The valve would close at 780 psig if the flowing production pressure did not change.

Calculate the valve spread (Δp_s) in psi for an initial injection-gas valve opening pressure on the basis of

$p_{pfD} = 400$ psig and a $p_{pfD} = 600$ psig at the instant the valve closes.

$$\Delta p_s = F_p(\Delta p_{pfD}) = 0.55(600 - 400) = 110 \text{ psi},$$

where Δp_{pfD} is the difference in p_{pfD} exerted over A_p at the initial injection-gas opening and closing pressures, psi.

Injection-Gas Volumetric Throughput Profiles for Single-Element, Unbalanced Valves

The injection-gas throughput performance of a single-element, unbalanced, gas lift valve is controlled by the effective area of the bellows, the bellows-assembly load rate, and the stem-seat configuration. The performance profiles of two types of unbalanced, single-element, gas lift valves are illustrated in Fig. 5.16. The injection-pressure-operated gas lift valve in Fig. 5.16a is a bellows-charged valve with a large effective bellows area, and the stem-seat configuration may be considered as having a ball and sharp-edged seat. The seat line is broken by a very shallow chamfer but the valve would perform in the same manner as a valve with a sharp-edged seat. The performance profile for a single-element, unbalanced, spring-loaded gas lift valve with a small effective bellows area and a large ball-seat contact area relative to the bellows area is illustrated in Fig. 5.16b. These injection-gas volumetric throughput profiles are established by measuring the gas passage through the valve while maintaining a constant injection-gas upstream pressure and varying the flowing production downstream pressure. The purpose of this form of performance test is to establish the slope of the linear portion of the gas throughput curve in the throttling range for a given type of gas lift valve and stem-seat configuration.

The performance profiles in Fig. 5.16 are based on actual valve tests. The spring-loaded gas lift valve with a small bellows has a very high bellows-assembly load rate as compared to the bellows-charged valve with a large

Fig. 5.16—Injection-gas volumetric throughput profiles for unbalanced, single-element, gas lift valves. (a) 1 1/2-in.-OD, bellows-charged gas lift valve. $A_b = 0.77$ sq in. and ball OD = 5/8-in. Seat taper = 45° and $A_p = 0.153$ sq in. Test-rack closing pressure $p_{vctD} = 900$ psig. Constant operating pressure $p_{ioD} = 950$ and 1,000 psig. Throttling range slope = 9.3 Mscf/D-psi. (b) 1-in.-OD, spring-loaded gas lift valve. $A_b = 0.23$ sq in. and ball OD = 5/8-in. Seat taper = 45° and $A_p = 0.153$ sq in. Test-rack closing pressure $p_{vctD} = 667$ psig. Constant operating pressure $p_{ioD} = 800$ and 1,000 psig. Throttling range slope = 2.5 Mscf/D-psi.

bellows. The spring-loaded valve is installed in a well in the same manner as an injection-pressure-operated gas lift valve, with the injection-gas pressure exerted over an area equal to the bellows area less the ball-seat contact area. Since the ball-seat contact area in the spring-loaded valve is larger than the area exposed to the injection-gas pressure, the valve is operated primarily by flowing production pressure. The production-pressure factor for the valve is approximately 2.5. The stem travel for the spring-loaded valve is limited to keep the ball on the stem within the taper of the seat; thus, the flowing production pressure is applied over a relatively constant area as an opening force throughout the operating pressure range of the valve. This type of valve is recommended for a continuous-flow installation design using its throttling range and represents one form of a flowing-production-pressure installation design.

The performance profile in Fig. 5.16a reveals that an unbalanced, bellows-charged, injection-pressure-operated gas lift valve with a sharp-edged seat and a production-pressure factor less than 0.25 will perform in a manner similar to a spring-loaded, unbalanced valve with a large production-pressure factor and a deep chamfered seat. This bellows-charged valve is not recommended for a continuous-flow installation design using the throttling range of the valve for valve spacing because of the steep slope of the throttling portion of the injection-gas throughput performance curve. A minor change in the injection-gas pressure results in a major change in the injection-gas throughput for a valve with a low production-pressure factor.

The differing operating characteristics of injection-gas and flowing production-pressure-operated gas lift valves can be observed from the performance profiles in Fig. 5.16. These operating characteristics are apparent from differences in injection-gas pressures and their corresponding closing flowing-production pressures. If the pressure difference in the constant operating injection-gas pressures is less than the corresponding flowing-production closing pressures, the valve is classified as an injection-pressure-operated valve. The valve is classified as production-pressure-operated when the difference in the constant operating injection-gas pressures exceeds the difference in the corresponding flowing-production closing pressures. The bellows-charged gas lift valve in Fig. 5.16a is an injection-pressure-operated valve, and the spring-loaded valve in Fig. 5.16b is production-pressure-operated.

Continuous-Flow Gas Lift

Introduction

Continuous-flow gas lift is analogous to natural flow, but there are generally two distinct flowing-pressure traverses. The traverse below the point of gas injection includes only formation gas, whereas the traverse above the point of gas injection includes both the formation and injection gases. These flowing-pressure traverses and corresponding gas/liquid ratios are illustrated in Fig. 5.17.

The advent of reliable multiphase flowing pressure-gradient curves provided the means to design a continuous flow installation properly. These gradient curves completely changed the design techniques used by gas lift design engineers. Maximum production rates can be estimated for the available injection-gas volume and pres-

Fig. 5.17—Principles of continuous flow operation illustrated by a pressure-depth diagram. The datum depth (D_d) for the BHP is the lower end of the production conduit. Injection gas is entering the production conduit through the fourth gas lift valve and the three upper unloading gas lift valves are closed. Although the bottom gas lift valve is open, no injection gas can enter this valve at depth (D_5) because the flowing production pressure exceeds the injection-gas pressure at this depth. The flowing pressure at depth traverse (g_{fb}) above the operating gas lift valve depth (D_{ov}) includes the injection plus the formation gas, and the traverse (g_{fb}) below D_{ov} contains only formation gas (see also nomenclature list at the end of the chapter).

sure, and the valve depths can be calculated accurately with reliable gradient curves.

There are numerous gas-lift installation design methods offered by different manufacturers. Several installation designs require unique valve construction or known gas-lift-valve injection-gas throughput performance. Only two installation design techniques will be illustrated in this section. These installations are designed to use the simplest type of single-element, unbalanced, gas lift valve with a bellows-charged dome. This type of valve is the most widely used in the industry and is manufactured by all major gas lift companies.

Gas-lift installation design calculations are divided into two parts. The first part is the determination of the gas lift valve depths, and the second part is the calculation of the test-rack opening pressures of the gas lift valves. The test-rack set opening pressures are calculated after the valve depths because the operating pressures and temperatures during unloading are based on these valve depths.

The primary objective of this section is to outline in detail installation design methods for calculating the valve depths and the test-rack opening pressures of the gas lift valves that will unload a well to a maximum depth of lift for the available injection-gas volume and pressure. The unloading operations, as illustrated by the two-pen pressure recorder chart in Fig. 5.18, should be automatic. As each lower gas lift valve is uncovered, the valve immediately above closes and the point of gas injection transfers

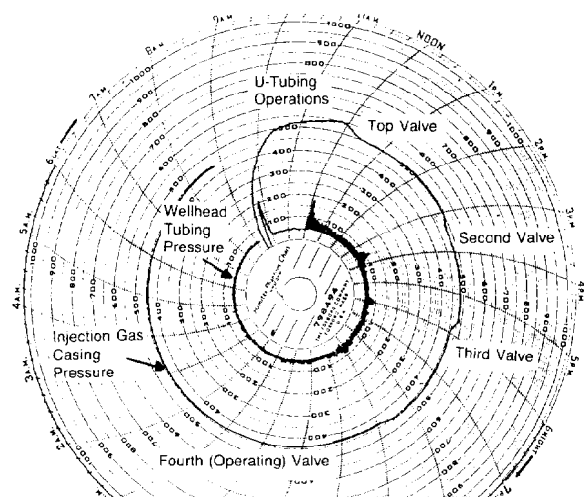

Fig. 5.18—Two-pen pressure recorder chart illustrating continuous-flow gas lift unloading operations with choke control of the injection gas. The static load fluid level was at the surface in the casing and tubing before the well was unloaded, which explains the first wellhead tubing pressure surge immediately after initial gas injection into the casing annulus. The wellhead pressure remains relatively constant during U-tubing operations before injection gas enters the tubing for the first time through the top gas lift valve. A surge in wellhead tubing pressure and a decrease in the injection gas casing pressure occur as the depth of gas injection transfers to each lower gas lift valve.

from the upper to the lower valve. All gas lift valves above an operating valve should be closed and the valves below should be open in a properly designed gas lift installation.

Initial Installation Design Considerations

Continuous-flow installation designs vary depending on whether complete and precise well data are known or unavailable. Reliable inflow well performance and an accurate multiphase flow correlation are required to establish the exact point of gas injection in deep wells. When the well data are limited or questionable, the point of gas injection cannot be calculated. A known point of gas injection is an unrealistic consideration for most wells because the reservoir pressure and water cut change as the reservoir is depleted. An exception will be wells where the maximum depth of lift can be reached initially with the available operating injection-gas pressure. The point of gas injection remains at this maximum depth for the life of the gas lift installation.

Retrievable gas lift valve mandrels are installed in many wells before little, if any, well production information is available. The engineer must locate these mandrels in wells before gas lift is required. The design considerations are similar for wells with a changing point of gas injection. In general, most gas lift installations will be in this category, where accurate well data are unknown or limited and the point of gas injection is unknown and/or changing as the reservoir is depleted. For this reason, the installation designs outlined in this section do not require complete well data. These continuous-flow gas lift installations are designed to lift a given daily production rate

from all valve depths. An orifice-check valve is recommended for the bottom valve in most installations. If a gas lift valve will be run, the test-rack opening pressure is set lower than the valves above so that the gas lift installation will produce at an actual daily production rate that is much less than the design rate without the valve closing.

Installation Design Methods

The two installation design methods outlined here can be classified as (1) the decreasing injection gas pressure design, and (2) the variable flowing pressure gradient method. Injection-pressure-operated gas lift valves with a small production-pressure factor (F_p) are recommended for the decreasing-injection-gas-pressure installation design method. Valves with a small F_p are sensitive primarily to a change in the injection-gas pressure. A decrease in the injection-gas pressure for each lower gas lift valve is essential to ensure the closure of upper unloading valves after gas injection has been established through a lower operating gas lift valve. This decreasing-injection-gas-pressure design is particularly applicable when the available injection-gas pressure is high relative to the required depth of lift, and an incremental decrease in injection-gas pressure can be added to the production-pressure effect for the top valve.

If a small-OD, injection-pressure-operated gas lift valve with a large port (high production-pressure factor) is required for ample gas passage to unload and to gas lift a well, the variable-gradient-valve-spacing design-line method should be used. The injection-pressure gas lift valves should have a production-pressure factor of at least 20 to 25% because a change in the flowing production pressure at valve depth rather than the injection-gas pressure establishes whether a gas lift valve is open or closed. Production-pressure-(fluid)-operated gas lift valves are applicable for the variable flowing-pressure-gradient gas lift installation design method. This design is considered to be particularly applicable for systems with low available injection-gas pressure since a constant surface operating injection-gas pressure is used to locate the valve depths in most installations. When the injection-gas pressure is high relative to the required depth of lift, the variable gradient design can be modified to include an incremental decrease in the operating injection-gas pressure with each succeeding lower gas lift valve. Decreasing the operating injection-gas pressure between valves will reduce the probability of multipoint gas injection, which could result in possible surging or heading conditions.

Although the continuous-flow installation designs outlined here do not require complete well data, these designs can be modified for a known point of gas injection. Generally, the calculated point of gas injection will be bracketed by installing at least one valve below the calculated valve depth in the event there is a slight error in the well information.

Safety Factors in the Simplified Continuous-Flow Installation Design Methods Without Gas Lift Valve Performance

The following safety factors are used for continuous-flow gas lift installation design with unbalanced, single-element, gas lift valves when the load rate and the gas throughput performance of the valve are not considered

in the calculations. The initial gas-lift-valve opening pressures are based on the static-force balance equations and represent the condition of no force applied by the valve stem onto the seat line of the port. Essentially, the valve is closed. These safety factors allow the injection-gas or flowing production pressure increase at valve depth needed to stroke the valve stem for generating an equivalent port area required to pass the injection-gas volume necessary for unloading and gas lifting most wells and to compensate for the actual locations of gas lift valves that are not to the nearest foot. Many operators will not break a stand to install a gas lift mandrel in the tubing string; therefore, the actual depth of the gas lift valve for a thribble (three tubing joints) may be to the nearest 45 to 50 ft of the calculated depth.

1. The operating injection-gas pressure used for the installation design calculations should be at least 50 psi less than the minimum injection-gas pressure available at the wellsite for most wells.

2. The unloading daily production rate is assumed equal to the design daily production rate. Generally, the actual unloading daily production rate will be less than the design production rate and can be controlled at the surface by the injection-gas volume.

3. No formation gas is assumed to be produced during the unloading operations. The total gas/liquid ratio is based on the daily injection-gas volume available for unloading the well.

4. The flowing-pressure-at-depth traverses above the unloading gas lift valves are assumed to be straight rather than curved lines.

5. The unloading flowing-temperature-at-depth traverse is assumed to be a straight rather than a curved line between an assigned unloading flowing wellhead temperature (T_{whu}) and the bottomhole temperature (BHT). The design unloading flowing temperature generally is between the static geothermal surface temperature and the final operating flowing temperature. A final flowing temperature that is higher than the design temperature increases the initial opening pressure of a bellows-charged gas lift valve and aids in keeping the upper valves closed while lifting from a lower gas lift valve.

6. An assigned valve-spacing pressure differential (Δp_v) of 50 psi across a valve for unloading is used commonly by many gas lift design engineers. The actual minimum flowing production pressure required to uncover the next lower unloading gas lift valve is greater by the assigned Δp_v .

7. The flowing-pressure traverse below the point of gas injection for locating the valve depths is assumed to be the static-load fluid gradient. No formation-produced fluids, including free gas, are considered in the valve spacing calculations.

An Orifice-Check Valve for the Operating Gas Lift Valve in Continuous-Flow Installations

An orifice being used for gas lifting a well should include a reverse-flow check valve. The check disk, or dart, should be closed by gravity or should be spring loaded for most applications. If a well with a packer produces sand, the check portion should be closed to prevent sand from accumulating on top of the packer when this valve is below the working fluid level and is not the operating valve. An inlet screen is recommended for orifice-check

Fig. 5.19—Two-pen pressure recording unloading chart from a continuous flow installation with an orifice-check valve. The heading of the flowing wellhead tubing pressure results from the opening and closing of the unloading gas lift valves because of a $2\frac{3}{4}$ -in. choke in the flowline and a frictional drag mechanism in the valve to prevent stem shatter. When the orifice-check valve is uncovered around 3:00 a.m., heading and the operating injection-gas pressure decrease. The problem is reservoir deliverability and not the gas lift installation.

valves with a small choke to prevent possible plugging. The individual openings in the inlet screen should be smaller than the choke in the orifice-check valve.

A properly designed continuous-flow gas lift installation with an orifice-check valve will not have a higher injection-gas requirement than the same well with an injection-pressure-operated gas lift valve, if the orifice is not too large. The injection-gas volume for lifting a well is controlled by the metering device on the injection gas line at the surface. An orifice-check valve rather than a more expensive and complicated pressure-operated gas lift valve should be considered for the bottom valve in most continuous-flow installations.

Advantages of the Orifice-Check Valve.

1. The construction of an orifice-check valve is the simplest of all types of valves. The cost and the possibility of a malfunction are less for the orifice-check valve than for a pressure-operated gas lift valve.

2. The orifice-check valve is a "flag" because of the change in operating injection-gas-line pressure downstream of the metering device on the injection gas line when this valve is uncovered and becomes the point of gas injection. If the operating injection-gas pressure decreases significantly after the orifice-check valve is uncovered during initial unloading operations, the problem is reservoir deliverability and not the gas lift installation, as illustrated in Fig. 5.19.

3. An orifice-check valve can prevent severe heading or surging in a continuous-flow gas lift installation by assuring a constant port size for injection-gas passage. The equivalent port area in an injection-pressure-operated gas lift valve with a high production-pressure factor or a production-pressure-operated gas lift valve will change with a varying flowing production pressure. A gas lift valve tending to cyclic opening and closing results in heading from a change in the injection-gas throughput of the valve. Note the decrease in heading when lifting from the orifice valve in Fig. 5.19.

4. No injection-gas pressure increase is required to stroke an orifice-check valve. The port size is always known and is equal to the choke size in the valve.

5. When the injection-gas-line pressure decreases below the minimum pressure required to hold an injection-pressure-operated gas lift valve open, this valve will close. An orifice-check valve will remain open and gas lift operations may continue as long as the injection-gas pressure at valve depth exceeds the flowing production pressure at the same depth.

6. An orifice-check valve is recommended as the bottom valve in most production-pressure-(fluid)-operated installations and in other continuous-flow installations with injection-pressure-operated gas lift valves having a high production-pressure factor. If the actual flowing production pressure at the depth of the bottom valve is less than predicted, a gas lift valve may close or restrict the injection-gas rate, whereas an orifice-check valve will remain fully open.

7. A properly sized orifice is required to control the injection-gas volume for gas lifting some wells. One application is gas lifting one zone of a dual gas lift installation with a common injection-gas source in the casing annulus. A design pressure differential of at least 100 to 150 psi across the orifice is necessary to assure a reasonably accurate gas-passage prediction.

8. The orifice-check valve is an excellent annular fluid transfer valve for differential gas lift valve installations with a packer. A differential valve will tend to close during initial U-tubing operations.

Disadvantages of the Orifice-Check Valve.

1. When the injection-gas-line pressure is high, relative to the flowing production pressure at the depth of the orifice-check valve, a high pressure differential occurs across the surface injection-gas metering device. Hydrates may form and shut off the injection gas. The orifice-check valve can be replaced with an injection-pressure-operated gas lift valve. The pressure loss is transferred to the gas lift valve in the well at BHT where hydrates cannot form.

2. The weak wells with an orifice-check operating valve will consume injection gas at lower injection-gas-line pressure than stronger wells with higher flowing production pressures at the depth of the operating orifice-check valve.

3. A hole in the tubing cannot be distinguished from an orifice-check valve during normal, uninterrupted, continuous-flow gas lift operation. The production conduit can be pressured up with injection gas to observe whether flow can be established from the production conduit to the injection-gas conduit. Reverse flow indicates that there is a hole in the production conduit or that the check is not holding.

4. An orifice-check valve generally is not recommended

for a small, closed, rotative, gas lift system when costly makeup gas is required to charge the system after a shut-down. A properly set injection-pressure-operated gas lift valve will close after a slight decrease in the injection-gas pressure and will prevent the unnecessary loss of injection gas from the small high-pressure system.

Depth of the Top Gas Lift Valve

The top gas lift valve should be located at the maximum depth that will permit U-tubing the load fluid from this depth with the available injection-gas pressure. If the well is loaded to the surface with a kill fluid, the depth of the top valve can be calculated using one of the following equations:

$$D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}}, \quad \dots \dots \dots (23)$$

$$D_1 = \frac{p_{ko} - p_{whu}}{(g_{sl} - g_g)}, \quad \dots \dots \dots (24)$$

or

$$D_1 = \frac{p_{ko} - p_{whu} - \Delta p_a}{(g_{sl} - g_g)}, \quad \dots \dots \dots (25)$$

where

D_1 = depth of top valve, ft,

p_{ko} = surface kick-off injection gas pressure, psig,

p_{whu} = surface wellhead U-tubing pressure, psig,

g_{sl} = static-load fluid gradient, psi/ft,

g_g = gas gradient based on p_{ko} and p_{kod} , psi/ft,

p_{kod} = kick-off injection gas pressure at D_d , psig,

D_d = vertical reference datum depth (lower end of production conduit), ft, and

Δp_a = assigned pressure differential for valve spacing, psi.

Eq. 23 does not include the increase in the injection-gas pressure to the depth D_1 . This equation is widely used because of a slight safety factor from neglecting this increase in gas pressure. Eq. 24 yields the same depth as a graphical solution without any pressure drop across the top gas lift valve at the instant this valve is uncovered. In other words, the top valve will not be uncovered if the actual kick-off injection-gas pressure is less than the design value or if the U-tubing wellhead pressure is higher than assumed. Eq. 25 includes injection-gas column weight and an assigned pressure drop at the instant the top valve is uncovered.

The surface U-tubing wellhead pressure is less than the flowing wellhead pressure for most installations. The difference between these two pressures will increase for longer flowlines and higher production rates. The wellhead U-tubing pressure is approximately equal to the separator, or production header, pressure because the rate of load fluid transfer is very low during the U-tubing operation and no injection gas can enter the flowline until the top gas lift valve is uncovered. Gas lift operations do not begin until injection gas enters the production conduit

through the top valve. Flowing wellhead pressure should be used to locate the depths of the remaining gas lift valves.

A load fluid traverse g_{sl} can be drawn from the wellhead U-tubing pressure to the intersection of the kick-off injection-gas-pressure-at-depth curve (p_{koD} traverse) on a pressure-depth worksheet. The top valve may be located at this intersection, which would be the same depth as calculated with Eq. 24. An arbitrary pressure drop across the top gas lift valve can be assumed in conjunction with the graphical method and this technique is the same as Eq. 25. If a pressure drop is assumed, this method becomes similar to the calculation of D_1 with Eq. 23. For this reason, Eq. 23 is recommended for most calculations.

If the depth to the static fluid level exceeds the calculated depth of the top gas lift valve and the well is not loaded, the top valve may be located at the static fluid level. This procedure is not recommended when a well may be loaded in the future or when the elevation of a well is lower than the tank battery, which is not located near the well. A check in the flowline may fail and fluid in the flowline will fill the tubing when a well is shut in. Theoretically, the top valve could be located below a static fluid level on the basis of the ratio of the capacity of the casing annulus to the capacity of the tubing. The primary application for this calculation would be in a casing flow installation, but this procedure is not recommended for typical tubing-casing sizes when the well is being gas lifted through the tubing.

Establishing Slope of Static-Load Fluid Traverse

There are several methods for establishing the slope of a static-load fluid traverse on the pressure-depth worksheet. This load fluid traverse is assumed to be the unloading pressure traverse below the point of gas injection for locating the depths of the gas lift valves. The static fluid level can be calculated on the basis of the static BHP and the load fluid gradient with the following equation:

$$L_{sf} = D_d - \frac{p_{wsd}}{g_{sl}}, \quad \dots \quad (26)$$

where L_{sf} is the static fluid level from surface for zero wellhead pressure, ft, and p_{wsd} is the static BHP at depth D_d , psig.

Plot the static BHP, p_{wsd} , at the datum depth and the L_{sf} at zero pressure and connect these points with a straight line. This line represents a pressure gradient traverse with a slope equal to the load fluid gradient. All unloading traverses below the point of gas injection for locating the gas lift valves are drawn parallel to this static-load fluid traverse.

Another procedure for establishing this static-load fluid traverse below each gas lift valve is to assume a pressure, p_{as} , greater than the operating injection-gas pressure at the lower end of the production conduit p_{iod} and to calculate the depth of this assumed pressure point on the basis of the static-load fluid gradient g_{sl} . Calculated D_c for p_{as} is

$$D_c = D_{uv} + \frac{p_{as} - p_{uvD}}{g_{sl}}, \quad \dots \quad (27)$$

where

D_c = calculated depth for assumed p_{as} , ft,

D_{uv} = depth of unloading valve, ft,

p_{as} = assumed pressure, psig, and

p_{uvD} = minimum flowing or production transfer pressure at D_{uv} , psig.

Plot p_{as} at D_c for this pressure point and draw a straight line between p_{uvD} at D_{uv} and p_{as} at D_c . The load fluid traverse may be terminated at the p_{iod} curve. The slope of this line is the load fluid gradient.

Example Problem 8.

Given:

1. p_{uvD} = 420 psig at 2,310 ft (D_{uv} = 2,310 ft).

2. p_{iod} = 1,140 psig at 6,000 ft.

3. g_{sl} = 0.45 psi/ft.

Find D_c for p_{as} = 1,200 psig (exceeds p_{iod}):

$$D_c = 2,310 + \frac{1,200 - 420}{0.45} = 4,043 \text{ ft.}$$

Draw a straight line originating at the point (420 psig at 2,310 ft) and extending to the point (1,200 psig at 4,043 ft) or the p_{iod} curve. This traverse below the valve at 2,310 ft will have a slope equal to the load fluid gradient g_{sl} .

Multiphase Flow Correlations and Flowing Pressure Gradient Curves

Accurate flowing-pressure-at-depth predictions are essential to good continuous-flow gas lift installation design and analysis. When computer programs for gas lift installation design and analysis are unavailable for daily routine calculations, the gas lift engineers and technicians must rely on published gradient curves to determine flowing pressures at depth. Many oil producing companies have their own multiphase flow correlations and publish in-house gradient curves. Gradient curves are available from the gas lift manufacturers and are published in books that can be purchased. It is not the purpose of this chapter to rank the various multiphase flow correlations or published gradient curves.

The widely accepted multiphase flow correlations are based on pseudosteady-state flow without serious heading through a clean production conduit with an unrestricted cross-sectional area. Accurate pressures cannot be obtained from gradient curves based on these correlations if the conduit is partially plugged with paraffin or scale. Emulsions prevent the application of gradient curves. The applicability of a particular set of gradient curves for a given well can be established only by comparing a measured flowing pressure to a pressure determined from the gradient curves. The measured production data must be accurate and repeatable before discounting the published gradient curves.

A set of typical gradient curves is given in Fig. 5.20. These gradient curves are used in the example installation design calculations in this section. Gas/liquid ratio (GLR) and not gas/oil ratio (GOR) is used for these installation design calculations. Most gradient curves for all oil are identified by GLR rather than GOR, although the values are the same. For this reason, the first step in

Fig. 5.20—Flowing pressure at depth gradient curves for 800 B/D (65% water) through 2 7/8-in.-OD tubing.

the application of gradient curves is to convert GOR to GLR if only GOR is reported and the well produces water. The GLR can be calculated for a given GOR and water cut with the following equation:

$$R_{glf} = f_o(R), \quad (28)$$

where

$$\begin{aligned} R_{glf} &= \text{formation GLR, scf/STB,} \\ f_o &= \text{oil cut (1 - water cut fraction), fraction,} \\ &\text{and} \\ R &= \text{GOR, scf/STB.} \end{aligned}$$

When gradient curves are used, depth is shifted and *never* pressure. If a flowing-pressure-at-depth traverse is being traced, the pressures on the pressure-depth worksheet must always overlie the same pressures on the gradient curves.

Example Problem 9.

Given:

1. Formation GOR = 500 scf/STB.
2. Water cut = 60%.

Calculate the formation GLR:

$$R_{glf} = (1 - 0.6)500 = 200 \text{ scf/STB.}$$

Flowing Temperature at Depth

The accurate prediction of the flowing-production-fluid temperature at valve depth is important in the design and

analysis of many gas lift installations with nitrogen-charged gas lift valves. The temperature of a wireline-retrievable valve is assumed to be the same as the temperature of the flowing fluids at the valve depth. A retrievable gas lift valve is located in a mandrel pocket inside the tubing and is in contact with the production from the well. The temperature of a conventional valve will be between the flowing fluid temperature and the geothermal temperature for the well.

One of the most widely used flowing temperature gradient correlations was published by Kirkpatrick⁶ in 1959. The family of flowing-temperature-gradient curves in Fig. 5.21 is based on data from high-water-cut wells being produced by gas lift through 2 7/8-in.-OD tubing over a wide range of production rates. Although the correlation does not include several important parameters, such as GLR and fluid properties, the estimated surface temperature and temperatures at depth have proven to be reasonably accurate for many gas lift operations.

Another flowing temperature correlation was published by Shiu and Beggs⁷ on the basis of a study by Shiu. This empirical method for calculating flowing temperature profiles is far more rigorous and is based on well data from several areas. The calculation procedure can be programmed easily for predicting surface flowing temperatures in vertical and inclined wells.

Considerations for Selecting the Bottom Gas Lift Valve

An orifice-check valve is recommended for the bottom valve in most continuous-flow installations. If a gas lift valve is used, the initial injection-gas opening pressure should be at least an additional 25 to 50 psi less than the calculated decrease in injection-gas pressure and a flowing production pressure equal to 50% of the design pressure. This procedure assures that the upper gas lift valves will remain closed after the point of gas injection transfers to the bottom gas lift valve and allows continued operation when the daily production rate and corresponding BHFP are much less than predicted. In addition, this decrease in the injection-gas operating pressure for the bottom gas lift valve indicates that the installation has unloaded to this valve and is being gas lifted from this depth.

Continuous-Flow Installation Design Based on a Constant Decrease in the Operating Injection-Gas Pressure for Each Succeedingly Lower Gas Lift Valve

This installation design method is based on all gas lift valves having the same port size and a constant decrease in the operating injection-gas pressure for each succeeding lower gas lift valve. Many continuous-flow installations use the same type of gas lift valve with one port size. This is particularly true for moderate-rate wells being gas lifted through 2 7/8- and 2 1/2-in.-OD tubing with 1 1/2-in.-OD gas lift valves having a 1/4-in. port. The gas lift valve selection must be based on a port size that will allow the injection gas throughput required for unloading and gas lifting the well. This installation design method is recommended for gas lift valves with a small production pressure factor. When the ratio of the port area to the bellows area is low, the decrease in the injection pressure between gas lift valves based on the production pressure effect for

Fig. 5.21—Flowing temperature gradient for different flow rates, geothermal gradients, and tubing sizes. Chart to be used directly for 2½-in. nominal tubing. For 2-in. nominal tubing multiply actual production rate by 2. For 3-in. nominal tubing divide actual production rate by 1.5.

the top valve will not be excessive. The effect of bellows-assembly load rate on the performance of the gas lift valves is not considered in the installation design calculations. Safety factors included in these design calculations should allow sufficient increase in the operating injection-gas pressure necessary to provide the valve stem travel for adequate gas passage through each succeeding lower unloading gas lift valve without excessive interference from upper valves.

Selection of a constant pressure decrease, or drop, in the operating injection-gas pressure for each succeeding lower gas lift valve should not be arbitrary, as proposed in some design methods. The pressure decrease

should be based on the gas lift valve specifications to minimize the possibility of upper valves remaining open while lifting from a lower valve. The production-pressure effect for the top gas lift valve would be a logical choice for this decrease in the operating injection-gas pressure between valves. Closing, or reopening, of an injection-pressure-operated gas lift valve is partially controlled by the production-pressure effect, which is equal to the production-pressure factor for the valve times the flowing production pressure at the valve depth. As the gas lift valve depths increase, the distance between valves and the change in the production-pressure effect decrease but the injection-gas requirement for unloading increases. An

increased stem travel, or stroke, is needed for the lower valves to generate the larger equivalent port area necessary for the higher injection-gas requirements with the lower pressure differentials that occur across these deeper valves. A constant decrease in the operating injection-gas pressure equal to the production pressure effect for the top valve allows a greater increase in the injection-gas pressure above the initial opening pressure for a lower gas lift valve before the valve above begins to open.

Another application for this simplified design method depends on the relationship between the available injection-gas pressure and the flowing production pressure at the maximum depth of lift. When the injection-gas pressure significantly exceeds this flowing production pressure, an arbitrary Δp_{io} decrease in the injection-gas pressure can be added to the additional production-pressure effect for the top valve for calculating the spacing and opening pressures of the unloading gas lift valves. The total decrease in the injection-gas pressure is distributed equally between each succeeding lower unloading gas lift valve rather than having a sizable injection pressure drop across the operating gas lift or orifice-check valve. This procedure eliminates the possibility of multipoint gas injection through upper unloading gas lift valves by ensuring that these valves will remain closed after the point of gas injection has transferred to the next lower gas lift valve.

Selection of Port Size. In many fields where gas lift is the artificial lift method, there has been a standardization of port size that performs successfully in those wells. When a port size must be selected, the first step is to estimate the maximum depth of lift. The final operating injection-gas pressure is based on the number of gas lift valves and on the decrease in the injection-gas pressure between each succeeding lower valve. Since this final injection-gas pressure is unknown until the installation is designed, an assumed pressure difference of approximately 200 psi between the unloading g_{fp} traverse and the p_{ioD} curve is assumed for locating the deepest gas lift valve depth. The operating injection-gas rate and a pressure drop across the deepest valve of 100 psi ($p_{ioD} = p_{pfd} + 100$ psi) should ensure the selection of the proper port size for most wells, which is Step 5 in the procedure for determination of the gas lift valve depths. The last unloading gas lift valve is above the bottom valve and will have a higher injection-gas capacity because of a greater gas pressure differential and higher available injection-gas pressure.

Determination of Valve Depths. The BHP's and BHT generally are referenced to the same depth, which is the lower end of the production conduit (D_d). The steps for establishing the gas lift valve depths are as follows.

1. Determine the unloading flowing production pressure at the lower end of the production conduit (p_{pfd}).

2. Plot the flowing wellhead pressure (p_{whf}) and the p_{pfd} on the pressure-depth worksheet and connect these two pressures with a straight line, which represents the unloading flowing-pressure traverse above the point of gas injection g_{fp} .

3. Determine the operating injection-gas pressure at the lower end of the production conduit (p_{iod}) and draw a straight line between the surface operating pressure (p_{io}) and p_{iod} to establish the p_{ioD} traverse.

4. Draw the unloading gas lift valve temperature-at-depth traverse (T_{uvD}) by assuming a straight-line traverse between the surface unloading flowing wellhead temperature (T_{whu}) and the bottomhole temperature (T_{vd}).

5. Select the port size for the type of gas lift valves to be installed in the installation on the basis of the unloading and operating injection-gas requirements.

6. Record the gas lift valve specifications, which include the effective bellows area (A_b), port area (A_p), A_p/A_b ratio, production-pressure factor (F_p), and the seat angle and ball size for valves with a tapered seat.

7. Calculate the depth of the top gas lift valve (D_1) on the basis of the kick-off injection-gas pressure (p_{ko}), load fluid gradient (g_{sl}), and the wellhead U-tubing pressure (p_{whu}) with Eq. 23.

$$D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}}$$

The top valve may be located graphically or at the static fluid level if this depth exceeds the calculated D_1 .

8. Draw a horizontal line between the g_{fp} traverse and the p_{ioD} curve at the depth D_1 and record the $(p_{pfd1})_{min}$ at the intersection of the g_{fp} traverse, the p_{ioD1} , and the T_{uvD1} at depth (D_1) on the unloading temperature traverse.

9. Calculate the initial injection-gas opening pressure at depth of the top gas lift valve (p_{oD1}).

$$p_{oD1} = p_{ioD1} \quad \dots \dots \dots (29)$$

10. Draw the static-load fluid traverse (g_{sl}) below the depth of the top gas lift valve with the traverse originating at $(p_{pfd1})_{min}$ and extending to the p_{ioD} curve.

11. Locate the depth of the second gas lift valve (D_2) on the basis of the assigned pressure differential (Δp_a) for spacing the gas lift valves and the p_{ioD} curve.

$$\Delta p_{sD2} = \Delta p_a, \quad \dots \dots \dots (30)$$

where Δp_{sD2} is the valve spacing pressure differential at depth of the second gas lift valve.

12. Draw a horizontal line between the g_{fp} traverse and the p_{ioD} curve at the depth D_2 and record the $(p_{pfd2})_{min}$, p_{ioD2} , and T_{uvD2} .

13. Determine the maximum flowing production pressure at the depth of the top gas lift valve ($p_{pfd1})_{max}$ immediately after the second valve is uncovered by drawing a straight line between p_{whf} and a p_{pfd2} equal to $(p_{ioD2} - \Delta p_a)$.

14. Calculate the additional production-pressure effect for the top gas lift valve Δp_{pe1} that represents the decrease in the operating injection-gas pressure for each succeeding lower gas lift valve without an arbitrary decrease in the injection-gas pressure between valves (Δp_{io}).

$$\Delta p_{pe1} = [(p_{pfd1})_{max} - (p_{pfd1})_{min}] F_p \quad \dots \dots \dots (31)$$

15. Calculate the initial injection-gas opening pressure at the depth of the second gas lift valve (p_{oD2}).

$$p_{oD2} = p_{ioD2} - \Delta p_{pe1} - \Delta p_{io} \quad \dots \dots \dots (32)$$

TABLE 5.4—CALCULATION OF THE TEST-RACK-SET OPENING PRESSURES OF THE GAS LIFT VALVES*

Valve Number	D (ft)	p_{oD} (psig)	$(p_{pfD})_{\min}$ (psig)	p_{bvD} (psig)	T_{uvD} (°F)	F_T	p_{vo} (psig)
1	2,311	1,054	420	1,014	127	0.874	947
2	3,679	1,067	598	1,037	143	0.849	940
3	4,660	1,071	726	1,049	154	0.832	931
4	5,351	1,068	816	1,052	162	0.820	921
5	5,825	1,010	439	974	168	0.812	844

*Valve description: 1½-in. OD gas lift valve. Valve specifications: $A_b = 0.77$ sq in. Port ID = ¼ in. $A_p/A_b = 0.064$. $(1 - A_p/A_b) = 0.936$.

16. Draw the static-load fluid traverse (g_M) below the depth of the second gas lift valve with the traverse originating at $(p_{pfD2})_{\min}$ and extending to the p_{ioD} curve.

17. Calculate the spacing pressure differential for the third gas lift valve (Δp_{sD3}).

$$\Delta p_{sD3} = \Delta p_{sD2} + \Delta p_{pe1} + \Delta p_{io}. \quad (33)$$

18. Locate the depth of the third gas lift valve (D_3) on the basis of Δp_{sD3} and the p_{ioD} curve.

19. Draw a horizontal line between the g_{fp} traverse and the p_{ioD} curve at the depth D_3 and record the $(p_{pfD3})_{\min}$, p_{ioD3} , and T_{uvD3} .

20. Calculate the initial injection-gas opening pressure at the depth of the third gas lift valve.

$$p_{oD3} = p_{ioD3} - 2(\Delta p_{pe1} + \Delta p_{io}). \quad (34)$$

21. Draw the static-load fluid traverse below the depth of the third valve.

22. Calculate the spacing pressure differential for the fourth valve.

$$\Delta p_{sD4} = \Delta p_{sD3} + \Delta p_{pe1} + \Delta p_{io}. \quad (35)$$

23. Locate the depth of the fourth valve.

24. Record $(p_{pfD4})_{\min}$, p_{ioD4} , and T_{uvD4} .

25. Calculate the initial injection-gas opening pressure at the depth of the fourth valve.

$$p_{oD4} = p_{ioD4} - 3(\Delta p_{pe1} + \Delta p_{io}). \quad (36)$$

Repeat Steps 21 through 25 until the maximum desired gas lift valve depth is attained or the calculated distance between gas lift valves is less than an assigned minimum distance between valves.

Calculation of the Test-Rack-Set Opening Pressures of the Gas Lift Valves. A tabulation form for these calculations is illustrated in Table 5.4. The equations that are needed to perform the calculations are as follows:

$$p_{bvD} = p_{oD}(1 - A_p/A_b) + (p_{pfD})_{\min}(A_p/A_b) \quad (37)$$

and

$$p_{vo} = \frac{F_T(p_{bvD})}{(1 - A_p/A_b)} \quad (38)$$

The unloading gas lift valve temperature at depth can be

read from the pressure-depth worksheet or calculated using the following equation:

$$T_{uvD} = T_{whu} + D[(T_{vd} - T_{whu})/D_d] \quad (39)$$

This temperature is used to obtain a value for F_T from Table 5.1.

If the test-rack opening pressures of the gas lift valves will be set at a tester temperature (T_{vs}) other than the chart base temperature of 60°F for Table 5.1, the following equation for p_{vos} must be used:

$$p_{vos} = \frac{F_T(p_{bvD})}{F_{Ts}(1 - A_p/A_b)} \quad (40)$$

where F_{Ts} is found in Table 5.1 for T_{vs} .

Example Problem 10.

Well information for installation design calculations :

1. Tubing size = 2⅞-in. OD.
2. Tubing length = 6,000 ft.
3. Maximum valve depth = 5,970 ft.
4. Daily production rate = 800 STB/D.
5. Water cut = 60%.
6. Formation GOR = 500 scf/STB.
7. Oil gravity = 35° API.
8. Gas gravity = 0.65.
9. Water specific gravity = 1.04.
10. BHT = 170°F at 6,000 ft.
11. Design unloading wellhead temperature = 100°F.
12. Load fluid gradient = 0.45 psi/ft.
13. U-tubing wellhead pressure = 60 psig.
14. Flowing wellhead pressure = 120 psig.
15. Static fluid level = 0 ft (loaded).
16. Surface kick-off injection-gas pressure = 1,100 psig.
17. Surface operating injection-gas pressure = 1,000 psig.
18. Kick-off injection-gas rate = 800 Mscf/D.
19. Operating injection-gas rate = 500 Mscf/D.
20. Injection-gas wellhead temperature = 80°F.
21. Gas lift valve bellows area = 0.77 sq in. (1½-in.-OD valve).
22. Gas lift valve with sharp-edged seat.
23. Test-rack-set temperature = 60°F.
24. Assigned pressure drop across valves = 50 psi.
25. Additional decrease in injection-gas pressure between valves = 0 psi.
26. Minimum distance between valves = 200 ft.

13. From the straight-line traverse between $p_{whf} = 120$ psig and $p_{pfD2} = 1,036$ psig,

$$(p_{pfD1})_{\max} = 695 \text{ psig at } 2,311 \text{ ft (Refer to Fig. 5.22).}$$

14. $\Delta p_{pe1} = [(p_{pfD1})_{\max} - (p_{pfD1})_{\min}] F_p = (695 \text{ psig} - 420 \text{ psig}) 0.068 = 19 \text{ psi}$.

15. $p_{oD2} = p_{ioD2} - \Delta p_{pe1} = 1,086 \text{ psig} - 19 \text{ psig} = 1,067 \text{ psig at } 3,680 \text{ ft}$.

16. Draw the g_{sl} traverse originating at 598 psig at 3,680 ft and extending to the p_{ioD} curve.

$$17. \Delta p_{sD3} = \Delta p_{sD2} + \Delta p_{pe1} = 50 \text{ psi} + 19 \text{ psi} = 69 \text{ psi.}$$

$$18. D_3 = 4,660 \text{ ft for } \Delta p_{sD3} = 69 \text{ psi.}$$

19. From the pressure-depth worksheet for $D_3 = 4,660 \text{ ft}$,

$$(p_{pfD3})_{\min} = 726 \text{ psig, } p_{ioD3} = 1,109 \text{ psig.}$$

$$T_{uvD3} = 154^\circ\text{F.}$$

$$20. p_{oD3} = p_{ioD3} - 2(\Delta p_{pe1}) = 1,109 \text{ psig} - 2(19 \text{ psi}) \\ = 1,071 \text{ psig at } 4,660 \text{ ft.}$$

21. Draw the g_{sl} traverse originating at 726 psig at 4,660 ft and extending to the p_{ioD} curve.

$$22. \Delta p_{sD4} = \Delta p_{sD3} + \Delta p_{pe1} = 69 \text{ psi} + 19 \text{ psi} = 88 \text{ psi.}$$

$$23. D_4 = 5,350 \text{ ft for } \Delta p_{sD4} = 88 \text{ psi.}$$

24. From the pressure-depth worksheet for $D_4 = 5,350 \text{ ft}$,

$$(p_{pfD4})_{\min} = 816 \text{ psig, } p_{ioD4} = 1,125 \text{ psig,}$$

$$T_{uvD4} = 162^\circ\text{F.}$$

25. $p_{oD4} = p_{ioD4} - 3(\Delta p_{pe1}) = 1,125 \text{ psig} - 3(19 \text{ psi}) = 1,068 \text{ psig at } 5,350 \text{ ft}$.

Repeat Steps 21 through 25 for Valve No. 5:

21. Draw the g_{sl} traverse originating at 816 psig at 5,350 ft and extending to the p_{ioD} curve.

$$22. \Delta p_{sD5} = \Delta p_{sD4} + \Delta p_{pe1} = 88 \text{ psi} + 19 \text{ psi} = 107 \text{ psi.}$$

$$23. D_5 = 5,825 \text{ ft for } \Delta p_{sD5} = 107 \text{ psi.}$$

24. From the pressure-depth worksheet for $D_5 = 5,825 \text{ ft}$,

$$(p_{pfD5})_{\min} = 877 \text{ psig, } p_{ioD5} = 1,136 \text{ psig,}$$

$$T_{uvD5} = 168^\circ\text{F.}$$

Note: The distance between the fifth gas lift valve and the maximum valve depth is only 145 ft, which is less

than the assigned 200-ft minimum distance between valves. In all probability, a sixth valve near 5,970 ft could not be justified on the basis of an increase in oil production from this well. An orifice-check valve with a $\frac{1}{4}$ -in. port could be installed near 5,970 ft to assure maximum production if the actual productivity of this well is less than predicted.

25. An orifice-check valve with a $\frac{1}{4}$ -in. port is recommended at 5,825 ft if an orifice-check valve will not be run near 5,970 ft. For a gas lift valve at 5,825 ft, assume a 50-psi additional decrease in the injection-gas pressure and a $(p_{pfD5})_{\min}$ based on 50% of the design value.

$$p_{oD5} = p_{ioD5} - 4(\Delta p_{pe1}) - 50 \text{ psi} = 1,136 \text{ psig} - 4(19 \text{ psi}) - 50 \text{ psi} = 1,010 \text{ psig at } 5,825 \text{ ft.}$$

$(p_{pfD5})_{\min} = 0.5(877 \text{ psig}) = 439 \text{ psig at } 5,825 \text{ ft}$ for calculating the test-rack-set opening pressure of the bottom gas lift valve.

The test-rack opening pressure for gas lift valve No. 5 (Table 5.4) is based on the additional production-pressure effect for the top gas lift valve plus an extra 50-psi decrease in the operating-injection pressure and a flowing production pressure equal to 50% of $(p_{pfD5})_{\min}$ for the design production rate. An orifice-check valve with a $\frac{1}{4}$ -in. orifice would be recommended for most installations.

Continuous-Flow Installation Design When Injection-Gas Pressure is High Relative to Depth of Lift

An additional incremental decrease in the injection-gas pressure can be added to the calculated decrease to ensure unloading a gas lift installation when the injection-gas pressure is high relative to the required depth of lift. The flowing production pressure at the depth of lift limits the maximum injection-gas pressure that can be used in terms of contributing to the lift process. An excessive injection-gas pressure drop across the operating gas lift valve represents an inefficient energy loss. Distributing the decrease in the injection-gas pressure between each succeeding lower unloading gas lift valve prevents multipoint gas injection through upper gas lift valves after the point of gas injection transfers to a lower valve. In other words, the gas lift installation can be unloaded without valve interference and the unloading process is apparent from the injection-gas pressure recording at the surface. A high available injection-gas pressure relative to the depth of lift may exist in areas where both shallow and deep wells are being gas lifted with injection gas from the same system, and the flowing production pressure in the shallow wells will limit the injection-gas pressure that can be used to gas lift these wells.

Example Problem 11. The same well information as given in the previous installation design (Example Problem 10), with the exception of the well depth and temperature and an assumed additional decrease in the injection-gas pressure between each succeeding lower gas lift valve, will be used to illustrate the advantage of this design method when the injection-gas pressure is high relative to the required depth of lift. The valve test-rack-set opening pressures are calculated in Table 5.5.

TABLE 5.5—TEST-RACK-SET OPENING PRESSURES FOR VALVES IN AN INSTALLATION WITH ADDITIONAL DECREASE IN INJECTION-GAS PRESSURE BETWEEN VALVES*

Valve Number	D (ft)	p_{iod} (psig)	p_{oD} (psig)	$(p_{pfd})_{min}$ (psig)	T_{uvD} (°F)	p_{bvD} (psig)	p_{vo} (psig)
1	2,311	1,054	1,054	409	123	1,013	953
2	3,706	1,087	1,008	583	137	981	899
3	4,584	1,107	949	693	146	933	841
4	4,970	1,116	829	370	150	800	716

*Additional decrease in injection-gas pressure = 60 psi.

Changes in well information:

2. Tubing length = 5,000 ft.
3. Maximum valve depth = 4,970 ft.
10. BHT = 150°F at 5,000 ft.
24. Additional decrease in injection-gas pressure between valves = 60 psi.

The g_{fp} traverse is based on a $p_{pfd} = 745$ psig at 5,000 ft and the p_{iod} traverse on $p_{iod} = 1117$ psig at 5,000 ft. Test-rack opening pressure for the bottom gas lift valve is based on an additional 50-psi decrease in the injection-gas pressure and a $(p_{pfd})_{min}$ equal to 50% of the design value. An orifice-check valve with a 1/4-in. orifice would be recommended for most wells.

Continuous-Flow Installation Design With Valve Depths Based on a Variable-Gradient Valve Spacing Design Line

The increasing-flowing-pressure-gradient-with-depth installation design is applicable for production-pressure-(fluid)-operated gas lift valves and injection-gas-pressure-operated gas lift valves with a high production-pressure factor (20 to 30% or greater). One advantage of the design is that there is no required decrease in the injection-gas pressure for each succeeding lower valve. The valves are opened (or closed) as a result of a change in the flowing production pressure at valve depth rather than a change in the injection-gas pressure. For this reason, the gas lift valves must be extremely sensitive to the flowing production pressure to operate properly.

The specifications for the gas lift valves do not affect the valve depths but are used to calculate the test-rack opening pressures. The distance between gas lift valves is controlled by several assumed design factors and the unloading flowing pressure traverse above the point of gas injection. The unloading traverse is based on the conduit size, design daily production rate, available injection gas volume for unloading, etc. The assumed percentage factor for calculating the surface pressure and the assigned design operating pressure differential for the lower gas lift valves locate the valve spacing design line that represents the transfer pressures for the upper unloading gas lift valves. The distance between the upper unloading valves will be less (more valves required) for a higher assumed percentage factor for calculating the valve spacing design line surface pressure; that is, the change in the flowing pressure gradient required to transfer from an upper to the next lower gas lift valve will be less. A lower design percentage factor requires fewer gas lift valves, but the chances of inefficient multipoint gas injection and not unloading to the optimal point of gas injection are increased. The percentage factor for calculating the pressure increase to be added to the flowing wellhead pressure

can be multiplied by the operating injection-gas pressure or by the difference between the operating injection gas and the flowing wellhead pressures. The basic concept is the same. Typically, a 20% factor is applied to the operating injection-gas pressure and a 25% factor to the pressure difference term.

The actual gas throughput performance of the gas lift valves is not included in these design calculations. Multipoint gas injection occurs during unloading operations. After the operating gas lift valve depth is attained, the upper gas lift valves should remain closed. The maximum flowing production pressure exists at the depth of the operating gas lift valve, and the flowing production pressure at the depths of the upper gas lift valves should be less than the production pressure required to open these valves.

Since the injection-gas pressure is not decreased for each succeeding lower gas lift valve and no spacing pressure differential is assumed in this design method, the design operating injection-gas pressure for valve spacing and test-rack opening pressure calculations should be at least 50 psi less than the minimum available injection-gas-line pressure at the wellsite. The lower design pressure allows a range in the injection-gas pressure to provide stem travel for the injection- and production-pressure-operated gas lift valves. If the available range of injection-gas pressure is 50 psi from design to full line pressure, a maximum increase of 50 psi above the initial opening pressure should assure ample stem travel for most injection-pressure-operated gas lift valves. Since the actual flowing production transfer pressure could be as much as 50 psi higher than the design transfer pressure for production-pressure-operated gas lift valves, the necessary stem travel to open these valves should present no problem during unloading operations.

If an operator prefers to design a production-pressure-(fluid)-operated installation on the basis of the injection-gas pressure at the wellsite, an assigned spacing pressure differential (Δp_a) should be used for locating the depths of this type of gas lift valve. The actual maximum transfer pressure will be equal to the design flowing production transfer pressure plus the assigned spacing pressure differential. The end result is similar to using a lower design operating injection-gas pressure, as noted above. Applying a spacing pressure differential of 50 psi rather than decreasing the design operating injection-gas pressure 50 psi does not provide the same additional opening force for stroking an injection-pressure-operated gas lift valve.

Determination of the Gas Lift Valve Depths. The BHP's and BHT usually are referenced to the same depth, which is the lower end of the production conduit (D_d). The steps

for establishing the gas lift valve depths on a pressure-depth worksheet are as follows.

1-4. Follow the same four steps as described for the installation design based on a constant decrease in the operating injection-gas pressure for each succeeding lower valve.

5. Calculate the surface pressure (p_{dl}), for the variable-gradient valve spacing design line on the basis of the assigned spacing design line percent factor F_{dl} , surface operating injection-gas pressure (p_{io}), and the flowing wellhead pressure (p_{whf}).

6. Determine the maximum depth for the variable-gradient valve spacing design line (D_{dl}) on the basis of the assigned design operating pressure differential (Δp_{ao}), the g_{fp} traverse, and the p_{ioD} curve or the maximum depth for a gas lift valve. Record the depth D_{dl} and the variable-gradient valve spacing design line pressure (p_{dlD}) at D_{dl} .

$$p_{dl} = p_{whf} + F_{dl}(p_{io})/100. \quad (41)$$

7. Draw the variable-gradient valve spacing design line by connecting the surface spacing design line pressure (p_{dl}) with the design line pressure at maximum depth (p_{dlD}). The design line represents the flowing production transfer pressure (p_{tD}) at depth for each gas lift valve.

8. Draw a continuation of the flowing production transfer pressure (p_{tD}) curve originating at p_{dlD} and paralleling the p_{ioD} curve to the datum depth D_d when additional gas lift valves will be run below D_{dl} .

9. Using Eq. 23, calculate the depth of the top gas lift valve (D_1) on the basis of the surface kick-off injection-gas pressure (p_{ko}), load fluid gradient (g_{sl}), and the wellhead U-tubing pressure (p_{whu}).

$$D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}}.$$

10. Draw a horizontal line between the valve spacing design line and the p_{ioD} curve at the depth D_1 . Record the p_{tD1} at the intersection of the spacing design line, p_{ioD1} , and the T_{uvD1} at depth D_1 on the unloading temperature traverse.

11. Record the initial injection-gas opening pressure at the depth of the top gas lift valve (p_{oD1}), which is the operating injection-gas pressure at D_1 (Eq. 29).

$$p_{oD1} = p_{oiD1}.$$

The initial injection-gas opening pressure for all valves is equal to the operating injection-gas pressure at depth if there is no decrease in the injection-gas pressure between valves.

12. Draw the static-load fluid traverse (g_{sl}) below the depth of the top gas lift valve with the traverse originating at p_{tD1} and extending to the p_{ioD} curve.

13. Locate the depth of the second gas lift valve (D_2) at the intersection of the static-load fluid traverse with the p_{ioD} curve if there is no pressure differential used for locating the valve depths.

14. Continue to determine the unloading gas lift valve depths graphically by repeating Steps 10 through 13 un-

til the maximum depth D_{dl} for the variable-gradient valve spacing design line is reached or exceeded.

15. Calculate the distance between the remaining gas lift valves (L_{bv}) on the basis of the assigned design operating pressure differential (Δp_{ao}) and the static-load fluid gradient (g_{sl}).

$$L_{bv} = \frac{\Delta p_{ao}}{g_{sl}}. \quad (42)$$

16. Calculate the remaining gas lift valve depths by assuming the previous constant distance between all remaining valves until the maximum depth of lift is attained.

17. Record p_{tD} , p_{ioD} , and T_{uvD} at the depth of each gas lift valve.

18. Record the initial injection-gas opening pressure at the depth of the gas lift valve, which is equal to the operating injection-gas pressure at the valve depth.

$$p_{oD} = p_{ioD}. \quad (43)$$

19. Determine the minimum equivalent port size for injection-pressure-operated gas lift valves on the basis of the corrected daily unloading injection gas volume, p_{ioD} and p_{tD} . The minimum port size for production-pressure-operated gas lift valves is based on the injection-gas requirement to establish p_{tD} for each valve depth.

20. Select the port size for the gas lift valves and record the effective bellows area (A_b), port area (A_p), A_p/A_b ratio and $(1 - A_p/A_b)$, the production-pressure factor (F_p), and the seat angle and stem-ball size for valves with a tapered seat. A port size larger than theoretically required for injection-pressure-operated gas lift valves may be advisable for greater production-pressure effect.

Calculation of the Test-Rack-Set Opening Pressures of the Gas Lift Valves. A tabulation form for these calculations is illustrated in Table 5.6. The equation for calculating the bellows-charged pressure at the design unloading valve temperature (p_{bvD}) is

$$p_{bvD} = p_{oD}(1 - A_p/A_b) + p_{tD}(A_p/A_b), \quad (44)$$

where p_{tD} is the flowing production transfer pressure at valve depth, psig.

The unloading temperature at the valve depth can be obtained from a T_{uvD} traverse on the pressure-depth worksheet or calculated with Eq. 39. The test-rack opening pressure is calculated with Eq. 38 for a tester setting temperature of 60°F and Eq. 40 for a tester temperature (T_{ts}) other than 60°F.

Example Problem 12. Well information for installation design calculations:

1. Tubing size = 2 7/8-in. OD.
2. Tubing length = 5,500 ft.
3. Maximum valve depth = 5,470 ft.
4. Daily production rate = 800 STB/D.
5. Water cut = 60%.
6. Formation GOR = 500 scf/STB.
7. Oil gravity = 35° API.
8. Gas gravity = 0.65.
9. Water specific gravity = 1.04.

TABLE 5.6—CALCULATION OF THE TEST-RACK-SET OPENING PRESSURES OF THE RETRIEVABLE GAS LIFT VALVES*

Valve Number	D (ft)	p_{ioD} (psig)	$(p_{io})_{min}$ (psig)	p_{bvD} (psig)	T_{uvD} (°F)	F_T	p_{vo} (psig)
1	1,756	832	446	736	119	0.887	868
2	2,650	848	530	769	129	0.871	890

7	5,238	895	745	858	157	0.827	943
8	5,470	849	375	732	160	0.823	800

*Valve description: 1-in.-OD gas lift valves. Valve specifications: $A_b = 0.31$ sq in. Port ID = $5/16$ in. $A_p/A_b = 0.247$. $(1 - A_p/A_b) = 0.753$.

10. BHT = 160°F at 5,500 ft.
11. Design unloading wellhead temperature = 100°F.
12. Load fluid gradient = 0.45 psi/ft.
13. U-tubing wellhead pressure = 60 psig.
14. Flowing wellhead pressure = 120 psig.
15. Static fluid level = 0 ft (loaded).
16. Surface kick-off and operating injection-gas pressure = 850 psig.
17. Surface design operating injection-gas pressure = 800 psig.
18. Kick-off injection-gas rate = 800 Mscf/D.
19. Operating injection-gas rate = 500 Mscf/D.
20. Injection-gas wellhead temperature = 80°F.
21. Gas lift valve bellows area = 0.31 sq in. (1-in.-OD valve).
22. Gas lift valve with sharp-edged seat.
23. Test-rack-set temperature = 60°F.
24. Design operating pressure differential = 150 psi.
25. Percent factor for valve spacing design line = 20%.

Solution—Valve Depths. The traverses for the pressures and temperatures used for calculating the gas lift installation design are drawn on a pressure-depth worksheet in Fig. 5.24.

Fig. 5.24—Continuous flow installation design with the valve depths based on a variable-gradient valve spacing design line.

$$1. \text{ Total GLR} = \text{injection GLR} = \frac{800,000 \text{ scf/D}}{800 \text{ STB/D}} = 1,000 \text{ scf/STB.}$$

From the appropriate gradient curves in Fig. 5.20 we obtain the following information.

Actual Depth (ft)	Chart Depth (ft)	Pressure (psig)
0	700	120
5,500	6,200	820

$$p_{pfd} = 820 \text{ psig at 5,500 ft.}$$

2. Draw the g_{fp} traverse by connecting 120 psig at the surface to 820 psig at 5,500 ft with a straight line.

3. p_{io} at surface of 800 psig increases to 900 psig at 5,500 ft (p_{iod}). Draw the p_{ioD} curve by connecting 800 psig at the surface to 900 psig at 5,500 ft with a straight line.

4. Plot the unloading temperature of 100°F at the surface and 160°F at 5,500 ft, and draw the T_{uvD} traverse by connecting 100°F at the surface to 160°F at 5,500 ft with a straight line.

5. From the pressure-depth worksheet for $\Delta p_{ao} = 150$ psi,

$$D_{dl} = 4,858 \text{ ft and } p_{dlD} = 738 \text{ psig at 4,858 ft.}$$

$$6. p_{dl} = p_{whf} + \frac{F_{dl}(p_{io})}{100} = 120 + \frac{20(800)}{100} = 280 \text{ psig at surface.}$$

7. Draw the variable-gradient valve spacing design line by connecting 280 psig at the surface to 738 psig at 4,858 ft with a straight line. This traverse represents the flowing production transfer pressures at valve depth (p_{TD}).

8. For locating valves below D_{dl} , draw a straight line originating at 738 psig at 4,858 ft and paralleling p_{ioD} curve to 750 psig at 5,500 ft (900 psig - 150 psi = 750 psig).

$$9. D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}} = \frac{850 - 60}{0.45} = 1,756 \text{ ft.}$$

10. From the pressure-depth worksheet for $D_1 = 1,756$ ft,

$$p_{tD1} = 446 \text{ psig}, p_{ioD1} = 832 \text{ psig}, \text{ and } T_{uvD1} = 119^\circ\text{F}.$$

11. $p_{oD1} = p_{ioD1} = 832$ psig at 1,756 ft.

12. Draw the g_{sl} traverse (0.45 psi/ft) below the top valve originating at 446 psig at 1,756 ft and extending to the p_{ioD} curve.

13. $D_2 = 2,650$ ft at the intersection of the p_{ioD} curve.

Repeat Steps 10 through 13 until the calculated valve depth exceeds D_{dl} . Calculations for the third gas lift valve are as follows.

10. From the pressure-depth worksheet for $D_2 = 2,650$ ft,

$$p_{tD2} = 530 \text{ psig}, p_{ioD2} = 848 \text{ psig}, \text{ and } T_{uvD2} = 129^\circ\text{F}.$$

11. $p_{oD2} = p_{ioD2} = 848$ psig at 2,650 ft.

12. Draw the g_{sl} traverse below the second valve.

13. $D_3 = 3,387$ ft.

Repeat Steps 10 through 13 for the fourth gas lift valve.

10. $p_{tD3} = 600$ psig, $p_{ioD3} = 862$ psig, and $T_{uvD3} = 137^\circ\text{F}$.

11. $p_{oD3} = p_{ioD3} = 862$ psig at 3,387 ft.

12. Draw the g_{sl} traverse below the third valve.

13. $D_4 = 3,994$ ft.

Repeat Steps 10 through 13 for the fifth gas lift valve.

10. $p_{tD4} = 657$ psig, $p_{ioD4} = 873$ psig, and $T_{uvD4} = 144^\circ\text{F}$.

11. $p_{oD4} = p_{ioD4} = 873$ psig at 3,994 ft.

12. Draw the g_{sl} traverse below the fourth valve.

13. $D_5 = 4,994$ ft.

Repeat Steps 10 through 13 for the sixth gas lift valve.

10. $p_{tD5} = 704$ psig, $p_{ioD5} = 882$ psig, and $T_{uvD5} = 149^\circ\text{F}$.

11. $p_{oD5} = p_{ioD5} = 882$ psig at 4,994 ft.

12. Draw the g_{sl} traverse below the fifth valve.

13. $D_6 = 4,905$ ft ($D_6 > D_{dl}$).

14. Since $D_6 > D_{dl}$, the p_{tD} traverse parallels the p_{ioD} curve ($p_{tD} = p_{ioD} - \Delta p_{ao}$), repeat Steps 10 and 11.

10. $p_{tD6} = 739$ psig, $p_{ioD6} = 889$ psig, and $T_{uvD6} = 154^\circ\text{F}$.

11. $p_{oD6} = p_{ioD6} = 889$ psig.

Remaining gas lift valve depths and pressures.

$$15. L_{bv} = \frac{\Delta p_{ao}}{g_{sl}} = \frac{150}{0.45} = 333 \text{ ft.}$$

16. $D_7 = D_6 + L_{bv} = 4,905 + 333 = 5,238$ ft.

17. From the pressure-depth worksheet for $D_7 = 5,238$ ft,

$$p_{tD7} = 745 \text{ psig}, p_{ioD7} = 895 \text{ psig}, \text{ and } T_{uvD7} = 157^\circ\text{F}.$$

18. $p_{oD7} = p_{ioD7} = 895$ psig at 5,238 ft.

Repeat Steps 16 and 18 until maximum valve depth is at-

tained. Calculations for the eighth gas lift valve are as follow:

16. $D_8 = D_7 + L_{bv} = 5,238 + 333 = 5,571$ ft $> 5,470$ ft, $D_8 = 5,470$ ft (maximum valve depth).

17. $p_{tD8} = 749$ psig, $p_{ioD8} = 899$ psig, and $T_{uvD8} = 160^\circ\text{F}$.

18. If a gas lift valve rather than an orifice-check valve will be installed as the bottom valve, assume that

$$p_{oD8} = p_{ioD8} - 50 \text{ psi} = 899 - 50 = 849 \text{ psig at } 5,470 \text{ ft,}$$

$$p_{tD8} = 0.5(749) = 375 \text{ psig at } 5,470 \text{ ft.}$$

19. $q_{ga} = 800$ Mscf/D (given),

$$T_{gD} = 80^\circ\text{F} + 4,858 \text{ ft} \left(\frac{160^\circ\text{F} - 80^\circ\text{F}}{5,500 \text{ ft}} \right) \\ = 151^\circ\text{F at } 4,858 \text{ ft,}$$

$$C_{gT} = 0.0544 \sqrt{0.65(151^\circ\text{F} + 460)} = 1.084, \text{ and}$$

$$q_{gc} = C_{gT}(q_{ga}) = 1.084(800 \text{ Mscf/D}) \\ = 867 \text{ Mscf/D.}$$

For $p_{ioD} = 888$ psig and $p_{dlD} = 738$ psig at 4,858 ft, equivalent port size = $1\frac{1}{4}$ to $1\frac{3}{4}$ in. for 867 Mscf/D from Fig. 5.5.

20. Minimum standard port size = $\frac{1}{4}$ -in. Select a $\frac{5}{16}$ -in. port for a greater production-pressure factor. For $\frac{5}{16}$ -in. OD port with a sharp-edged seat and $A_b = 0.31$ sq in.,

$$A_p/A_b = 0.247, (1 - A_p/A_b) = 0.753, \text{ and}$$

$$F_p = 0.329 \text{ from Table 5.2.}$$

The test-rack opening pressure for gas lift valve No. 8 (Table 5.6) is based on a 50-psi decrease in the operating injection-gas pressure and a flowing production-transfer pressure equal to 50% of the flowing production-transfer pressure at the depth of this bottom valve. An orifice-check valve with a $\frac{1}{4}$ -in. orifice would be recommended for most installations.

Production-Pressure-(Fluid)-Operated Gas Lift Valves for a Variable Gradient Valve Spacing Continuous-Flow Installation

As previously noted in the discussion of a variable gradient valve spacing continuous-flow installation, production-pressure-(fluid)-operated gas lift valves are particularly applicable for this type of design. The depths of the valves remain the same for production-pressure and injection-pressure operation. The recommended port sizes and the test-rack setting pressures are different.

The flowing production pressure at valve depth during unloading operations varies significantly as compared to the injection-gas pressure. The effective bellows area less the port area is exposed to this changing flowing production pressure for production-pressure-operated gas lift valves. Since the flowing production pressure provides

TABLE 5.7—FLOWING PRODUCTION PRESSURE AT VALVE DEPTH FROM GRADIENT CURVES

Assume Total Gas/Liquid Ratio (scf/STB)	Actual Depth (ft)	Chart Depth (ft)	Pressure (psig)
100	0	500	120
	1,756	2,256	540 > p_{iD1}
200	0	600	120
	1,756	2,356	402 < p_{iD1}

the primary opening force to open a production-pressure-operated valve, the upper valves will open fully during unloading operations because of the wide range in the flowing production pressure at the upper valve depths. The smallest possible port or choke size based on the injection-gas requirement for unloading and operating is recommended to limit the maximum injection-gas throughput of the upper valves. A large port or choke size in the upper unloading gas lift valves may prevent valve closure without a drastic decrease in the operating injection-gas pressure. The test-rack opening pressures of the upper valves are considerably lower than the opening pressures for the deeper valves, since the primary opening force for these valves is based on the flowing production-transfer-pressure traverse rather than the injection-gas-pressure-at-depth traverse. Inefficient gas lift operations result from multipoint gas injection and the inability to unload to a lower valve with single-point gas injection when upper valves will not close.

Since the depths of the valves remain the same for injection-pressure and production-pressure operation, the previous continuous-flow installation design with a graphical pressure-depth display in Fig. 5.24 will be used to illustrate the calculations for production-pressure-operated valves.

The injection-gas requirement to unload and to lift a well increases with the depth of lift for an assumed constant production rate. After the valve depths are determined as outlined in the previous example problem, the first step before calculating the test-rack opening pressure of production-pressure-operated gas lift valves is to establish the necessary port size. The gradient curves in Fig. 5.20 will be used to establish the injection-gas requirement for each gas lift valve. The object is to determine the approximate total gas-liquid ratio (TGLR) curve that will pass through a flowing wellhead pressure of 120

psig at the surface and 446 psig at 1,756 ft. The TGLR curves that bracket 446 psig at 1,765 ft are given in Table 5.7.

Example Problem 13. Installation Design Calculations. The TGLR is between 100 and 200 scf/STB since the flowing production pressures for these GLR's bracket the design flowing-production-transfer pressure of 446 psig. An approximate TGLR can be calculated by proportional interpolation, and this TGLR can be obtained for each valve depth and flowing-production-transfer pressure as outlined for the top gas lift valve. A tabulation of these values for the unloading TGLR are given in Table 5.8. After the TGLR is established, an equivalent port size can be obtained from Fig. 5.5 on the basis of the daily injection-gas throughput rates that have been corrected to chart basis. This information completes Table 5.8.

The smallest standard port size based on the daily injection-gas requirement in Table 5.8 is assumed for the valve opening pressure calculations in a tester. Since the flowing production pressure rather than the injection-gas pressure at valve depth is exerted over the effective bellows area less the port area for a production-pressure-operated gas lift valve, the equation for the bellows-charged pressure at valve temperature differs from the equation for an injection-pressure-operated gas lift valve. The equation for a production-pressure-operated gas lift valve is

$$p_{bvD} = p_{iD}(1 - A_p/A_b) + p_{ioD}(A_p/A_b). \quad (45)$$

The test-rack-set opening pressure is calculated using Eq. 38 or Eq. 40, which is the same for injection-pressure-operated gas lift valves. A summary of the calculations for production-pressure-operated gas lift valves in this installation is tabulated in Table 5.9. An orifice-check valve or injection-pressure-operated gas lift valve is recommended for the bottom valve in a production-pressure-operated valve installation. If the BHFP is lower than predicted, maximum production is not possible with a production-pressure-operated gas lift valve because this type of valve will not remain open for a low BHFP.

If an injection-pressure-operated gas lift valve will be run instead of an orifice-check valve with a ¼-in. choke, the tester-set opening pressure should be based on an operating pressure less than the design operating injection-gas pressure. One recommendation is to assume a 50-psi lower operating injection-gas pressure and the flowing production pressure at valve depth equal to the flowing wellhead

pressure. The tester-set opening pressure of the bottom injection-pressure-operated gas lift valve No. 8 is based on these assumptions.

The design daily production rate of 800 STB/D was assumed for calculating the injection-gas requirement for the upper five gas lift valves. This design production rate cannot be gas lifted from the sixth or deeper valve depths on the basis of the gradient curves in Fig. 5.20. The maximum production rate from the well decreases as the required depth of lift increases. The three valves below the valve at 4,494 ft in Table 5.9 were arbitrarily assumed to have a 1/4-in. port, since this port size should assure adequate injection-gas throughput. A 3/16-in. port size may provide ample injection-gas passage. If the smaller port sizes assigned in Table 5.9 are unavailable, chokes can be installed upstream of the port, as illustrated in Fig. 5.12, for valves with a crossover seat or downstream of the port for valves without a crossover seat.

Casing (Annular) Flow Installation Design

The design calculations for an annular flow installation are similar to those for a continuous flow installation through the tubing. Intermittent gas lift is not recommended for casing flow. Since the gross liquid production is generally thousands of barrels per day, selecting valve port sizes for adequate gas passage is very important for annular flow installations. Actual gas lift valve performance based on bellows-assembly load rate is an important factor in the design calculations for casing flow installations because of the high injection-gas requirements. The increase in the injection-gas pressure to overcome the bellows-assembly load rate and to attain the needed equivalent port area for a required injection-gas throughput should be considered.

Selection of the proper size of gas-injection tubing string that will deliver the required daily injection-gas requirement for unloading and operating is absolutely essential. An initial assumption can be an injection tubing size that will deliver the maximum daily injection-gas requirement with no pressure loss—i.e., the increase in the injection-gas pressure with depth as a result of gas column density is offset by the flowing frictional pressure loss. This should be the smallest nominal tubing size considered for the gas-injection string. Charts for static injection-gas pressure at depth cannot be used for the valve spacing calculations.

The Cullender and Smith⁸ correlation is recommended

for calculating the pressure loss in the injection-gas tubing string. This method for calculating the flowing injection-gas pressure at depth was derived for a gas producing well and not for gas injection. The only difference in the calculations is the friction term. When gas is being injected rather than being produced, the sign for the friction term changes—i.e., the friction term becomes negative in the Cullender and Smith equation for gas injection.

The depth of the top valve in a casing flow installation can be deeper than that in a tubing flow installation if the fluid level is not at the surface and if this fluid level is known. The top valve can be located below the fluid level by taking advantage of the ratio of the tubing to the annular capacities. The fluid level in the casing annulus will rise only a few feet when depressing the fluid level in the tubing many feet. The following equation can be used to calculate the top valve depth if the static fluid level is not near the surface.

$$D_1 = L_{sf} + \frac{p_{ko} - p_{whu} - \Delta p_a}{g_{sl}(F_{tc} + 1)}, \dots \dots \dots (46)$$

where F_{tc} is the ratio of capacities of tubing/casing annulus, consistent units.

The check disk in the reverse flow check valve seats in the opposite direction for casing flow as compared to a tubing flow installation and allows gas passage from the injection-gas tubing to the casing. In the retrievable series the valve is similar to a production-pressure-operated valve, except the integral check valve is reversed (for gas flow from gas-injection tubing to casing).

Since bellows-charged gas lift valves have a lower bellows-assembly load rate than a spring-loaded valve, a bellows-charged valve is recommended for high injection-gas volumetric throughput as required for most casing flow installations. Fortunately, the valve temperature at depth is not difficult to predict accurately in high-volume wells. The flowing surface temperature will be near the BHFT; therefore, the operating temperature of all valves in a high-volume, casing-flow, gas lift installation will be approximately the same. An important caution: never use the surface injection-gas temperature to estimate the valve temperature at depth. The injection gas will attain the flowing fluid temperature within about a thousand feet from the surface. The flowing wellhead temperature of

Fig. 5.25—Intermittent gas lift cycle of operation. (a) Operating valve closed and slug entering flowline. (b) Formation fluid feed-in. (c) Initial opening of operating gas lift valve. (d) Operating valve open and slug being displaced.

the fluid production should be used to establish the operating valve temperature at depth. This same consideration is applicable to the Cullender and Smith injection-gas-pressure-at-depth calculations.

Intermittent Gas Lift

Introduction

Intermittent gas lift is applicable to low-productivity wells and to high-productivity wells with a very low reservoir pressure. Chamber installations may be required to gas lift the low-BHP wells with a high productivity index. Occasionally, high-cycle-frequency intermittent gas lift operation has proven more efficient than continuous flow for lifting a viscous crude or for an emulsion condition. Gas lift normally is not recommended for lifting a highly viscous crude. Emulsion-breaking chemical injected into the injection gas line to individual wells has solved the emulsion problem in many gas lift installations.

As the name implies, the reservoir fluid is produced intermittently by displacing liquid slugs with high-pressure injection gas, as illustrated in Fig. 5.25.⁹ The injection gas can be controlled by a time-cycle controller or a choke. Electronic timers are replacing the older clock-driven intermitter pilots. Not all gas lift valves will operate on choke control. The number of intermittent gas lift installations on time-cycle control far exceeds the number of choke-controlled installations.

Disadvantages of Intermittent Gas Lift

Intermittent gas lift has several disadvantages compared to continuous flow operations. If the desired production can be gas lifted by continuous flow, this method is preferable. It is difficult to handle the high instantaneous gas volumes properly in the low- and high-pressure sides of a closed rotative gas lift system. Choke control of the injection gas into a well eliminates the removal of injection gas at high instantaneous rates from the high-pressure system but does not solve the problem of the large gas volume beneath the slug that enters the low-pressure system fol-

lowing displacement of the liquid slug to the surface. Gas volume storage requires pressure difference and physical capacity. The difference between the compressor discharge pressure and the operating injection-gas casing pressure usually will exceed the difference between the separator and compressor suction pressures. For this reason, retaining the needed injection-gas volume in the low-pressure side of a small, closed rotative gas lift system can be difficult unless the injection gas cycles are staggered properly. Staggering of the injection-gas cycles is less precise on choke control than with a time-cycle controller. The electronic timers have improved the accuracy of controlled injection, whereby the injection cycles can be scheduled to prevent more than one well receiving injection gas at the same time. Therefore, total injection plus formation gas can be scheduled to enter the low-pressure system at a more constant rate with accurate time cycle than with choke control of the injection gas.

Severe surging in the BHP can present a serious production problem in unconsolidated sand wells where sand production cannot be controlled properly. Sand bridging can plug off production and result in cleanout costs. Pressure surges in a chamber installation may be far more severe than in a regular intermittent installation. A wireline-release type of lock with an equalizing valve is recommended for the standing valve in a chamber to prevent the standing valve from being blown out of its seating nipple following blowdown after an injection-gas cycle. Some companies have resorted to increasing the operating injection-gas pressures to lift by continuous flow from near TD rather than intermittent-lift wells that produce sand.

The total energy in the formation and injection gas is not fully utilized with intermittent gas lift. The high-pressure gas under the slug is spent in the flowline and does not contribute to the lift process. This is one reason for using continuous-flow operations for a high-GLR well if possible. Plunger lift may be the best method for lifting certain high-GLR wells.

The injection-gas requirements are usually higher for intermittent than for continuous-flow gas lift operations. The tubing beneath the slug must be filled with injection gas to displace the liquid slug to the surface. The tubing under the liquid slug cannot be half or two-thirds filled with high-pressure gas. For this reason, the gas requirements for intermittent lift of low-GLR wells that will not partially flow can be estimated with a reasonable accuracy. Unfortunately, articles have been published that imply that a well, or group of wells, is being lifted with a certain type of gas lift valve that results in an injection-gas requirement of only a fraction of the gas volume needed to fill the tubing beneath the liquid slug. Although gas orifice meter charts are published to prove these claims, the truth is that these wells are partially flowing. Only minimal agitation and displacement of the liquid slug is required to lift these wells. Most of the energy needed to lift the well is being furnished by the formation and not the gas lift system.

The injection-gas requirements for intermittent and continuous-flow gas lift should be compared before eliminating continuous flow operations. With the advent of several reliable multiphase flow correlations, the predictable range of continuous flow has been extended to much lower daily production rates. A careful investigation of

the proper production conduit size for lifting a well by continuous flow may permit this type of gas lift in place of intermittent gas lift, where intermittent lift can result in operational problems.

Types of Intermittent Gas Lift Installations

Intermittent gas lift is used for tubing and not annular flow. Most installations will have a packer and some will include a standing valve in the tubing. Although illustrations of most intermittent gas lift installations will show a standing valve, many actual installations with very low productivity indices will not have a standing valve. The injectivity of a well is less than the productivity; therefore, very little fluid will be pushed back into a tight formation during the injection-gas cycle. If a well produces sand, a standing valve is recommended only if it is essential. A seating nipple should be installed at the lower end of the tubing string in intermittent installations where a standing valve may be needed.

When the working fluid level in a well does not result in a minimum starting slug length that results in a production pressure at the depth of the operating gas lift valve equal to 50 to 60% of the operating injection-gas pressure at depth, a chamber installation or plunger should be considered. The calculated depths of the unloading gas lift valves is the same as a regular intermittent-lift installation. The chamber design converts a few feet of fluid above the formation into many feet of fluid in the tubing above the standing valve before injection gas enters the production conduit. The standing valve is required for efficient chamber operation to ensure U-tubing all fluid from the chamber into the tubing rather than allowing fluid to be pushed into the formation. If a chamber is not installed, a plunger downhole stop and bumper spring can be set by wireline immediately above the operating gas lift valve. The plunger will reduce the injection-gas slippage through the liquid slug and decrease the liquid fallback. Smaller starting liquid slugs can be gas lifted efficiently with the plunger acting as a sealing interface between the liquid slug and injection gas.

Effect of Installation Design Methods on Unloading Injection-Gas Pressure

The intermittent gas lift installation design methods outlined here differ from designs presented in earlier gas lift literature. When the first single-element, bellows-charged gas lift valves were installed for intermittent gas lift service, the valve opening pressures were decreased at least 25 psi, and in some instances as much as 50 psi, for each succeeding lower valve to ensure unloading the well. The surface casing pressure would decrease as each lower gas lift valve was uncovered. A typical two-pen pressure recorder unloading chart from this type of design is displayed in Fig. 5.26.

A 25- to 50-psi decrease in the surface operating injection-gas pressure is required for a balanced type of gas lift valve to unload a well. The term "balance" implies that the production pressure at valve depth has no effect on the initial injection-gas opening pressure of the valve. When the depth of lift is deep and the maximum available injection-gas pressure for lifting the well is low, balanced-type gas lift valves are a poor choice for intermittent gas lift installations. An installation with 10 gas lift valves will have a 270-psi loss in the available

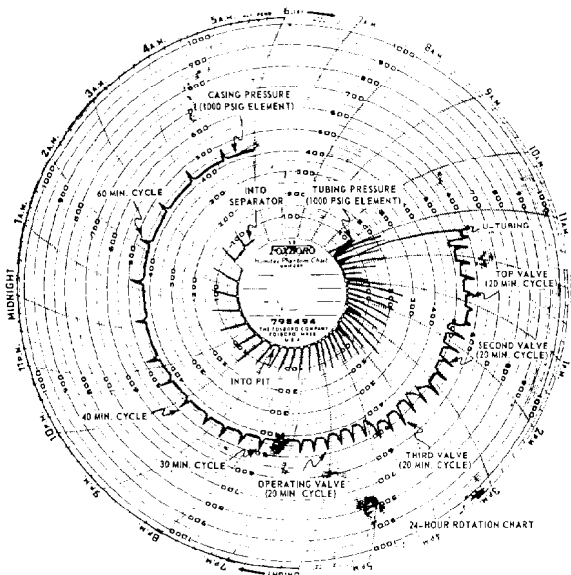

Fig. 5.26—Two-pen pressure recording chart illustrating intermittent gas lift unloading operations with valves having decreasing opening pressures.

injection-gas pressure on the basis of a decrease of 30 psi for each valve, and this does not include the pressure drop below line pressure for the top valve.

Most of the current design methods for an intermittent gas lift installation do not require any decrease in surface operating injection-gas pressure for each succeeding lower valve. Unbalanced gas lift valves with a high production-pressure factor are used in these intermittent installation designs. The operating gas lift valve will always be the valve with the highest production pressure at valve depth that is less than the injection-gas pressure at the same depth. The valve with the highest production pressure will have the lowest initial injection-gas opening pressure, as can be noted from Fig. 5.15, for a valve with a high production-pressure factor. Rather than using a decrease in the injection-gas pressure to control the initial opening pressure of a valve, the production pressure at valve depth provides the difference in the initial opening pressures between gas lift valves. The operating principles for this design method are illustrated in Table 5.10.

TABLE 5.10—GAS LIFT VALVE INITIAL SURFACE OPENING PRESSURES AFTER CONTROLLER OPENS ON THE BASIS OF PRODUCTION PRESSURE AT VALVE DEPTH*

D (ft)	p_{vcD}^{**} (psig)	$p_{p/D}$ (psig)	p_{pe} (psi)	p_{oD} (psig)	Surface p_o^{\dagger} (psig)

* Surface closing pressure for all gas lift valves: $p_{vc} = 600$ psig. Gas pressure at depth factor: $F_g = 2.3$ psi/100 psi/1,000 ft. Gas lift valve: 1 1/2-in. OD with 1/2-in. ID sharp-edged seat.

** Valve closing pressure at valve depth.

[†] Initial valve opening pressure at surface.

The 1½-in.-OD valves with a ½-in.-ID sharp-edged seat has a production-pressure factor of 0.342 from Table 5.2. The working fluid level in the tubing for Table 5.10 is assumed to be at 4,600 ft at the instant the time-cycle controller on the injection-gas line opens. The wellhead tubing gas pressure is 60 psig at 4,600 ft, and the production fluid gradient is 0.40 psi/ft for this example.

Since the production pressure at valve depth exceeds the calculated injection-gas pressure at the same depth, the valve at 6,500 ft cannot be the operating valve. The bottom valve at 6,500 ft is open with the check closed, and the valve is under the fluid level in the casing annulus. The gas lift valve at 6,000 ft is the operating valve because this valve has the lowest surface initial opening pressure of all valves above the fluid level in the casing annulus with the highest production pressure at valve depth that is less than the injection-gas pressure at the same depth. There will be no interference from opening of the upper gas lift valves before the valve at 6,000 ft opens since the initial injection-gas opening pressure of this valve is 70 psi less than the next upper gas lift valve. This type of design is ideal for dual intermittent gas lift installations with a common injection-gas source. The surface closing injection-gas pressure is constant and does not change with the depth of lift.

The point of gas injection will adjust automatically to the BHFP. The principles of operation based on using the production-pressure effect rather than decreasing the injection-gas pressure for each succeeding lower valve are apparent in Table 5.10.

This design concept is better than installations with production-pressure-operated gas lift valves because the closing pressure of the injection-pressure-operated gas lift valves is controllable. The closing pressure of production-pressure-operated valves depends on a decrease in the production pressure at valve depth after a slug surfaces, which may or may not occur for a high injection-gas cycle frequency. The actual closing pressure of production-pressure-operated gas lift valves can approach their set pressures if the backpressure is excessive and the production pressure at valve depth does not decrease until the valves close.

Prediction of Daily Production Rates

Two basic factors control the maximum production from a high-rate intermittent gas lift installation: (1) the total liquid production per cycle, and (2) the maximum number of injection-gas cycles per day. An intermittent gas lift installation should be designed to maximize the liquid recovery per cycle on low- and high-capacity wells. All restrictions in and near the wellhead should be eliminated. For this reason, streamlined wellheads are recommended. If the wellhead cannot be streamlined, all unnecessary elbows and tees should be removed to reduce the number of bends between the tubing and flowline. If the velocity of the liquid slug is reduced before the entire column of liquid can be displaced into the horizontal flowline, additional injection-gas breakthrough, or gas slippage, will occur and decrease the liquid recovery per cycle. Performance of the operating gas lift valve, or valves, is important for efficient liquid-slug displacement. The operating gas lift valve should have a large port that will open quickly to ensure ample injection-gas volumetric throughput for efficiently displacing the liquid slug.

The gas lift valve should not open slowly and meter a small injection-gas volume into the production conduit, which would tend to aerate and to percolate through the liquid slug rather than displace the slug. Rapid increase in the injection-gas casing pressure after a time-cycle controller opens will improve the gas lift valve performance and ensure a more efficient displacement of a liquid slug in a time-cycle-operated intermittent lift installation. Ample injection-gas volume must be available at the wellsite from the high-pressure injection-gas system. If the line pressure in the high-pressure system decreases immediately to the casing pressure, poor valve action is the fault of the high-pressure system and not the gas lift installation in the well.

The size and length of the flowline can significantly affect the maximum cycle frequency. A flowline should always be at least one size larger than the tubing. The maximum number of injection-gas cycles per day is controlled by the time required for the wellhead pressure to return to the separator or production header pressure after a slug surfaces. Reducing the separator pressure increases the starting slug length for the same flowing BHP but does not solve the problem of decrease in wellhead pressure. When comparing or predicting the maximum production from two high-capacity wells on intermittent gas lift, the size and length of the flowlines must be considered. If one installation requires 45 minutes and another 10 minutes for the wellhead pressure to approach the production header pressure after a slug surfaces, the difference in maximum production (assuming that both wells have the deliverability) is not the result of the gas lift installation in the well but of the surface facilities.

One definition of liquid fallback is the difference between the starting liquid slug volume, or length, and the produced slug volume, or length. The purpose of a properly designed intermittent gas lift installation is to recover as much as possible of the starting slug, thus reducing the liquid fallback. An important parameter that can be observed is the average slug velocity. The operating gas lift valve will open in less than 30 seconds after a time-cycle controller opens in most intermittent lift installations. An approximate slug velocity can be estimated by assuming the valve opens 15 seconds after the controller opens and recording the time elapsed from this instance until the slug surfaces. In most installations, the depth of the operating gas lift valve is known or can be estimated from an acoustical survey. If the average liquid slug velocity is not near or exceeding 1,000 ft/min, the liquid fallback may be excessive. A slug velocity less than 800 ft/min can result in excessive fallback.

The maximum number of injection-gas cycles per day can be estimated by assuming 2 to 3 min/1,000 ft of lift for typical flowline sizes and lengths. The actual time can be less for installations on a production platform without flowlines and much longer for intermittent installations with small ID and/or long flowlines, such as a well with 2⅞-in.-OD tubing and a 2-in. flowline that is 2 miles in length. Also, emulsions and other unique well problems can decrease the maximum number of injection cycles per day and the recoverable liquid production per cycle.

Injection Gas Requirement for Intermittent Lift

Multiphase flow correlations are not applicable for the prediction of the gas requirement to lift a well by inter-

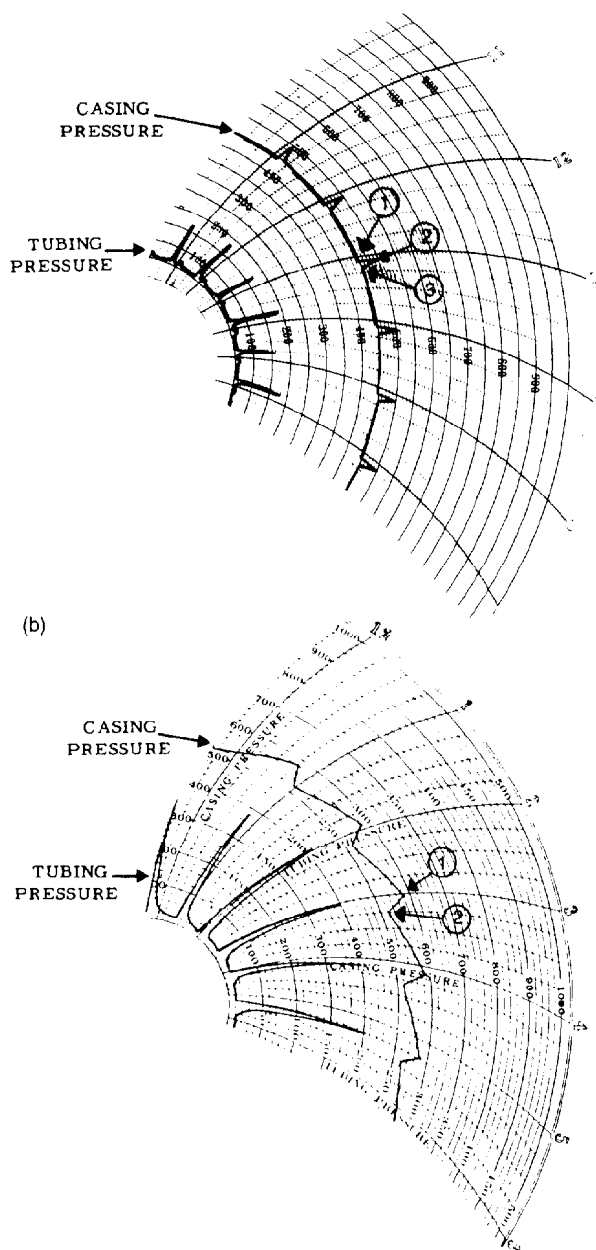

Fig. 5.27—Two-pen pressure recording charts from intermittent gas lift installations with time cycle and choke control of the injection gas. (a) Time-cycle control: (1) time-cycle controller opens, (2) time-cycle controller closes, and (3) gas lift valve closes. (b) Choke control: (1) gas lift valve opens and (2) gas lift valve closes.

mittent gas lift. Expansion and aeration of the injection and formation gas are used from the flowing production pressure at the operating gas lift valve depth to the flowing production wellhead pressure during continuous flow operations. Since intermittent gas lift is the displacement of a liquid slug by high-pressure gas, the injection-gas requirement is not based on aeration but on the volume of gas needed to fill the tubing between the bottom of the slug when it reaches the surface and the depth of the deepest gas lift valve that opens during an injection gas cycle. The injection-gas pressure following the liquid slug at the instant this slug surfaces is spent in the flowline

and does not contribute to the lift process. The energy in the formation gas does little to assist in lifting most wells.

One method for calculating the injection-gas requirement is to assume the produced slug to be a solid liquid column without any afterflow production in the tailgas. The theoretical pressure under this liquid slug at the instant the slug surfaced would be the wellhead production pressure plus the length of the produced slug times the liquid gradient. The actual average pressure in the tubing under a liquid slug is more than this pressure based on the solid slug length and a dry gas gradient because of the injection-gas penetration of the slug during the lift process and the frictional losses. An average injection-gas pressure in the tubing equal to the theoretical pressure under the produced liquid slug plus the surface closing pressure of the operating gas lift valve divided by two is a realistic assumption on the basis of numerous BHP measurements in intermittent gas lift installations. The pressure loss through the operating gas lift valve is assumed equal to the increase in gas column pressure to the depth of the valve.

The total volume of injection gas per cycle depends on the average pressure in the tubing under the slug and the physical capacity of the tubing. When the depth of lift is several thousand feet and the equivalent produced slug length is only a few hundred feet, the length of this slug may be subtracted from the tubing length above the operating gas lift valve for calculating the capacity of tubing to be filled with injection gas each cycle. This assumption implies that the rate of decrease in the pressure of the expanding injection gas volume beneath the liquid slug is less than the rate of decrease in the pressure exerted by the slug length remaining in the tubing as the upper portion of the slug enters the flowline.

Comparison of Time Cycle to Choke Control of the Injection Gas

The advantage of choke-controlled injection-gas volume for an intermittent gas lift installation is the low volumetric injection-gas rate from the high-pressure system into a well. Several conditions must be met before choke control of the injection gas can be used successfully. The gas lift valve must be suited for choke-control operation, and the casing annulus must provide adequate storage capacity for the injection-gas volume needed to displace the slug. Gas lift valves designed to operate on choke control are more complicated and expensive than an unbalanced, single-element, gas lift valve. Clean, dry gas is extremely important and very-low-capacity wells are more difficult to choke control because of the small surface injection-gas choke size required for the low daily injection gas volume needed to lift the well. A pressure-reducing regulator, to maintain a constant maximum valve opening casing pressure between valve operating cycles, may be necessary to permit the use of a larger-sized choke in the injection-gas line. Other limitations of choke control of the injection gas include the maximum liquid slug size that can be lifted each cycle and the maximum number of injection-gas cycles per day. Time-cycle control of the injection gas should be considered for high-rate intermittent-lift operations. Time-cycle and choke-control operations are illustrated by two-pen pressure recorder charts in Fig. 5.27.

Most intermittent gas lift installations use time-cycle-operated controllers on the injection-gas line because of the many advantages of time cycle over choke control of the injection gas. The rugged unbalanced, single-element, bellows-charged gas lift valves with a large port can be used, and much larger liquid slugs can be lifted because injection gas in the annulus can be supplemented with gas from the high-pressure system. The differences in time cycle and choke control of the injection gas can be explained by use of Fig. 5.28.

The curve for injection-gas requirement per cycle in Fig. 5.28 represents the injection-gas volume needed to fill the tubing beneath the liquid slug for displacing this slug to the surface. The volume of injection gas stored in the casing annulus between the initial opening and theoretical closing pressures of the operating gas lift valve is represented by the injection gas volume stored within the casing annulus curve. The slope of this curve depends on the capacity of the casing annulus and the gas lift valve spread. The maximum theoretical valve spread would occur with a production pressure at the operating gas lift valve depth equal to zero, which is not possible. However, the volume of injection gas at standard conditions stored within the casing annulus can be calculated for this condition of valve opening pressure. An operating valve will have no spread when the initial opening injection-gas pressure, production pressure, and theoretical closing pressure are the same. Again, the volume of injection gas at standard conditions in the casing at the theoretical closing pressure of the operating gas lift valve can be calculated. The volume of gas stored in the casing annulus at zero flowing production pressure is the difference between the above two volumes of injection gas at standard conditions. There is no gas available from the casing when the initial valve opening pressure is equal to its closing pressure and the spread is zero. This represents the second point for the curve. The curve defines the injection-gas volume stored in the casing annulus between a production pressure of zero and the theoretical valve closing pressure.

The size of the largest liquid slug that can be lifted by choke control with a pilot valve using the injection-gas volume stored in the casing annulus is based on the intersection of the two curves. The maximum production pressure is limited to a production pressure at this intersection where the injection-gas volume available to lift the slug is equal to injection-gas volume required to displace the slug. The well could be lifted by choke control with a production pressure less than the pressure at this intersection, but insufficient gas is available from the casing annulus for higher production pressures.

Points 1 and 2 on the dashed line represent a production pressure much higher than the pressure defined by the point of intersection. The higher production pressure represents a larger liquid slug, which requires a greater volume of injection gas than the smaller slugs. The injection gas available from the casing annulus as the result of valve spread is represented by Point 1. The greater remaining volume of injection gas required to displace the slug is furnished from the high-pressure system by setting a time-cycle controller to remain open after the gas lift valve has opened. In other words, the injection-gas volume between Points 1 and 2 is supplied from the high-pressure system by proper setting of the time-cycle controller.

Fig. 5.28—Injection-gas volumes per cycle for intermittent gas lift operations.

The previous calculations represent several simplifying assumptions. The total available injection-gas volume per cycle should include the small volumetric gas rate through the choke while the operating gas lift valve is open for a choke-controlled installation. The advantages of being able to overrun the initial opening pressure of an operating gas lift valve with a time-cycle controller are apparent for optimizing the injection-gas volume per cycle and selecting the number of injection-gas cycles per day. Electronic timers have increased the reliability and sequence repeatability of gas injection for time-cycle-control operations.

Intermittent Gas Lift Installation Design Methods

There are many published methods and variations in these methods for designing intermittent gas lift installations. These methods can be divided into one type of design that is based on a production rate and another design that can be described as a percentage-load technique. Intermittent pressure gradient spacing factors are used for installation designs based on an assumed daily production rate. Production rate is not a consideration for a percent-load design method. The procedures for calculating a percent-load installation vary between gas lift manufacturers and between operators who have introduced slight variations in these calculations. The gas lift valve depths in most designs can be calculated or determined graphically.

Gas Lift Valves for Intermittent Lift

Most gas lift valves used for intermittent lift will be the unbalanced, single-element, bellows-charged valve with a large port. The majority of intermittent-lift designs require a gas lift valve with a large production-pressure factor. Single-element, spring-loaded gas lift valves are not recommended for intermittent lift because of the higher bellows-assembly load rate of the spring-loaded as compared to the bellows-charged gas lift valve with the same bellows and port size. The operating gas lift valve should tend to "snap" open and to provide a large port size for

injection-gas throughput so that the liquid slug can be displaced efficiently with minimal injection-gas slippage and liquid fallback. Time-cycle control of the injection gas is recommended for intermittent-lift installations with unbalanced, single-element gas lift valves. These valves may not operate on choke control of the injection gas. Most installations with unbalanced, single-element valves will not work satisfactorily on choke control.

There are gas lift valves that have been designed for choke-controlled intermittent gas lift operation. These valves will have a large port for gas passage and may be designed to operate on either time cycle or choke control of the injection gas. Several gas lift valves are designed for only choke-control operation. A properly selected pilot-operated gas lift valve will function in most wells on time cycle or choke control. There are differential-pressure opening (difference between the production and injection gas pressure for initial valve opening) and constant-injection-gas-pressure closing gas lift valves. Certain types of differential-pressure opening valves cannot be opened by an increase in injection-gas pressure and others can be opened. It is extremely important to select the proper gas lift valve if choke control for intermittent lift is mandatory.

Intermittent Pressure Gradient Spacing Factor

The intermittent pressure gradient spacing factor is similar to a flowing pressure gradient above the point of gas injection in a continuous-flow installation. This factor will increase with daily production rate and a decrease in the size of the tubing. These intermittent spacing factors ac-

count for (1) liquid fallback from injection-gas penetration of the displaced liquid slug while the slug is in the tubing, (2) fluid transfer from the casing annulus to the tubing during unloading, (3) fluid production after BHFP drawdown occurs, and (4) increase in wellhead tubing pressure with depth in deep wells with a high surface-tubing pressure.

The fluid level in the tubing immediately after an injection gas cycle is not at the operating valve depth. There is always an accumulation of liquid fallback because of gas slippage through the liquid slug during displacement. Consequently, the minimum flowing production pressure between injection-gas cycles is greater than the surface wellhead-tubing gas pressure at the operating valve depth because of liquid fallback.

The intermittent pressure gradient spacing factors (F_s) given in Fig. 5.29 were published many years before flowing pressure gradient curves were available for continuous-flow installation designs. The same unloading pressure gradients were used for intermittent-lift and continuous-flow installation design. These data were reported to have been compiled from a limited number of flowing pressure surveys from low-GLR, high-water-cut wells with 2 $\frac{3}{8}$ - and 2 $\frac{7}{8}$ -in.-OD tubing. Other tubing sizes were added at a later date. One of several important parameters missing from this correlation is depth. All these conditions accounted for by these spacing factors with the exception of fluid transfer during unloading increase with depth of lift. The only two correlating parameters in Fig. 5.29 are production rate and conduit size. Since the rate of injection-gas penetration of the slug is

Fig. 5.29—Intermittent pressure-gradient spacing factors for varying daily production rates and different tubing sizes.

reported to be relatively constant, the liquid fallback will increase with depth because the liquid slug requires more time to reach the surface in deeper wells. These published intermittent spacing factors may be too low for very deep intermittent lift and too high for shallow lift.

Selection of Surface Closing Pressure of Gas Lift Valves

The surface closing pressure of an operating gas lift valve will be the minimum surface injection-gas pressure between gas injections if there are no leaks in the wellhead and tubing, which includes the gas lift valves. The maximum surface injection-gas pressure will occur at the instant the time-cycle controller closes or the operating gas lift valve opens on choke control of the injection gas. The available operating injection-gas-line pressure at the well-site must exceed the maximum surface casing pressure during an injection gas cycle. For this reason, an assumed gas lift valve surface closing pressure of 15% less than the available injection-gas-line pressure at the well-site is recommended for line pressures between 700 and 1,000 psig. This is the same as assuming a surface closing pressure equal to 85% of the available injection-gas-line pressure. A minimum of 100 psi difference is suggested for lower injection-gas pressures and a maximum of 200 psi for higher pressures. The maximum surface casing pressure during an injection-gas cycle for intermittent-lift operations is usually 8 to 10% higher than the surface closing pressure of the operating gas lift valve for approximate injection-gas-requirement calculations in typical tubing/casing combinations such as 2 $\frac{3}{8}$ -in.-OD tubing in 5 $\frac{1}{2}$ -in.-OD casing.

When a time-cycle controller opens, the injection-gas-line pressure upstream of the controller will decrease. To have an injection-gas volume stored in the high-pressure injection-gas lines, there must be a pressure difference in addition to the capacity of the high-pressure system. If the difference between the injection-gas-line pressure and the surface closing pressure of the operating gas lift valve is insufficient, the casing pressure will not increase at a rate necessary to ensure rapid opening of an unbalanced, single-element, gas lift valve after the controller opens. A near-instant increase in casing pressure after the controller opens improves the gas throughput performance of a single-element valve and decreases the liquid fallback. It is better to design an intermittent installation with a pressure difference between the injection-gas-line and valve closing pressures that is slightly excessive rather than insufficient to ensure fast opening of the operating gas lift valve.

Selection of Valve Port Size

Constant surface closing and percent-load intermittent gas lift installation designs require unbalanced, single-element, gas lift valves with a large port relative to the effective bellows area. The design principle is based on the production-pressure effect, which is the production pressure at the valve depth times the production-pressure factor for the valve. The valve with the highest production pressure that is less than the injection-gas pressure at valve depth will be the deepest operating gas lift valve in the installation. There is no reason to decrease the surface closing pressure for each succeeding lower unloading gas lift valve because the point of gas injection will

transfer automatically from an upper to the next lower valve after the production pressure at the lower valve depth becomes less than the injection-gas pressure at the same depth. This same design technique can be used for pilot-operated gas lift valves. The calculations for pilot valves apply to the pilot section of the valve that must have a large production-pressure factor.

There may be variations in the port size or surface closing pressure of the bottom gas lift valve. If the casing is large relative to the tubing size, such as 2 $\frac{3}{8}$ -in.-OD tubing in 7-in.-OD casing, a smaller-ported gas lift valve may be used for the bottom valve. The 1 $\frac{1}{2}$ -in.-OD unloading gas lift valves may have a $\frac{7}{16}$ - or $\frac{1}{2}$ -in. port and the bottom valve a $\frac{3}{8}$ -in. port to reduce the valve spread (that is, the difference between the initial opening and closing pressures of the bottom valve). This consideration is important for installations in wells with an anticipated low BHFP. The design surface closing pressure can be the same as the assumed closing pressure for the unloading gas lift valves with larger ports. Another variation in the installation design is to decrease the surface closing pressure of the bottom gas lift valve. The purpose of decreasing the closing pressure of the bottom valve is to provide a visible change in operating injection-gas pressure when the well is unloaded to this valve depth. This procedure is referred to as "flagging" the bottom valve, and a typical decrease in surface closing pressure would be 25 to 50 psi.

Intermittent Gas Lift Installation Design Based on Valves With a Constant Surface Closing Pressure and an Increasing Intermittent Spacing Factor Gradient With Depth

There are two advantages to a properly designed constant surface closing pressure installation design.

1. There is no decrease in operating injection-gas pressure with depth of lift. This is particularly important in deep wells with low available injection-gas pressure.
2. The depth of lift always will be the deepest valve depth where the highest production pressure in the tubing is less than the injection-gas pressure at the same depth.

Intermittent gas lift installation design based on valves with a constant surface closing pressure has been used to gas lift dual zones with a common injection-gas source in the casing annulus. The advantage of being able to predict the operating injection-gas pressure for lifting both zones with the same injection-gas pressure is apparent for duals. The higher-BHP zone may produce a slug during every injection-gas cycle and the weaker zone may operate only every other cycle. This type of operation has been observed in dual intermittent gas lift installations.

The primary disadvantage of this type installation is the difficulty of establishing the depth of the operating gas lift valve from the surface operating injection-gas pressure since the operating pressure does not decrease with each succeeding lower valve. Determining the fluid level acoustically or recording the time for a liquid slug to surface are two methods for establishing the approximate depth of lift. A slug velocity of 1,000 ft/min can be assumed for most installations. Decreasing the surface closing pressure of the bottom gas lift valve is another method used by some operators to indicate that a well has unloaded to and is operating from the deepest valve. A

decrease in the surface closing pressure of the operating gas lift should be considered if a plunger is being installed in an intermittent-lift installation. Many intermittent gas lift installations with a low productivity index will operate from the maximum possible depth of lift, which usually is limited by the packer depth.

If the daily production rate exceeds the rate for an assigned minimum intermittent spacing factor gradient, the valve depths for this design method are based on an increasing spacing factor gradient with depth. As the point of gas injection transfers to each succeeding lower gas lift valve, the drawdown in BHP and corresponding production rate will increase after the unloading BHP becomes less than the static BHP. This design method uses an increasing intermittent spacing factor gradient with an increasing production rate from a decreasing BHFP rather than a constant spacing factor for locating all valve depths on the basis of the final design production rate.

The minimum intermittent spacing factor gradient is used to locate the depth of all gas lift valves above a depth at which initial drawdown in BHP can occur on the basis of the static BHP and the load fluid gradient. A minimum intermittent spacing factor equal to 0.04 psi/ft is recommended for most installation designs. The maximum intermittent spacing factor gradient is based on the tubing size and the design daily production rate and is obtained from Fig. 5.29. The maximum spacing factor begins at a minimum depth at which the BHFP for the design daily production rate could occur. The actual depth may be deeper, and this maximum intermittent spacing factor is used below this given minimum depth when the calculated distance between the gas lift valves using the maximum spacing factor exceeds the assigned minimum distance between valves. The intermittent spacing factor gradient increases between the depth for initial BHP drawdown and the given depth for the design daily production rate. The concept of an increasing spacing factor with each succeeding lower valve is illustrated in Fig. 5.30.

Determination of the Gas Lift Valve Depths. The BHP's and BHT usually are referenced to the same depth, which is the lower end of the production conduit (D_d). The steps for establishing the gas lift valve depths on a pressure-depth worksheet are as follows.

1. Plot the static BHP (p_{wsd}) at the lower end of the production conduit (D_d) on the pressure-depth worksheet and draw the static-load fluid gradient (g_{sl}) traverse originating at p_{wsd} and extend this traverse to the static fluid level (L_{sf}) for zero wellhead pressure, where L_{sf} is calculated with Eq. 26.

$$L_{sf} = D_d - \frac{p_{wsd}}{g_{sl}} \quad (26)$$

2. Draw an unloading traverse above the point of gas injection on the basis of the minimum intermittent spacing factor $(F_s)_{\min}$ and the surface wellhead tubing pressure between the gas-injection cycles.

$$p_{pfd} = p_{wh} + (F_s)_{\min}(D_d) \quad (47)$$

Draw a straight line between the wellhead pressure, p_{wh} , at the surface and p_{pfd} for $(F_s)_{\min}$.

Fig. 5.30—Increasing intermittent spacing factor gradient with depth for spacing gas lift valves.

3. Determine the depth at which an initial drawdown in BHP occurs. This depth (D_i) is found at the intersection of the traverse for the $(F_s)_{\min}$ in Step 2 with the static-load fluid traverse in Step 1. The depth D_i can be calculated with the following equation:

$$D_i = \frac{g_{sl}(D_d) + p_{wh} - p_{wsd}}{g_{sl} - (F_s)_{\min}} \quad (48)$$

Record the unloading flowing production pressure at D_i between the gas-injection cycles (p_{pfdi}).

4. Determine the maximum intermittent spacing factor $(F_s)_{\max}$ from Fig. 5.29 for the given tubing size and design production rate. Draw an unloading traverse above the point of gas injection based on the $(F_s)_{\max}$.

$$p_{pfd} = p_{wh} + (F_s)_{\max}(D_d) \quad (49)$$

Draw a straight line between p_{wh} at the surface and p_{pfd} for $(F_s)_{\max}$.

5. For a given minimum depth of lift at which the design production rate may be gas lifted (D_p), record the unloading flowing production pressure between the gas-injection cycles (p_{pfdp}). This pressure occurs at the intersection of the assigned D_p depth and the traverse for the $(F_s)_{\max}$ in Step 4.

6. Draw a straight line on the pressure-depth worksheet between the pressure and depth point (p_{pfdi}) at which initial drawdown occurs in Step 3 and the pressure and depth point (p_{pfdp}) at which the design production rate may be gas lifted. This unloading intermittent spacing factor traverse above the point of gas injection represents the increase in the intermittent spacing factor with depth and daily production rate and is the minimum flowing production pressure at depth (p_{pfd}) between the gas-injection cycles.

TABLE 5.11—CALCULATION OF THE TEST-RACK-SET OPENING PRESSURES OF THE GAS LIFT VALVES ON THE BASIS OF A CONSTANT SURFACE CLOSING PRESSURE*

Valve Number	D (ft)	p_{vcD} (psig)	p_{bvD} (psig)	T_{uvD} (°F)	F_i	p_{vo} (psig)
1	1,756	707	707	106	0.910	864
2	2,992	727	727	125	0.877	856
3	4,147	745	745	142	0.850	850
4	5,018	758	758	155	0.830	844
5	5,679	768	768	165	0.816	841
6	5,950	773	773	169	0.810	840

*Valve description: 1½-in.-OD gas lift valves. Valve specifications: $A_p = 0.77$ sq in. Port ID = ½ in. $A_p/A_D = 0.255$. $(1 - A_p/A_D) = 0.745$. Surface closing pressure of gas lift valves: $p_{vc} = 680$ psig.

7. Select a surface closing pressure for the gas lift valves (p_{vc}) on the basis of approximately 85% of the available injection-gas-line pressure at the wellsite:

$$p_{vc} = 0.85(p_{io}). \quad (50)$$

Determine the valve closing pressure at the lower end of the production conduit (p_{vcd}) and draw a straight line between p_{vc} at the surface and p_{vcd} , which represents the p_{vcD} traverse.

8. Draw the unloading gas lift valve temperature at depth traverse (T_{uvD}) on the pressure-depth worksheet by assuming a straight-line traverse between the surface unloading flowing wellhead temperature (T_{whu}) and the bottomhole valve temperature (T_{vtd}).

9. Using Eq. 23, calculate the depth of the top gas lift valve (D_1) on the basis of the surface kick-off injection-gas pressure (p_{ko}), load fluid gradient (g_{sl}), and the wellhead U-tubing pressure (p_{whu}):

$$D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}}.$$

The top valve may be located graphically or at the static fluid level if this depth exceeds the calculated D_1 .

10. Draw a horizontal line on the pressure-depth worksheet between the unloading intermittent spacing factor traverse and the p_{vcD} traverse at the depth D_1 and record the $(p_{pfD1})_{\min}$ at the intersection of the intermittent spacing factor traverse, the p_{vcD1} , and the T_{uvD1} on the unloading temperature traverse.

11. Draw the static-load fluid gradient (g_{sl}) traverse below the depth of the top gas lift valve on the pressure-depth worksheet with the traverse originating at $(p_{pfD1})_{\min}$ and extending to the p_{vcD} traverse.

12. Locate the depth of the second gas lift valve (D_2) on the pressure-depth worksheet at the intersection of the g_{sl} traverse and the p_{vcD} traverse.

13. Draw a horizontal line on the pressure-depth worksheet between the unloading intermittent spacing factor traverse and the p_{vcD} traverse at the depth D_2 and record the $(p_{pfD2})_{\min}$, p_{vcD2} , and T_{uvD2} .

Repeat Steps 11 through 13 until the maximum desired gas lift valve depth is attained. A minimum distance between gas lift valves can be assigned on the basis of a

percent load for locating the lower valves in deep intermittent gas lift installations.

Calculation of the Test-Rack-Set Opening Pressures of the Gas Lift Valves. A tabulation form for these calculations is illustrated in Table 5.11. The bellows-charged pressure at the valve unloading temperature (p_{bvD}) is calculated by the following equation:

$$p_{bvD} = p_{vcD}. \quad (51)$$

The flowing production pressure at valve depth is assumed equal to the injection-gas pressure at the same depth when the valve closes for this equation to be valid. This assumption is reasonable for the deeper gas lift valves with large ports. The pressure in the tubing will approach the injection-gas pressure at valve depth immediately before the valve closes. Eq. 51 will not accurately describe the closing pressure for the upper one or two valves as the point of gas injection transfers to the next lower valve.

The unloading valve temperature at the depth of the valve can be estimated from a T_{uvD} traverse on the pressure-depth worksheet or calculated using Eq. 39. The test-rack opening pressure is calculated using Eq. 38 for a tester setting temperature of 60°F and Eq. 40 for a tester setting temperature (T_{vs}) other than 60°F.

Example Problem 14. Well information for installation design calculations:

1. Tubing size = 2⅞-in. OD.
2. Tubing length = 6,000 ft.
3. Maximum valve depth = 5,950 ft.
4. Static BHP = 1,600 psig at 6,000 ft.
5. Daily production rate = 300 STB/D.
6. Minimum intermittent spacing factor = 0.04 psi/ft.
7. Minimum depth of lift for design production rate = 5,000 ft.
8. BHT = 170°F at 6,000 ft.
9. Design unloading wellhead temperature = 80°F.
10. Load fluid gradient = 0.45 psi/ft.
11. U-tubing wellhead pressure = 60 psig.
12. Flowing wellhead pressure = 100 psig (high cycle frequency).
13. Static fluid level = 0 ft (loaded).
14. Injection-gas wellhead temperature = 80°F.
15. Surface kick-off injection-gas pressure = 850 psig.
16. Surface operating injection-gas pressure = 800 psig.
17. Gas lift valve bellows area = 0.77 sq in. (1½-in. OD valve).
18. Gas lift valve with sharp-edged seat and port ID = ½ in.
19. Test-rack setting temperature = 60°F.
20. Minimum distance between gas lift valves = 350 ft.

Solution—Valve Depths. The traverse for the pressures and temperatures used for calculating the gas lift installation design are drawn on a pressure-depth worksheet in Fig. 5.31.

$$1. L_{sf} = D_1 - \frac{p_{wsd}}{g_{sl}} = 6,000 - \frac{1,600}{0.45} = 2,444 \text{ ft.}$$

Draw a straight line between 0 psig at 2,444 ft and 1,600 psig at 6,000 ft.

2. For $(F_s)_{\min} = 0.04$ psi/ft,

$$p_{pfd} = p_{wh} + (F_s)_{\min}(D_d) = 100 + 0.04(6,000) \\ = 340 \text{ psig at 6,000 ft.}$$

Draw a straight line between 100 psig at the surface and 340 psig at 6,000 ft.

3. $D_i = 2,927$ ft at intersection of $(F_s)_{\min}$ traverse in Step 2 with g_{sl} traverse in Step 1 on the pressure-depth worksheet or calculated as follows:

$$D_i = \frac{g_{sl}(D_d) + p_{wh} - p_{wsd}}{g_{sl} - (F_s)_{\min}} \\ = \frac{0.45(6,000) + 100 - 1,600}{(0.45 - 0.04)} = 2,927 \text{ ft,}$$

$$p_{pfd_i} = 217 \text{ psig at 2,927 ft.}$$

4. $(F_s)_{\max} = 0.074$ psi/ft for 300 B/D through $2\frac{7}{8}$ -in.-OD tubing from Fig. 5.29.

$$p_{pfd} = p_{wh} + (F_s)_{\max}(D_d) = 100 + 0.074(6,000) \\ = 544 \text{ psig at 6,000 ft.}$$

Draw a straight line between 100 psig at the surface and 544 psig at 6,000 ft.

5. From the pressure-depth worksheet for $D_p = 5,000$ ft,

$$p_{pfd_p} = 470 \text{ psig at 5,000 ft.}$$

6. Draw a straight line between $p_{pfd_i} = 217$ psig at 2,927 ft and $p_{pfd_p} = 470$ psig at 5,000 ft.

7. Calculate the valve surface closing pressure.

$$p_{vc} = 0.85(800) = 680 \text{ psig at surface.}$$

p_{vc} of 680 psig at surface increases to p_{vcd} of 774 psig at 6,000 ft. Draw the p_{vcd} traverse by connecting 680 psig at surface to 774 psig at 6,000 ft with a straight line.

8. Plot the unloading temperature of 80°F at the surface and 170°F at 6,000 ft and draw the T_{uvD} traverse by connecting 80°F at surface to 170°F at 6,000 ft with a straight line.

$$9. D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}} = \frac{850 - 60}{0.45} = 1,756 \text{ ft.}$$

10. From the pressure-depth worksheet for $D_1 = 1,756$ ft,

$$(p_{pfd_1})_{\min} = 170 \text{ psig, } p_{vcd_1} = 707 \text{ psig, and}$$

$$T_{uvD_1} = 106^\circ\text{F.}$$

11. Draw the g_{sl} traverse (0.45 psi/ft) originating at 170 psig at 1,756 ft and extending to the p_{vcd} traverse.

12. $D_2 = 2,992$ ft at the intersection of the p_{vcd} traverse.

Fig. 5.31—Intermittent gas lift installation design based on a constant valve surface closing pressure and an increasing intermittent spacing factor gradient.

13. From the pressure-depth worksheet for $D_2 = 2,992$ ft [since $D_2 > D_i$, $(p_{pfd_2})_{\min}$ on intermitting spacing factor traverse between p_{pfd_i} and p_{pfd_p}],

$$(p_{pfd_2})_{\min} = 225 \text{ psig, } p_{vcd_2} = 727 \text{ psig, and}$$

$$T_{uvD_2} = 125^\circ\text{F.}$$

Repeat Steps 11 through 13 for the third gas lift valve:

11. Draw the g_{sl} traverse originating at 225 psig at 2,992 ft and extending to the p_{vcd} traverse.

12. $D_3 = 4,147$ ft.

13. $(p_{pfd_3})_{\min} = 366$ psig, $p_{vcd_3} = 745$ psig, and $T_{uvD_3} = 142^\circ\text{F.}$

Repeat Steps 11 through 13 for the fourth gas lift valve:

11. Draw the g_{sl} traverse below the third valve.

12. $D_4 = 5,018$ ft.

13. $(p_{pfd_4})_{\min} = 471$ psig, $p_{vcd_4} = 758$ psig, and $T_{uvD_4} = 155^\circ\text{F.}$

Repeat Steps 11 through 13 for the fifth gas lift valve:

11. Draw the g_{sl} traverse below the fourth valve.

12. $D_5 = 5,679$ ft.

13. $(p_{pfd_5})_{\min} = 520$ psig, $p_{vcd_5} = 768$ psig, and $T_{uvD_5} = 165^\circ\text{F.}$

Repeat Steps 11 through 13 for the sixth (bottom) gas lift valve:

11. Draw the g_{sl} traverse below the fifth valve.

12. $D_6 = 5,950$ ft (maximum valve depth).

13. $(p_{pfd_6})_{\min} = 540$ psig, $p_{vcd_6} = 773$ psig, and $T_{uvD_6} = 169^\circ\text{F.}$

Note that the minimum distance between valves of 350 ft was not used in the design of this installation. The maximum valve depth of 5,950 ft was reached before the calculated distance between valves was less than 350 ft.

The calculated test-rack opening pressure of Valve 6 (Table 5.11) is based on a $\frac{1}{2}$ -in. port. A valve with the same surface closing pressure and a $\frac{3}{8}$ -in. port can be run as the bottom valve to reduce the spread for a lower-than-predicted BHFP. The test-rack opening pressure for a valve with a $\frac{3}{8}$ -in. port would be 730 psig at 60°F on the basis of an A_p/A_h ratio of 0.143.

Percent Tubing Load Installation Designs for Intermittent Lift

Intermittent gas lift installations can be designed to require a given production pressure at valve depth for opening the gas lift valves with an available operating injection gas pressure. The production pressure is expressed as a percent load of the injection-gas pressure and can be defined as follows:

$$F_{pe} = 100 \left(\frac{p_{pfD}}{p_{ioD}} \right), \dots\dots\dots (52)$$

where F_{pe} is the production-pressure load factor, percent.

The test-rack opening pressures of the valves are based on the design injection-gas operating pressure and production load pressure at the depths of the valves. Since the transfer from an upper to the next lower gas lift valve is based on the difference in the production load pressure at each valve depth, the gas lift valves must have a large production-pressure factor, F_p . The gas lift valve with the highest production pressure at valve depth that is less than the operating injection-gas pressure at the same depth will be the operating gas lift valve.

The gas lift valve depths may be based on the percent-load production pressure or on other arbitrary percentages of the available operating injection gas pressure. Two widely used percent spacing and load design methods can be described as follows: (1) 85 to 50% spacing-load design, and (2) 40 to 70% spacing and 50% load design.

The valve depths and the test-rack opening pressures are based on the percent load for the first method. All constant percentages for spacing-load designs result in approximately the same distance between gas lift valves. The distance between the gas lift valves theoretically will increase slightly with depth because of an increase in the injection-gas pressure with depth, as can be noted from the following equation for the 85 to 50% spacing-load design:

$$L_{bv} = \frac{0.85(p_{ioD}) - 0.5(p_{ioD})}{g_{sl}},$$

Therefore,

$$L_{bv} = \frac{0.35(p_{ioD})}{g_{sl}}, \dots\dots\dots (53)$$

where L_{bv} is the distance between gas lift valves, feet.

The 40 to 70% spacing and 50% load design operate on principles similar to the other spacing-load percent design but do not result in an increasing distance between lower gas lift valves.

These installations are simple to calculate and will perform efficiently in most wells requiring intermittent lift. One disadvantage is the number of gas lift valves required for deep wells when the available injection-gas pressure is low.

Intermittent Gas Lift Installation Design Based on 40 to 70% Spacing and 50% Load

The 40 to 70% flowing production or transfer pressure line is used to locate the gas lift valve depths, and the opening pressures of the gas lift valves are based on 50% of the operating injection-gas pressure at depth. The basis

for this design method corresponds more closely to the principles of intermittent gas lift operations than the percentage spacing-load designs. As the depth of lift increases, the liquid fallback increases and the distance between gas lift valves should be less to compensate for a higher minimum flowing production pressure at valve depth between gas injections. The 40 to 70% spacing design results in the distance between gas lift valves decreasing with depth that is similar to most other types of gas lift installation designs.

The calculated theoretical closing pressure of a gas lift valve requires that the flowing production pressure be equal to the injection-gas pressure at the instant a valve closes. If the production pressure is less than the injection-gas pressure, which is usually true, the actual closing pressure will be higher than the theoretical closing pressure. For this reason, an operating injection-gas pressure for design purposes that is 50 psi less than the available injection-gas pressure at the wellsite is recommended for percent-load designs. This assumption will ensure good gas lift operation as a result of a rapid increase in the casing pressure after the time-cycle controller opens for an injection-gas cycle.

Determination of the Gas Lift Valve Depths. The BHP's and BHT usually are referenced to the same depth, which is the lower end of the production conduit (D_d). The steps for establishing the gas lift valve depths on a pressure-depth worksheet are as follows.

1. Determine the design operating injection-gas pressure at the lower end of the production conduit (p_{iod}). Generally, the design operating injection-gas pressure at the surface is assumed to be 50 psi less than the injection-gas pressure available at the wellsite to ensure a surface closing pressure that will not exceed 85% of the available injection-gas-line pressure.

2. Calculate the 40 to 70% valve spacing transfer production pressures at the surface (p_{pt}) and at the lower end of the production conduit (p_{ptd}):

$$p_{pt} = 0.4(p_{io}) \dots\dots\dots (54)$$

and

$$p_{ptd} = 0.7(p_{iod}), \dots\dots\dots (55)$$

Plot p_{pt} at the surface and p_{ptd} at the depth D_d and draw a straight line between these two pressures (p_{ptD} traverse).

3. Draw the unloading gas lift valve temperature at depth traverse (T_{wD}) by assuming a straight line between the surface unloading flowing wellhead temperature (T_{whu}) and the BHT at the lower end of the production conduit (T_{vd}). An unloading flowing wellhead temperature near the surface geothermal temperature for the area can be assumed for typical intermittent gas lift operations.

4. Calculate the depth of the top gas lift valve (D_1) on the basis of the surface kick-off injection-gas pressure (p_{ko}), the static-load fluid gradient (g_{sl}), and the wellhead U-tubing pressure (p_{whu}), or D_1 may equal the static fluid level if this depth exceeds calculated D_1 and the well will not be loaded in the future. With Eq. 23,

$$D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}}.$$

TABLE 5.12—CALCULATION OF THE TEST-RACK-SET OPENING PRESSURES OF THE GAS LIFT VALVES BASED ON A 40 TO 70% SPACING AND 50% LOAD*

Valve Number	D (ft)	p_{ioD} (psig)	Load p_{pfD} (psig)	p_{bvD} (psig)	T_{uvD} (°F)	F_T	p_{vo} (psig)
1	1,699	831	416	750	105	0.912	850
2	2,681	849	425	766	120	0.886	844

7	6,838	926	463	836	183	0.791	821
8	7,538	938	469	846	193	0.778	818
9	7,970	946	473	854	200	0.769	816

*Valve description: 1½-in.-OD gas lift valves. Valve specifications: $A_b = 0.77$ sq in. Port ID = 7/16 in. $A_p/A_b = 0.195$ ($1 - A_p/A_b = 0.805$).

5. Draw a horizontal line between the p_{pfD} traverse and p_{ioD} traverse at depth D_1 . Record p_{pfD1} , p_{ioD1} , and T_{uvD1} at depth D_1 .

6. Draw the static-load fluid gradient (g_{sl}) traverse below the depth of the top gas lift valve with the traverse originating at p_{pfD1} and extending to the p_{ioD} traverse.

7. Locate the depth of the second gas lift valve (D_2) at the intersection of the static-load fluid gradient traverse with the p_{ioD} traverse. There is no pressure differential used for locating the gas lift valve depths because the p_{ioD} traverse is based on a pressure equal to 50 psi less than the minimum injection-gas pressure available at the wellsite.

8. Draw a horizontal line on the pressure-depth worksheet between the p_{pfD} traverse and p_{ioD} traverse at depth D_2 . Record p_{pfD2} , p_{ioD2} , and T_{uvD2} at depth D_2 .

9. Continue to determine the gas lift valve depths graphically by repeating Steps 6 through 8 until the maximum depth of lift is attained.

Calculation of the Test-Rack-Set Opening Pressures of the Gas Lift Valves. A tabulation form for these calculations is illustrated in Table 5.12. Since this is a 50% load intermittent gas lift installation design, the test-rack-set opening pressure of each valve is based on a load production pressure equal to 50% of the design operating injection-gas pressure at the valve depth:

$$p_{pfD} = 0.5(p_{ioD}). \quad (56)$$

The bellows-charged dome pressure at the valve unloading temperature (p_{bvD}) is calculated with the following equation:

$$p_{bvD} = p_{ioD}(1 - A_p/A_b) + p_{pfD}(A_p/A_b). \quad (57)$$

The unloading valve temperature at the depth of the valve can be estimated from a T_{uvD} traverse on the pressure-depth worksheet or calculated using Eq. 39. The test-rack opening pressure is calculated using Eq. 38 for a tester setting temperature of 60°F and Eq. 40 for a tester setting temperature (T_{ts}) other than 60°F.

Example Problem 15. Well information for installation design calculations:

1. Tubing length = 8,000 ft.
2. Maximum valve depth = 7,970 ft.
3. BHT = 200°F at 8,000 ft.
4. Load fluid gradient = 0.465 psi/ft.
5. Static fluid level = 0 ft.
6. Design unloading wellhead temperature = 80°F.
7. U-tubing wellhead pressure = 60 psig.
8. Flowing wellhead pressure = 60 psig (low gas injection frequency).
9. Surface kick-off injection-gas pressure = 850 psig.
10. Surface available injection-gas pressure = 850 psig (same as kick-off).
11. Available injection-gas pressure at depth = 1,006 psig at 8,000 ft.
12. Surface design operating injection-gas pressure = 800 psig.
13. Percentage for valve spacing line at surface = 40%.
14. Percentage for valve spacing line at 8,000 ft = 70%.
15. Percent fluid load = 50%.
16. Gas lift valve bellows area = 0.77 sq in. (1½-in.-OD valve).
17. Gas lift valve with sharp-edged seat and port ID = 7/16 in.
18. Test-rack setting temperature = 60°F.

Since this design method is not based on a daily production rate, the required data for the installation design are less than for most types of gas lift installations. The available injection-gas pressure at depth was calculated by use of Eq. 1 for the actual injection-gas gravity and temperature-at-depth gradient for the well. A gas-pressure-at-depth factor (F_g) based on the available injection-gas pressure at depth was used to calculate the injection-gas design pressure at depth. The value of F_g is 2.294 psi/100 psi/1,000 ft for this installation (refer to Eq. 3).

Solution—Valve Depths. The traverses for the pressures and temperatures used for calculating the gas lift installation design are drawn on a pressure-depth worksheet in Fig. 5.32.

1. For an available injection-gas pressure of 850 psig at the wellsite, use a surface $p_{io} = 800$ psig.

$p_{io} = 800$ psig at surface increases to $p_{iod} = 947$ psig at 8,000 ft.

Fig. 5.32—Intermittent gas lift installation design based on a 40 to 70% spacing and 50% load.

Establish the design p_{ioD} traverse by drawing a straight line between 800 psig at the surface and 947 psig at 8,000 ft.

$$2. p_{pt} = 0.4(p_{io}) = 0.4(800) = 320 \text{ psig at surface,}$$

$$p_{ptd} = 0.7(p_{ioD}) = 0.7(947) = 663 \text{ psig at 8,000 ft.}$$

Draw a straight line between 320 psig at the surface and 663 psig at 8,000 ft to establish the p_{ptD} traverse.

3. Plot the unloading temperature of 80°F at the surface and 200°F at 8,000 ft and draw the T_{uvD} traverse.

$$4. D_1 = \frac{p_{ko} - p_{whu}}{g_{sl}} = \frac{850 - 60}{0.465} = 1,699 \text{ ft.}$$

5. From the pressure-depth worksheet for $D_1 = 1,699$ ft,

$$p_{pfD1} = 416 \text{ psig, } p_{ioD1} = 831 \text{ psig, and } T_{uvD1} = 105^\circ\text{F.}$$

6. Draw the g_{sl} traverse (0.465 psi/ft) originating at $p_{ptD} = 393$ psig at 1,699 ft and extending to the p_{ioD} traverse.

7. $D_2 = 2,681$ ft at the intersection of the p_{ioD} traverse.

8. From the pressure-depth worksheet for $D_2 = 2,681$ ft,

$$p_{pfD2} = 425 \text{ psig, } p_{ioD2} = 849 \text{ psig, and } T_{uvD2} = 120^\circ\text{F.}$$

Repeat Steps 6 through 8 for the third gas lift valve:

6. Draw the g_{sl} traverse from $p_{pfD2} = 435$ psig at 2,681 ft to the p_{ioD} traverse.

7. $D_3 = 3,608$ ft.

8. $p_{pfD3} = 433$ psig, $p_{ioD3} = 866$ psig, and $T_{uvD3} = 134^\circ\text{F.}$

This procedure is repeated until the maximum valve depth is attained (see Fig. 5.32 and Table 5.12).

The bottom gas lift valve in the test-rack opening pressure tabulation (Table 5.12) has a $\frac{7}{16}$ -in. port. If there is a possibility that this well may have a very low BHFP, a valve with a $\frac{3}{8}$ -in. port could be selected to reduce the spread in psi between the initial opening and closing pres-

ures of the bottom gas lift valve. The test-rack opening pressure for a valve with a $\frac{3}{8}$ -in. port would be 766 psig at 60°F on the basis of an A_p/A_b ratio of 0.143.

Intermittent Lift Chamber Application and Installation Design

A chamber installation is recommended for gas lifting wells with very low BHFP's and is applicable particularly for high-productivity wells with a low BHP. There are two fundamental types of chambers and many variations of each type depending on the casing size, permissible expenditure, well conditions, and the availability of special equipment for assembling a chamber installation. The more expensive chamber requires two packers. The other is an insert type that uses a bottle assembled from the largest pipe that can be run inside the casing or open hole in an openhole completion. Production accumulates in the large chamber rather than in the tubing string. Since a few feet in the chamber will represent many more feet of head in the tubing, the chamber significantly reduces the backpressure against the formation for a given volume of liquid feed-in.

The chamber must be designed properly to perform efficiently. There are accumulation chambers in wells that do not operate by the chamber principle. The chamber principle implies that the injection gas will U-tube the liquid from the chamber and into the production tubing before any injection gas enters the tubing. Other configurations in which the injection gas does not displace the liquid into the dip tube and production conduit before entering the lower end of the dip tube are not chamber installations.

A two-packer and insert chambers are illustrated in Fig. 5.33. All three chambers are designed for the injection gas to enter the chamber above the liquid and to displace the liquid into the dip tube and tubing before injection gas can enter the lower end of the dip tube. These chambers have a bleed valve near the top of the chamber to vent the gas and to allow filling with liquid production. A reliable standing valve is essential for efficient operation in most installations.

The two-packer chamber installation in Fig. 5.33a has wireline-retrievable gas lift, bleed, and standing valves. Conventional gas lift valves and nonretrievable bleed and standing valves may be used. The insert chamber installations in Figs. 5.33b and 5.33c are less expensive and are used to deplete low-capacity wells where little expenditure can be justified. The insert chamber in Fig. 5.33c is used to lower the point of gas injection in a well with a long openhole or perforated interval and low BHFP. The chamber length (L_c) is based on the capacities of the chamber annulus (V_{ca}) and the tubing above the chamber (V_t) for all installations in Fig. 5.33 and the capacity of the tubing annulus (V_{ta}) between the operating valve and the top of the chamber for the insert chamber in Fig. 5.33c.

Purposes of Intermittent Gas Lift Chamber Installations. The primary reasons for installing a chamber installation are (1) to attain the minimum possible average BHFP, (2) to lower the point of gas injection, and (3) to use an injection-gas pressure that significantly exceeds the BHFP in a well. The point of gas injection in a chamber installation is the lower end of the dip tube. The bottom

of a chamber can be located near TD in a long openhole or perforated-interval completion. Since a few feet of liquid in the chamber are converted into several feet of liquid in the tubing during unloading of a chamber, high injection-gas pressure can be used to lift a well in which the formation pressure would support only a few hundred feet of production.

Design Considerations for Chamber Installations. The unloading gas lift valve depths and the test-rack opening pressures are calculated in the same manner as the unloading gas lift valves for an intermittent gas lift installation without a chamber. An exception is the recommended maximum distance between the bottom unloading and the chamber operating gas lift valves. Several considerations are important in the design of a chamber installation to ensure operation from the chamber and the maximum liquid recovery with a minimum injection-gas requirement.

1. The chamber length should be calculated on the basis of an injection-gas pressure between 60 and 75% of the initial opening pressure at depth of the operating chamber valve to provide adequate pressure differential across the liquid slug at the instant the injection gas enters the lower end of the dip tube.

2. A bleed valve with a large port is necessary for high-rate chamber installations with a high injection-gas cycle frequency. The large bleed port is needed to vent the injection gas that is trapped in the chamber annulus between cycles.

3. Since the flowing tubing pressure at the depth of the operating chamber gas lift valve may be equal to the well-head tubing pressure plus a few psi gas column weight, the operating gas lift valve must have the proper spread to prevent excessive injection gas usage per cycle. Pilot-operated gas lift valves are used widely for this application since a large port is available with controlled spread characteristics.

4. The bottom unloading gas lift valve should be located within one to three joints of the operating chamber valve for unloading the chamber. The point of gas injection for the chamber valve is at the lower end of the dip tube and not at the depth of the chamber valve.

5. The initial opening pressure of the chamber-operating gas lift valve should be at least 50 psi less than the initial opening pressure of the bottom-unloading gas lift valve to ensure operation from the chamber.

6. The top of a chamber should not be located above the working fluid level in a well to minimize the injection-gas requirement.

7. A locking device is recommended for the standing valve in most chamber installations to prevent the standing valve from being blown out of its seating nipple by the high pressure differential across the standing valve immediately after a slug surfaces.

Chamber Length Equation. The chamber length equation is based on two assumptions. The first is that the top of the chamber is located at the working fluid level. This assumption implies that the chamber and the dip tube are full at the instant the chamber-operating gas lift valve opens. The second assumption requires that the inside diameter of the chamber and the size of the dip tube do not change for the entire length of the chamber. The chamber length equation (Eq. 58) applies to the types of cham-

Fig. 5.33—Two-packer and insert types of chamber installations.
(a) Two-packer. (b) Insert. (c) Insert.

bers illustrated in Figs. 5.33a and 5.33b and would have to be modified slightly to account for the capacity of the tubing annulus above the chamber in Fig. 5.33c.

$$L_c = \frac{p_{iDov} - p_{tDov}}{g_l(F_{at} + 1)} \quad (58)$$

where

L_c = chamber length, ft,

p_{iDov} = injection-gas pressure at the depth of the chamber-operating valve for calculating chamber length, psig,

p_{tDov} = tubing pressure at the depth of the chamber-operating gas lift valve based on p_{wh} , psig,

g_l = pressure gradient based on liquid production, psi/ft, and

F_{at} = ratio of capacities of the chamber annulus to the tubing above the chamber (V_{ca}/V_t), consistent units.

The actual effective chamber length is the distance from the top of the chamber to the lower end of the dip tube, which is the point of gas injection. The injection-gas pressure for calculating the chamber length should be less than the initial opening pressure of the chamber-operating gas lift valve. An adequate pressure differential across the liquid slug is necessary at the instant the injection gas enters the lower end of the dip tube to attain a slug velocity that ensures maximum liquid recovery with a minimum injection-gas volume per cycle. A recommended value for p_{iDov} would be

$$p_{iDov} = 0.6 \text{ to } 0.75 (p_{oDov}), \quad (59)$$

where p_{oDov} is the initial injection-gas opening pressure of the operating-chamber pilot valve at depth, psig.

Fig. 5.34—Plunger in an intermittent gas lift installation.

Example Problem 16.

Given for chamber length calculations:

1. Two-packer chamber installation (Fig. 5.33a).
2. Casing size=7-in. OD, 26 lbf/ft.
3. Tubing and dip tube size=2 $\frac{7}{8}$ -in. OD.
4. Initial injection-gas opening pressure of operating chamber-pilot valve, p_{oDov} =800 psig at 6,000 ft.
5. Production liquid gradient, g_l =0.40 psi/ft.
6. Tubing pressure at operating chamber valve depth, p_{iDov} =100 psig at 6,000 ft for p_{wh} =85 psig at surface.

Calculate the approximate chamber length.

From the appropriate tables for the annular volumes between tubing and casing and the capacities of tubing,

$$V_{ca}=0.1697 \text{ cu ft/ft for } 2\frac{7}{8}\text{-in.-OD tubing in 7-in.-OD, 26-lbf/ft casing.}$$

$$V_t=0.0325 \text{ cu ft/ft for } 2\frac{7}{8}\text{-in.-OD, 6.5-lbf/ft EUE tubing.}$$

$$F_{at}=\frac{V_{ca}}{V_t}=\frac{0.1697}{0.0325}=5.22.$$

$$p_{iDov}=0.70(p_{oDov})=0.70(800)=560 \text{ psig at 6,000 ft.}$$

$$L_c=\frac{p_{iDov}-p_{oDov}}{g_l(F_{at}+1)}=\frac{560-100}{0.40(5.22+1)}=185 \text{ ft.}$$

Plunger Application for Intermittent Gas Lift

An important consideration related to intermittent gas lift operations is the injection-gas breakthrough and resulting

loss in the liquid production per cycle from the injection gas penetrating the liquid slug during the time required to displace this slug to the surface. The produced liquid slug can be a small fraction of the starting slug size because of injection-gas breakthrough. The losses are greater when the injection-gas pressure is low and the required depth of lift is near total depth in a deep well. For example, a 12,000-ft well with a BHFP of 300 psig and an available injection-gas pressure of only 450 psig can be gas lifted intermittently with the proper plunger. The well could not be gas lifted successfully from this depth without a plunger.

A typical plunger installation for intermittent gas lift operation is shown in Fig. 5.34. A plunger can be expected to decrease the injection-gas requirement for an intermittent gas lift installation from 30 to 70% depending on the depth of lift, injection-gas pressure, and adjustment of the injection-gas volume to the well before the plunger is installed. There will be no liquid slug recovery by intermittent gas lift from very deep wells with low injection-gas pressure unless a plunger is installed. The plunger provides a solid interface between the starting liquid slug and the displacing injection gas. The plunger will practically eliminate liquid fallback as a result of gas penetrating the liquid slug. The increase in liquid recovery and the decrease in the injection-gas requirement per cycle from installing a plunger are minimal in an intermittent gas lift installation with small liquid slugs being lifted at an exceedingly high slug velocity. Another advantage of a plunger is that it will cut paraffin in a well with a paraffin problem. Plungers are installed in some wells for the sole purpose of keeping the tubing free of paraffin deposition.

A plunger can be installed in an existing conventional gas lift installation by wireline methods. There is no need to pull the tubing. A standing valve and a bottomhole collar lock or stop with a bumper spring can be installed with wireline tools. A standing valve normally is recommended but not required in wells with a low permeability. The bottomhole bumper spring is located immediately above the operating gas lift valve and a standing valve is stationed below the valve. The remaining equipment is on the surface and includes a lubricator with a bumper spring and a plunger catcher mechanism. A plunger arrival detector to shut in the tubing is not needed for an intermittent gas lift installation since the tubing is not shut in between injection-gas cycles.

A plunger velocity of 800 to 1,000 ft/min is recommended for the most efficient lift on the basis of a study by Lea.¹⁰ A plunger may stall or tend to stop and start at plunger velocities less than 350 to 400 ft/min. Plunger velocities in excess of 1,200 to 1,500 ft/min are not recommended because of possible damage to the plunger on arrival at the surface and because of an apparent tendency to bypass a thicker than normal liquid boundary on the tubing wall. An average plunger velocity can be approximated by noting the times when a time-cycle controller opens and when the plunger arrives at the surface.

The addition of a plunger to an intermittent gas lift installation should be considered when (1) the available injection-gas pressure is low relative to the required depth of lift in a low-BHFP well, (2) the wellhead flowing pressure is excessive after a slug surfaces because of a small-ID flowline, excessive number of bends at the wellhead,

flowline choke, etc., and (3) a paraffin deposition problem exists. Actually, a plunger will increase the efficiency of most intermittent gas lift installations.

Well conditions that prohibit the use of a plunger are (1) bore opening through surface wellhead and Christmas tree valves that differ from the tubing ID; (2) excessive well deviation, which prevents a plunger from descending to its bottomhole bumper spring; (3) tight spots in the tubing; (4) wireline-retrievable, unloading, gas lift valve side-pocket mandrels—the operating gas lift valve can be retrievable; (5) appreciable sand production; and (6) high-rate intermittent gas lift operations.

The fall-time required for a plunger to descend to the bottom bumper spring can reduce the maximum production from a high-cycle-frequency intermittent gas lift installation. Manufacturers are continuing to pursue the development of a plunger that will operate successfully in wells with side-pocket mandrels. Special tandem plungers are available for wells with side-pocket mandrels. Plungers have worked in wells with a deviation near 50°, but the maximum deviation for plunger operation would depend on the construction of the plunger. The manufacturers should be able to provide the information related to their plunger operation in a deviated well.

There are numerous types of plunger sealing elements, bypass valves, plunger weights and lengths, and other features that may have been developed for unique applications. Some plungers will be particularly applicable for gas lift and other types may not. Select the proper plunger to match the well conditions and application for trouble-free service and efficient operation.

Unloading Procedures and Proper Adjustment of Injection Gas Rate

Introduction

The importance of properly unloading a gas lift installation cannot be overemphasized in terms of possible damage to gas lift valves and for attaining the optimum depth of lift. Needle valves for obtaining injection-gas operating pressure downstream of the injection-gas control device and the flowing wellhead production pressure upstream of the flowline should be in good working order before beginning the unloading operations. If a permanent meter tube is not installed in the injection-gas line to the well, provisions should be made for the installation of a portable meter tube during unloading and adjustment of the injection-gas rate to the well. Preferably, the meter tube and the orifice meter or flow computer should be located near the well's injection-gas control device so that the effect of changes in the adjustment of the injection-gas volume can be observed.

A two-pen pressure recorder should be installed before unloading all gas lift installations. The ranges of the pressure elements in the recorder should be checked before hookup. A typical recorder will have a 0- to 500- or 0- to 1,000-psi-range element for the flowing wellhead production pressure and a 0- to 1,000 or 0- to 2,000-psi-range element for the injection-gas pressure, depending on the kick-off and available operating injection-gas pressure at the wellsite. These pressure elements should be calibrated periodically with a dead-weight tester to ensure accurate recordings.

Recommended Practices Before Unloading

If the injection-gas line is new, it should be blown clean of scale, welding slag, etc., before being connected to a well. This precaution prevents damage and plugging of the surface control equipment and entry of debris with the injection gas into the casing annulus. Debris may cause serious gas lift valve operational problems.

The surface facilities for a gas lift installation should be checked before the well is unloaded. This includes all valves between the wellhead and the battery, the separator gas capacity, the stock-tank room, etc. It is important to check the pop-off safety release valve for the gas gathering facilities if this is the first gas lift installation in the system.

If a well is loaded with drilling fluid, it should be circulated clean to the perforations before gas lift valves are run. Abrasive materials in the drilling fluid can damage the gas lift valve seats and/or may result in valve malfunction during unloading operations. If the gas lift valves are run before the drilling fluid is replaced with a suitable load fluid, the well should not be reverse circulated because circulation would occur through the gas lift valves. The checks in the gas lift valves for tubing flow are designed to prevent flow from the tubing to the casing annulus; therefore, all circulation should occur around the lower end of the tubing for normal circulation.

Recommended Procedure for Unloading Gas Lift Installations

Preventing excessive pressure differentials minimizes the chance for equipment failure because of fluid and sand cutting. The following procedure avoids excessive pressure differential across the valves during the unloading operation. The permissible rate of increase in the injection-gas pressure downstream of the control device can be greater for an open installation without a packer than for an installation with a packer. Most of the load fluid from the casing annulus can U-tube through the lower end of the tubing in an open installation, whereas all the load fluid in the annulus must pass through the gas lift valves in an installation with a packer. The initial U-tubing is the most critical operation during the unloading procedure. There is no reason to hurry the U-tubing of the load fluid to uncover the top gas lift valve. Since the tubing remains full of load fluid during the U-tubing operation, there will be no drawdown in BHFP. Gas lifting does not begin until the initial U-tubing is completed and injection gas enters the tubing through the top valve. The load-fluid production rate is controlled by the rate of increase in the injection-gas pressure, which in turn depends on the injection-gas rate. Since most gas lift installations include a packer, the load fluid enters the tubing through the gas lift valves. If there are sand and debris in the load fluid and full-line injection-gas pressure is applied to the casing by opening a large valve on the injection-gas line, the gas lift valves may leak after the well is unloaded. An instantaneous pressure differential will occur across every gas lift valve that is approximately equal to the full-line injection-gas pressure because the casing and tubing are full of load fluid. The resulting high fluid velocity through the small gas lift valve ports may fluid-cut the seats—particularly if sand or debris is in the load fluid. The following procedure is recommended for monitoring and

controlling the unloading operations for all gas lift installations to prevent damage to the gas lift valves and surface facilities.

1. Install a two-pen pressure recorder that is accurate and in good working condition. The injection pressure downstream of the gas-control device and the wellhead tubing pressure should always be recorded during the entire unloading operation.

2. If the well has been shut in and the tubing pressure exceeds the separator pressure, bleed down the tubing through a $\frac{3}{4}$ - or $\frac{5}{8}$ -in. flowline choke. Do not inject lift gas before or while the tubing is being bled down.

3. Remove all wellhead and flowline restrictions including a fixed or adjustable choke if the well will not flow after all load fluid has been produced. If the gas lift installation is in a new well or a recompletion that could flow, a $\frac{2}{4}$ - to $\frac{3}{4}$ -in. flowline choke is recommended until after the well has cleaned up and obviously will not flow naturally. The selected range of the element for the flowing wellhead pressure pen in the two-pen recorder should be able to handle the maximum flowing wellhead pressure with a choke in the flowline.

4. Inject lift gas into the casing at a rate that will not allow more than a 50-psi increase in casing pressure per 10-minute interval. Continue until the casing pressure has reached at least 300 psi. Most companies will use a standard choke size in the injection-gas line for U-tubing and initial unloading operations. A typical injection-gas choke size will range from $\frac{3}{4}$ to $\frac{1}{2}$ in.

5. After the casing pressure has reached 300 to 500 psig, the injection-gas rate can be adjusted to allow a 100-psi increase per 10-minute interval until gas begins to circulate through the top gas lift valve (top valve is uncovered). After the top gas lift valve is uncovered and gas has been injected through this valve, a high pressure differential cannot occur across the lower gas lift valves. Any time the casing injection-gas pressure is increased above the opening pressure of the top valve, this valve will open and prevent a further increase in the injection-gas pressure. Gas lifting begins with the injection gas entering the top valve.

6. If the gas lift installation does not unload to the bottom valve or the design operating gas lift valve depth, adjustment of the injection-gas rate to the well will be required. An excessive or inadequate injection-gas rate can prevent unloading. This is particularly true for intermittent gas lift on time-cycle control where the maximum number of injection-gas cycles per day decreases with depth of lift. It may be necessary to decrease the number of injection-gas cycles per day and to increase the duration of gas injection as the point of gas injection transfers from an upper to a lower valve. Proper adjustment of the injection gas volume to a well is not permanent for most installations. The injection-gas requirements change with well conditions; therefore, continuous monitoring of the injection volume and the wellhead and injection-gas pressures is recommended to maintain efficient gas lift operations.

Depressing the Fluid Level, or "Rocking" a Well

If the top gas lift valve cannot be uncovered with the available injection-gas pressure, the fluid level can be depressed when there is no standing valve in the tubing. The injection-gas-line pressure is applied simultaneously

to the tubing and casing. Several hours may be required to depress the fluid level sufficiently in a "tight" low-permeability well. The tubing pressure is released rapidly and the source of the major portion of the fluid entering the tubing will be load fluid from the annulus. This procedure may be required several times to lower the fluid level in the casing annulus below the depth of the top gas lift valve.

A gas lift installation with high-production-pressure-factor valves may cease to unload after the top valve has been uncovered. This type of gas lift valve has a high degree of tubing sensitivity and requires a minimum production pressure at valve depth to open the valve with the available injection-gas pressure. This problem occurs more frequently with the top one or two gas lift valves and may be referred to as a "stymie" condition. The stymie condition can be corrected by applying an artificial increase in production pressure at valve depth by "rocking" the well. The valve cannot detect the difference between a liquid column and a pressure increase from partially equalizing the tubing and casing pressure with injection gas. If a well should stymie, the well can be rocked in the following manner:

1. With the wing valve closed, inject lift gas into the tubing until the casing and tubing pressures indicate that the gas lift valve has opened. A small copper tubing or flexible high-pressure line can be used for this purpose. When a valve opens, the casing pressure will begin to decrease and to equalize with the tubing pressure. The tubing pressure also should begin to increase at a faster rate with injection gas entering the tubing through the valve and surface connection.

2. Stop gas injection into the tubing and open the wing valve to lift the liquid slug above the valve into the flowline as rapidly as possible. A flowline choke may be required to prevent venting injection gas through the separator relief valve. Some surface facilities are overloaded easily and bleeding off the tubing must be controlled carefully.

3. The rocking process may be required several times until a lower gas lift valve has been uncovered. As the depth of lift increases, the possibility of stymie decreases because of the increase in the minimum production pressure that can be attained at the greater depths.

A stymie condition may occur in intermittent gas lift installations with very large ported gas lift valves and production-pressure-operated gas lift installations during unloading operations from the upper gas lift valves before significant BHP drawdown and reservoir fluid production are established.

Controlling the Daily Production Rate From Continuous-Flow Installations

The daily production rate from a continuous-flow gas lift installation should be controlled by the injection-gas volumetric flow rate to the well. A flowline choke should not be used for this purpose. Excessive surface flowline backpressure will increase the injection-gas requirement. Production-pressure-operated gas lift valves and injection-pressure-operated valves with a large production-pressure factor are particularly sensitive to high wellhead flowing pressure. Inefficient multipoint gas injection can result and can prevent unloading an installation to the maximum depth of lift for the available operating injection-gas pressure when the flowing wellhead backpressure is excessive.

Adjustment of a Time-Cycle-Operated Controller for Intermittent Lift Operations

When initially unloading an intermittent gas lift installation, an excessive injection-gas-cycle frequency may prevent "working down" (i.e., unloading the gas lift installation beyond a certain depth). A high injection-gas-cycle frequency can be used to transfer load fluid from the annulus for uncovering the upper unloading gas lift valves. As the depth of lift increases, the maximum possible number of injection-gas cycles per day decreases and the volume of injection gas required per cycle increases. If the number of injection cycles per day becomes excessive and there is insufficient time between gas injections for the casing pressure to decrease to the closing pressure of an upper unloading gas lift valve, the unloading process will discontinue until the number of injection-gas cycles is reduced. Many installations will require several adjustments of the time-cycle controller before the operating valve depth is reached.

The following procedure is recommended for final adjustment of a time-cycle-operated controller to minimize the injection-gas requirement when lifting from the operating gas lift valve.

1. Adjust the controller for a duration of gas injection that will ensure an excessive volume of injection gas used per cycle (approximately 500 cu ft/bbl/1,000 ft of lift). For most systems 30 sec/1,000 ft of lift will result in more gas being injected into the casing annulus than is actually needed.

2. Reduce the number of injection-gas cycles per day until the well will not lift from the required valve depth and/or the producing rate declines below the desired or maximum daily production rate.

3. Reset the controller for the number of injection-gas cycles per day immediately before the previous setting in Step 2. This establishes the proper injection-gas-cycle frequency.

4. Reduce the duration of gas injection per cycle until the producing rate decreases and then increase the duration of gas injection by 5 to 10 seconds for fluctuations in injection-gas-line pressure.

A time-cycle-operated controller on the injection-gas line can be adjusted as outlined previously, provided the line pressure remains relatively constant. If the line pressure varies significantly, the controller is adjusted to inject ample gas volume with minimum line pressure. When the line pressure is above the minimum pressure, excessive injection gas is used each cycle. One solution to this problem is a controller that opens on time and closes on a set increase in casing pressure. Several electronic timers are designed to operate in conjunction with pressure control.

Nomenclature

- A = area, sq in.
 A_b = total effective area of bellows, sq in.
 A_p = valve port area for sharp-edged seat or area of ball seat-line contact for tapered seat, sq in.
 C_d = discharge coefficient (determined experimentally), dimensionless

- C_{gT} = approximate gravity and temperature-correction factor for choke charts, dimensionless
 d_1 = orifice ID for known volumetric gas rate, in.
 d_2 = orifice ID for unknown volumetric gas rate, in.
 D = true vertical depth of gas column or valve depth, ft
 D_1 = depth of top valve, ft
 D_c = calculated depth for assumed p_{as} , ft
 D_d = reference datum depth (usually lower end of production conduit) for BHT and BHP's, ft
 D_{dl} = maximum depth for variable gradient valve spacing design line, ft
 D_i = depth at which initial BHP drawdown can be established, ft
 D_{ov} = depth of operating valve, ft
 D_p = minimum depth at which design production rate can be lifted, ft
 D_{uv} = depth of unloading valve, ft
 e = Napierian logarithm base = 2.718...
 f_o = oil cut, fraction
 F_{at} = ratio of capacities of chamber annulus/tubing above chamber, consistent units
 F_{cf} = critical flow pressure ratio

$$= \left(\frac{2}{k+1} \right)^{k/(k-1)}$$
 F_{dl} = assigned percent factor for variable gradient valve spacing design line, percent
 F_{du} = ratio of downstream pressure/upstream pressure, consistent units
 F_g = gas-pressure-at-depth factor, psi/100 psig/1,000 ft
 F_p = production-pressure factor
 F_{pe} = production-pressure load factor, percent
 F_s = intermittent pressure-gradient spacing factor, psi/ft
 $(F_s)_{\max}$ = maximum intermittent pressure-gradient spacing factor, psi/ft
 $(F_s)_{\min}$ = minimum intermittent pressure-gradient spacing factor, psi/ft
 F_{tc} = ratio of capacities of tubing/casing annulus, consistent units
 F_T = temperature correction factor for nitrogen at 60°F
 F_{T_N} = temperature correction factor for nitrogen at T_{vs}
 g = acceleration of gravity, ft/sec²
 g_{fb} = flowing pressure gradient (traverse) below point of gas injection, psi/ft
 g_{fp} = flowing pressure gradient (traverse) above point of gas injection, psi/ft
 g_g = gas gradient, psi/ft

- g_l = pressure gradient based on liquid production, psi/ft
 g_{sl} = static-load fluid gradient, psi/ft
 k = ratio of specific heats, dimensionless
 L_{bv} = distance between gas lift valves, ft
 L_c = chamber length, ft
 L_{sf} = static fluid level for zero wellhead pressure, ft
 n = number of pound-moles, lbm/mol
 p = pressure, psi
 \bar{p} = average pressure, psi
 p_1 = upstream pressure, psi
 p_2 = downstream pressure, psi
 p_{as} = assumed pressure, psi
 p_b = bellows-charged dome pressure at 60°F, psi
 p_{bvD} = bellows-charged dome pressure at T_{vD} or T_{uvD} , psi
 p_{bvx} = bellows-charged dome pressure at T_{vx} , psi
 p_{dl} = surface pressure for variable-gradient valve spacing design line, psi
 p_{dlD} = pressure for variable-gradient valve spacing design line at D_{dl} , psi
 p_{iDov} = injection-gas pressure at the depth of the chamber-operating valve for calculating chamber length, psi
 p_{io} = surface-operating injection-gas pressure, psi
 p_{iod} = operating injection-gas pressure at D_d , psi
 p_{ioD} = operating injection-gas pressure at depth, psi
 p_{ko} = surface kick-off injection-gas pressure, psi
 p_{kod} = kick-off injection-gas pressure at D_d , psi
 p_{koD} = kick-off injection-gas pressure at depth, psi
 p_o = initial valve opening pressure at surface, psi
 p_{oD} = initial valve opening pressure at valve depth, psi
 p_{oDov} = initial injection-gas opening pressure of the operating chamber valve at depth, psi
 p_{pe} = production-pressure effect, psi
 p_{pf} = flowing production pressure, psi
 p_{pfd} = unloading flowing production pressure at D_d , psi
 p_{pfd} = flowing production pressure at valve depth, psi
 p_{pfDi} = flowing production pressure at depth where initial drawdown in BHP occurs, psi
 $(p_{pfd})_{\max}$ = maximum flowing production pressure at valve depth while lifting from next lower valve, psi
 $(p_{pfd})_{\min}$ = minimum flowing production pressure at valve depth, psi
 p_{pfDp} = flowing production pressure at minimum depth where design production rate can be lifted, psi
 p_{pft} = test-rack downstream flowing production pressure, psi
 p_{pt} = surface valve-spacing transfer production pressure, psi
 p_{ptd} = valve-spacing transfer production pressure at D_d , psi
 p_{ptD} = valve-spacing transfer production pressure at valve depth, psi
 p_{sc} = standard pressure base, psi
 p_{tD} = flowing production transfer pressure at depth, psi
 p_{tDov} = tubing pressure at the depth of the chamber operating gas lift valve based on p_{wh} , psi
 p_{uvD} = minimum flowing or production transfer pressure at valve depth, psi
 p_{vc} = valve closing pressure at surface, psi
 p_{vcd} = valve closing pressure at D_d , psi
 p_{veD} = valve closing pressure at valve depth, psi
 p_{vcr} = test-rack valve closing pressure at 60°F, if, and only if, the upstream and downstream pressures across the valve port are equal at the instant the valve closes, psi
 p_{vctD} = test-rack closing pressure at valve depth, psi
 p_{vo} = test-rack valve opening pressure at 60°F, psi
 p_{voD} = valve opening pressure at T_{vD} when $p_{pfd}=0$, psi
 p_{vos} = test-rack valve opening pressure at T_{vx} , psi
 p_{wfd} = BHFP at depth D_d , psi
 p_{wh} = wellhead pressure, psi
 p_{whf} = flowing wellhead pressure, psi
 p_{whu} = wellhead U-tubing pressure, psi
 p_{wsd} = static BHP at depth D_d , psi
 Δp_a = assigned valve spacing pressure differential, psi
 Δp_{ao} = assigned design operating pressure differential across operating valve, psi
 Δp_{io} = assigned decrease in operating injection-gas pressure between valves, psi
 Δp_{oD} = difference in p_{oD} based on a change in p_{pfd} , psi
 Δp_{ov} = actual pressure differential across operating valve, psi
 Δp_{pe} = additional production-pressure effect, psi
 Δp_{pfd} = difference in p_{pfd} exerted over A_p , psi
 Δp_s = valve spread, psi
 Δp_{sD} = valve spacing pressure differential at

valve depth, psi
 q_{gsc} = gas flow rate at standard conditions
 (14.7 psia and 60°F), Mscf/D
 q_{g1} = known volumetric gas rate, Mscf/D
 q_{g2} = unknown volumetric gas rate, Mscf/D
 q_{ga} = actual volumetric gas rate, Mscf/D
 q_{gc} = chart volumetric gas rate, Mscf/D
 R = gas constant = 10.73,
 psia-cu ft/lbm-mol-°R
 R = GOR, scf/STB
 R_{glf} = formation GLR, scf/STB
 T = temperature, °F or °R
 \bar{T} = average temperature, °F or °R
 T_1 = upstream temperature, °R
 T_{gD} = temperature of injection gas at depth,
 °F or °R
 T_{sc} = standard temperature base, °F or °R
 T_{uvD} = unloading gas lift valve temperature at
 depth, °F
 T_{vd} = BHT at D_d , °F
 T_{vD} = valve temperature at depth, °F
 T_{vs} = test-rack valve or tester setting temper-
 ature (other than 60°F), °F
 T_{wh} = wellhead temperature, °F
 T_{whf} = flowing wellhead temperature, °F
 T_{whu} = assigned unloading flowing wellhead
 temperature, °F
 T_{ws} = BHT, °F
 V = volume or capacity, cu ft
 V_c = capacity of conduit, cu ft
 V_{ca} = capacity of casing or chamber annulus,
 cu ft
 V_g = volume of gas at standard conditions,
 scf
 V_{gx} = approximate gas volume, scf
 V_t = capacity of tubing, cu ft
 V_{ta} = capacity of tubing annulus, cu ft
 z = compressibility factor, dimensionless
 \bar{z} = compressibility factor for \bar{p} and \bar{T} ,
 dimensionless
 γ_g = gas specific gravity (air=1.0),
 dimensionless

Chapter 6

Hydraulic Pumping

Hal Petrie, National-Oilwell*

Introduction

A well will flow if it has sufficient reservoir potential energy (pressure) to lift fluid to the surface. Artificial lift is applied to a well if the reservoir pressure is not sufficient to cause the well to flow, or when more production is desired in a flowing well. In either case, energy must be transmitted downhole and added to the produced fluid. Hydraulic pumping systems transmit power downhole by means of pressurized power fluid that flows in wellbore tubulars. Hydraulic transmission of power downhole can be accomplished with good efficiency. With 30°API oil at 2,500 psi in 2 $\frac{7}{8}$ -in. tubing, 100 surface hhp can be transmitted to a depth of 8,000 ft with a flow rate of 2,353 B/D and with a frictional pressure drop of 188 psi. This pressure loss is 7.5% of the applied power. If the transmission pressure is raised to 4,000 psi, the required flow rate drops to 1,471 B/D and the frictional pressure loss declines to only 88 psi. This is 2.2% of the applied surface power. Even higher efficiencies can be achieved with water as the hydraulic medium because of its lower viscosity.

The downhole pump acts as a transformer to convert the energy of the power fluid to potential energy or pressure in the produced fluids. The most common form of hydraulic downhole pump consists of a set of coupled reciprocating pistons, one driven by the power fluid and the other pumping the well fluids. Another form of hydraulic downhole pump that has become more popular is the jet pump, which converts the pressurized power fluid to a high-velocity jet that mixes directly with the well fluids.^{1,2} In the turbulent mixing process, momentum and energy from the power fluid are added to the produced fluids. Rotating hydraulic equipment has also been tested in oil wells.^{3,4} In this case, a hydraulic turbine driven by the power fluid rotates a shaft on which a multistage centrifugal or axial-flow pump is mounted. This type of

pump has not had widespread commercial use. The "free pump" feature, common to most designs, allows the pump to be circulated in and out of the well hydraulically without pulling tubing or using wireline services.

The operating pressures used in hydraulic pumping systems usually range from 2,000 to 4,000 psi. The most common pump used to generate this pressure on the surface is a triplex or quintiplex positive-displacement pump driven by an electric motor or a multicylinder gas or diesel engine. Multistage centrifugal pumps have also been used,⁵ and some systems have operated with the excess capacity in water-injection systems.⁶ The hydraulic fluid usually comes from the well and can be produced oil or water. A fluid reservoir at the surface provides surge capacity and is usually part of the cleaning system used to condition the well fluids for use as power fluid. Appropriate control valves and piping complete the system. A schematic of a typical hydraulic pumping system is shown in Fig. 6.1.

A wide variety of well conditions can be handled by hydraulic pumping systems. Successful applications have included setting depths ranging from 1,000 to 18,000 ft.⁷ Production rates can vary from less than 100 to more than 10,000 B/D. Surface packages are available in sizes ranging from 30 to 625 hp. The systems are flexible because the downhole pumping rate can be regulated over a wide range with fluid controls on the surface. Chemicals to control corrosion, paraffin, and emulsions can be injected downhole with the power fluid. Fresh water can also be injected to dissolve salt deposits. When pumping heavy crudes, the power fluid can serve as an effective diluent to reduce the viscosity of the produced fluids. The power fluid can also be heated for handling heavy crudes or low-pour-point crudes. Hydraulic pumping systems are suitable for wells with deviated or crooked holes that cause problems for conventional rod pumping. The surface facilities have a low profile and can be clustered into a central battery to service numerous wells. This can be

*The original chapter on this topic in the 1962 edition was written by C.J. Coberly and F. Barton Brown.

Fig. 6.1—Typical hydraulic pumping system installation.

advantageous in urban sites, offshore locations, and environmentally sensitive areas. Jet pumps can be circulated around the 5-ft-radius loop of subsea through-flowline (TFL) installations⁸ joining gas-lift valves as the only artificial lift devices suitable for these systems.

Downhole Pumps

Types of Installations

The two basic types of installations are the *fixed pump* and the *free pump* designs. In the fixed installation, the downhole pump is attached to the end of a tubing string and run into the well. Free pump installations are designed to allow downhole pump circulation into and out of the well inside the power-fluid tubing string. The downhole pump can also be installed and retrieved by wireline operations.

Fixed Pump Installations (Conventional Installations).

In the fixed insert design, the pump lands on a seating-shoe set in tubing that has a larger ID than the OD of the pump. Power fluid is directed down the inner tubing string, and the produced fluid and the return power fluid flow to the surface inside the annulus between the two tubing strings, as shown in Fig. 6.2a. This system provides a passage for venting free gas in the annular space between the outer tubing string and the inside of the well casing. To take full advantage of the gas venting passage, the pump should be set below the perforations. The power-

Fig. 6.2—Downhole pump installations.

fluid string is usually $\frac{3}{4}$, 1, or $1\frac{1}{4}$ in., depending on the size of the production tubing. This once-common system is now used mainly to fit a large-diameter downhole pump into restricted casing sizes and still retain the gas-vent feature. It can also be used to lift one or both zones of a dual well with parallel strings.

In the fixed casing design, the tubing, with the pump attached to its lower end, is seated on a packer, as shown in Fig. 6.2b. With this configuration, the power fluid is directed down the tubing string, and the mixed power fluid and the produced well fluids return to the surface in the tubing/casing annulus. Because the well fluids enter the pump from below the packer, all the free gas must be handled by the pump. This type of installation is normally

Fig. 6.3—Free-pump cycle.

used in wells without much gas and with large-diameter, high-capacity pumps. If space permits, a gas-vent string can be run from below the packer to the surface. As with the fixed insert design, this installation is no longer common, and both types have been largely supplanted by the various free pump installations. Note that in both of the fixed-type installations, the power fluid mixes with the produced fluids after passing through the pump.

Free Pump Installations. The free pump feature is one of the most significant advantages of hydraulic pumping systems. Free pump installations permit circulating the pump to bottom, producing the well, and circulating the pump back to the surface for repair or size change. Free pump installations require that a bottomhole assembly (BHA) be run in on the tubing string. The BHA consists of a seating shoe and one or more seal bores above it and serves as a receptacle for the pump itself. BHA's are of robust construction and use corrosion-resistant sealing bores to ensure a long life in the downhole environment. Once run in on the tubing string, they normally remain in place for years, even though the downhole pump may be circulated in and out numerous times for repair or resizing. As shown in Fig. 6.3, a wireline-retrievable standing valve is landed in the seating shoe below the pump. The pump is run in the hole by placing it in the power-fluid tubing string and circulating power fluid in the normal direction. When the pump reaches bottom, it enters the seal bores, begins stroking, and opens the standing valve. During normal pumping, this valve is always held

open by well fluids drawn into the pump suction. During pump-out, the normal flow of fluids is reversed at the surface with appropriate valving, and pressure is applied to the discharge flow path of the pump. This reversal of flow closes the standing valve and permits the pump to be circulated to the surface. Circulating the pump out normally takes from 30 minutes to 2 hours, depending on the well depth and the circulating flow rate.

The benefits of being able to circulate the downhole pump in and out of the well include reduced downtime and the ability to operate without a pulling unit for tubing, cable, or rod removal. Another significant advantage is that pressure and temperature recorders can be mounted on the pump to monitor downhole conditions with different pumping rates. At the conclusion of the test, circulating the pump to the surface also retrieves the recorder. Leakage of tubing pressure can be checked by substituting a dummy pump for the normal production unit. Steaming, acidizing, or other chemical treatment of the formation can be done if the pump is circulated out and the standing valve is wirelined out. A flow-through blanking tool may be run instead of the pump for such treatments if isolation of the power fluid and discharge flow paths is desired.

The casing free installation, shown in Fig. 6.2c, is attractive from an initial-cost standpoint because it uses only one string of tubing. At first glance it seems to be the same as the fixed casing design. The crucial difference is that, instead of being attached to the end of the power-fluid string, the pump fits inside it to allow circulation into and

Fig. 6.4—Free-pump, parallel, closed-power BHA.

out of the well. For a given-diameter pump, this requires a larger-diameter power-fluid string, which reduces the annular flow path for the discharge fluids. In most cases, more than adequate flow area remains. Tubing as small as 1 1/2 in. can be run in systems with 2 7/8-in. tubing used as casing. In 1 1/2-in. tubing, only jet pumps can be used. In 2 3/8-in. or larger tubing, either jet or reciprocating pumps can be used. Usually, 2 3/8-in. power-fluid tubing is used in 4-in. or larger casing, 2 7/8-in. tubing in 5 1/2-in. or larger casing, and 3 1/2-in. tubing in 6 3/8-in. casing or larger. Only a very few free-pump installations have been made for 4 1/2-in. or larger tubing strings. Because the BHA sits on a packer, the pump must handle all the gas from the well in addition to the liquids. A gas-vent string can be run to below the packer if gas interference limits pump performance. Such an installation is shown in Fig. 6.2d. In both the vented and unvented systems, the power fluid mixes with the produced fluids and returns to the surface.

In wells where the produced fluids should be kept off the casing wall or where gas venting is desired, the parallel free installation should be considered. This installation, which requires two parallel tubing strings, normally does not require a packer. As shown in Fig. 6.2e, the BHA is suspended on the power-fluid tubing string, and the return string is either screwed into the BHA or is run separately with a landing spear that enters a bowl above the BHA. The tubing/casing annulus serves as a gas-vent passage, and to take full advantage of this, the unit should be set below the perforations.

If the well is not pumped off fully, well fluids will rise above the BHA until the bottomhole pressure (BHP, pump-suction pressure) increases to the point that the well inflow rate and BHP match the inflow performance relationship (IPR) curve of the well. This will expose some of the casing above the perforations to well fluids. In some cases, this may be desirable to prevent collapse of the casing, but in corrosive wells, such as those encountered in CO₂ flooding or with H₂S present, it may be undesirable. In such a case, a packer may be set above the perforations, although the gas-vent feature is then lost unless another gas-vent string is run to below the packer.

The size of the downhole pump dictates the power-fluid tubing size, and the casing size dictates how large the parallel return string can be. When the return string is limited in size, fluid friction may restrict the obtainable production or the practical setting depth.

Closed Power-Fluid Systems

All the installations discussed so far are open power-fluid types. This means that the power fluid and the produced fluid are mixed together after leaving the downhole pump and return to the surface together in a common flow passage. Jet pumps are inherently open power-fluid pumps because the energy transfer depends on mixing the power fluid and produced fluid. Reciprocating pumps, however, keep the power and produced fluids separate during the energy transfer process because there is a separate piston (or piston face) for each fluid. If the BHA has appropriate seal bores and passages to keep the two fluids separated, the power fluid can be returned to the surface in a separate tubing string. The extra tubing string for the power-fluid return classifies these installations in the

parallel free category. An example of a *closed power-fluid installation* is shown in Fig. 6.4. The principal advantage of closed power-fluid installations is that only the produced fluids need to go through the surface separating facilities, and the power fluid remains in a separate, closed loop. The resulting smaller surface facilities may be desirable in certain areas, such as townsite leases and offshore installations. In principle, the power-fluid cleanliness can be maintained better because it is not contaminated with well fluids. When water is used as the power fluid, it is generally necessary to add small amounts of corrosion inhibitors and lubricants. These would be lost in the open system, but are retained in the closed system. Offsetting the advantages of the closed system are the higher initial cost of the extra tubing string and more complex pump and BHA. Most closed power-fluid installations are found in the urban and offshore wells of California.

Reverse Flow Systems

Two considerations—the need to keep produced fluid off the casing and to minimize fluid-friction losses—have led to the use of reverse-flow installations (also known as reverse-circulation installations) in some wells. A reverse-flow casing installation is shown in Fig. 6.5. These systems are most commonly used with jet pumps, although a few installations have been made with reciprocating pumps. The casing system uses the tubing/casing annulus for power fluid, and the tubing string, which contains the pump, is used for the combined power fluid and production. This protects the casing with inhibited power fluid and is most useful when severe corrosion is anticipated. It does require the use of a heavier wall casing to avoid bursting it when power-fluid pressure is applied. The parallel system uses the smaller-size string for power fluid and the larger main string that contains the pump for the combined power fluid and production. The primary advantages of this system are reduced friction, gas venting, and protection of the casing. As discussed in the section on the parallel free design, complete casing isolation requires a packer below the BHA. Both types of reverse-flow installations may require a latch or friction hold-down to position the pump in the BHA during startup or to retain it in position during pumping, depending on the balance of forces on the downhole pump.

In reverse-flow installations, the pump is wirelined often in and out of the well, but a modified form of the free pump feature can be used. With jet pumps, the pump is run in with a pusher-type locomotive, which then circulates to the surface during pumping. To retrieve the pump, a similar blanked-off locomotive with a fishing tool attached is circulated down and latched to the pump. When flow is established in the normal pumping mode direction, the pump will surface. This sequence of operations is shown in Fig. 6.6. Fig. 6.7 shows a reverse-flow installation with a reciprocating pump. Because the engine and pump valving in these pumps does not permit flow-back to the pump suction for unseating the pump, a BHA side line must be run to the bottom of the pump. The latch assembly on top of the pump keeps it on seat during normal pumping. To retrieve the pump, a releasing tool is dropped or wirelined before the pump is circulated to the surface. Once the latch is released, the flow of fluid in the normal pumping mode will surface the pump.

Fig. 6.5—Reverse-flow jet-pump casing type in sliding sleeve.

Fig. 6.6—Reverse-flow, free-pump cycle.

TFL Installations

TFL installations have been developed for offshore locations to allow circulation of various downhole tools to the bottom of remote wells from a central platform. A typical installation is shown in Fig. 6.8. Because a 5-ft-radius loop is an integral part of the subsea wellhead installation, the size of the tools that can be circulated through it is limited. Of the various artificial-lift tools, only gas-lift valves and hydraulic jet pumps are sufficiently compact to be compatible with the system. When jet pumps are used, they may be normal-flow or reverse-flow types. Fig. 6.9 is an example of the reverse-flow installation used with TFL. The normal-flow installation is the simplest because it is essentially a parallel free installation and does not require special latches or holdowns. However, the pump has more complex internal fluid passages and the discharge fluid passes through the crossover port of the downhole H-member, which serves as a BHA. Because of the potential for erosion and corrosion of the crossover

member, many operators prefer the reverse-flow installation shown in Fig. 6.9. Here, only the power fluid passes through the crossover port, and the pump flow passages are of a simpler design and can have a higher capacity. Note the compactness of the pump and the use of universal joints that allow flexibility between the pump and the lower seal section. Circulating the pump in and out, however, is more complex, and the procedures described for non-TFL reverse-flow installations must be used.

The dual-sleeve side-door choke is probably the most important item in the string other than the pump itself when TFL operations are performed. This item is run open as shown to allow bypass past the pump for circulating tools into and out of the hole because not much fluid can be circulated through the pump nozzle. Once pump operations are ready to begin, the sleeve is closed by pressuring both strings. When pulling the pump, the sleeve is reopened by pressuring the tubing string that the pump is landed in, and circulation is then re-established.

Dual Wells. Hydraulic pumps lend themselves to the complex problem of the production of two separate zones in a single wellbore. When the two zones have different reservoir pressures, it is not practical to allow communication between them because the higher-pressure zone will flow into the lower-pressure zone. To meet the artificial lift requirements of the two distinct zones, two downhole pumps are usually required. It would be highly unusual if the same power-fluid pressure and rate were required for each zone; consequently, a separate power-fluid line for each pump is usually required. A number of plumbing configurations are possible. One option is shown in Fig. 6.10. The two pumps are physically connected and are run in and retrieved as a unit. In some cases, dual zones have been produced separately by use of double pump ends with a common engine.

Tandem Pumps. When the well capacity requirements exceed what can be produced by a single pump, it is possible to install two pumps in parallel or tandem to double the displacement of the downhole equipment. Again, the pumps are physically connected to form a single unit, but each pump is free to run independently.

Historically, tandem pump installations have used reciprocating pumps. The downhole arrangement is similar to that of Fig. 6.10, but without the passages that route fluid from two separate zones. It is possible to use jet pumps in the same manner, but this is rarely done because it is usually possible to get sufficient capacity in a single jet pump. Since the introduction of jet pumps about 1970, high-volume hydraulically pumped wells have generally used jet pumps instead of tandem reciprocating pumps.

Principles of Operation— Reciprocating Pumps

The pump end of a hydraulic downhole pump is similar to a sucker-rod pump because it uses a rod-actuated plunger (also called the pump piston) and two or more check valves. The pump can be either single-acting or double-acting. A single-acting pump follows rod-pump design practices closely and is called single-acting because it displaces fluid to the surface on either the upstroke or downstroke (but not on both). An example is shown schematically in Fig. 6.11. Fig. 6.12 shows a double-acting pump that has suction and discharge valves for both sides of the pump plunger, which enables it to displace fluids to the surface on both the upstroke and downstroke.

With either system, motion of the plunger away from a suction valve lowers the pressure that holds the valve closed, it opens as the pressure drops, and well fluids are allowed to enter the barrel or cylinder. At the end of the stroke, the plunger motion reverses, which forces the suction valve to close and opens the discharge valving.

In a sucker-rod installation, the rod that actuates the pump plunger extends to the surface of the well and connects to the pumping unit. In hydraulic pumps, however, the rod is quite short and extends only to the engine piston. The engine piston is constructed similarly to the pump plunger and is exposed to the power-fluid supply, which

Fig. 6.12—Double-acting pump end.

is under the control of the engine valve. The engine valve reverses the flow of the power fluid on alternate half-strokes and causes the engine piston to reciprocate back and forth. Four-way engine valves are used with engines that switch from high-pressure power-fluid to low-pressure power-fluid exhaust on both sides of the engine piston in an alternating manner. These engine (or reversing) valves are used with double-acting pump ends to give equal stroking force on both upstroke and downstroke. An example of such an engine connected to a double-acting pump is illustrated in Fig. 6.13.

Three-way engine valves are used with unequal-area engine pistons that always have high-pressure power fluid on one side, and switch the power-fluid pressure from high to low pressure on the other face of the piston. This type of reversing valve is common with single-acting pumps that do not require a high force on the half-stroke that is not displacing produced fluid to the surface. An example of this type of engine attached to a single-acting pump is illustrated in Fig. 6.14.

The engine or reversing valve can be signaled by a variety of means. Commonly, ports on a rod direct pressures to control areas on the engine valve at the extremes of the upstroke and downstroke, causing the valve to shift hydraulically. The shifting of the engine valve redirects the flow of power fluid to the engine piston and causes the reversal of the rod-and-plunger system. Alternatively, the engine valve can be mechanically bumped from one position to the other by the rod and plunger system as it

Fig. 6.13—Double-acting downhole unit.

Fig. 6.14—Single-acting downhole unit.

nears the ends of the upstroke and downstroke. Combinations of mechanical and hydraulic shifting are possible. The engine valve may be located above the rod-and-plunger system, in the middle of the pump, or in the engine piston.

Note that the two designs illustrated and discussed do not exhaust the design possibilities offered by the various pump manufacturers. Examples of combinations of these and other design concepts can be seen in the cross-section schematics of the various pump types that accompany the pump specifications in Tables 6.1 through 6.4 and Figs. 6.15 through 6.18. Common to all the designs, however, is the concept of a reversing valve that causes an engine piston (or pistons) to reciprocate back and forth. This strokes the pump plunger (or plungers) that lifts fluid from the well.

Because the engine and pump are closely coupled into one unit, the stroke length can be controlled accurately. With a precise stroke length, the unswept area or clearance volume at each end of the stroke can be kept very small, leading to high compression ratios. This is very

Fig. 6.15—Manufacturer "A" pump types for Table 6.1.

important in maintaining high volumetric efficiency when gas is present and generally prevents gas locking in hydraulic pumps. The engine valves and their switching mechanisms usually include controls to provide a smooth reversal and to limit the plunger speed under unloaded conditions. The unloaded plunger speed control is often called governing and minimizes fluid pound when the pump is not fully loaded with liquid. In this way, shock loads in the pump and water hammer in the tubing strings are softened, which reduces stresses and increases life.

Pressures and Forces in Reciprocating Pumps

Reciprocating hydraulic pumps are hydrostatic devices. This means that the operation of the unit depends on pressures acting against piston faces to generate forces, and that the fluid velocities are low enough that dynamic effects can be neglected. A pressurized fluid exerts a force against the walls of its container. This force is perpendicular to the walls regardless of their orientation. If the pressurized container consists of a cylinder with one end blanked off and the other end fitted with a movable plung-

 - E. Multiple seal, external porting, opposed pistons with central engine.

Fig. 6.16—Manufacturer "B" pump types for Table 6.2.

er, as shown in Fig. 6.19, a force will have to be applied to the plunger to resist the force exerted by the pressurized fluid. A force of 1,000 lbf will be required to restrain a plunger whose cross-sectional area is 1 sq in. if the pressure in the cylinder is 1,000 psi.

$$F = pA, \dots\dots\dots (1)$$

where

F = force, lbf,
 p = pressure, psi, and
 A = area, sq in.

This is the condition of static equilibrium for the plunger when all forces balance and no movement is taking place. Suppose next that a supply line is connected to the blanked-off end of the cylinder, as shown in Fig. 6.20, and that a pump supplies fluid at a rate of 1 cu in./sec while maintaining the pressure at 1,000 psi. This will cause the plunger to move in the cylinder at the constant speed of 1 in./sec against the 1,000-lbf restraining force. In this condition of dynamic equilibrium, work can be done by the system because work is defined as force times distance.

$$W = FL, \dots\dots\dots (2)$$

where W = work, in.-lbf, and L = distance, in.

If the plunger moves 12 in., it will do 12,000 in.-lbf of work (or 1,000 ft-lbf of work). Because the plunger is moving at 1 in./sec, it will take 12 seconds to complete its travel. Power is defined as the rate of doing work.

$$P = W/t, \dots\dots\dots (3)$$

where

P = power, ft-lbf/sec,
 t = time, seconds, and
 W = work, ft-lbf.

In this example, the power is 1,000 ft-lbf of work in 12 seconds, or 83.3 ft-lbf/sec. Horsepower is defined as 550 ft-lbf/sec (or 6,600 in.-lbf/sec), which means that the horsepower of this system can be represented as

$$P_h = \frac{P}{550}, \dots\dots\dots (4)$$

where P_h = horsepower, hp.

Notes:

1. Pump size: nominal × engine diameter × pump diameter.

2. Types:

Powerlift I: single seal, internal porting.

Powerlift II: Multiple seal, external porting, opposed pistons with central engine.

In our example, 83.3 ft-lbf/sec corresponds to 0.15 hp. If we were to supply the pressurized fluid at 2 cu in./sec, the plunger would move the 12 in. in 6 seconds. The work done would be the same, but because it would be done in half the time, the hp would be twice as great.

Note that we have interpreted the hp in terms of the work done through the plunger per unit time. This power is supplied by the pump pressurizing the fluid. The plunger transforms the fluid power to mechanical. This is the action of a hydraulic motor. The hydraulic equivalent of 0.15 hp is a flow rate of 1 cu in./sec at 1,000 psi. If the flow rate in cubic inches per second is multiplied by the pressure in pounds force per square inch, the product will have units of inch-pounds per second, which are the dimensions of power. Conversion of units will show that 1 cu in./sec is the same as 8.905 B/D. If 8.905 B/D at 1,000 psi is 0.15 hp, it follows that

$$P_h = q \times p \times 0.000017, \dots \dots \dots (5)$$

where q = flow rate, B/D, and p = pressure, psi.

Eq. 5 shows that the same power can be obtained with high flow rates at low pressure, or with lower flow rates at a higher pressure. This is a very useful feature of hydraulic power transmission. Only the flow rate and the pressure enter into this relationship; the density, or specific gravity, of the fluid does not.

The process described can be reversed. A force of 1,000 lbf applied to the plunger in Fig. 6.20 can force fluid out of the line at a pressure of 1,000 psi. In this case, the mechanical power of the plunger would be transformed into fluid power as it is done in pumps.

A useful consequence of the relationship expressed in Eq. 1 is demonstrated in Fig. 6.21. Two plungers of different diameters are connected together by a rod. The section of the assembly occupied by the connecting rod is vented to the atmosphere. The face area of the larger plunger is 2 sq in. and the face of the smaller plunger is 1 sq in. Fluid at 1,000-psi pressure is supplied to the cylinder that contains the larger plunger. This causes the plunger to push through the rod and against the smaller plunger with a force of 2,000 lbf. To restrain the motion of the rod-and-plunger system, an opposing force of 2,000

 Types: 900—Single-seal, single-acting, internal-porting;
 924—Single-seal, double-acting, internal-porting.

lbf must be applied to the smaller plunger. This can be accomplished with fluid in the smaller cylinder at 2,000 psi. If these pressures are maintained and fluid is supplied to the larger cylinder at a constant rate, the rod-and-plunger system will move to the right at a constant rate. Fluid will be forced out of the smaller cylinder at half the rate it is supplied to the larger cylinder, but with twice the pressure. This hydraulic transformer process is reversible, which would entail supplying 2,000-psi fluid to the smaller cylinder to make 1,000-psi fluid flow out of the larger cylinder at twice the flow rate supplied to the smaller cylinder. In either case, the input and output horsepowers are the same because no losses have been considered.

The characteristics of such a rod-and-plunger system can be used to advantage in hydraulic pumps. In shallow wells where the pressure requirements of the pump are low, a large pump plunger can be used in conjunction with a small engine piston without requiring excessively high pressures to be supplied to the engine. In deeper wells, where the discharge pressure of the pump will be high, a small pump plunger is used in conjunction with a large engine piston to reduce the power-fluid pressure requirement. The smaller pump plunger will, however, produce less fluid at the same stroking rate than the larger pump

plunger. Hydraulic pump manufacturers offer a variety of engine and pump combinations to meet the requirements of different flow rates and depth settings (see examples in Tables 6.1 through 6.4).

Pressures and Force Balance in Downhole Pumps

By looking at the pressures and forces in a downhole hydraulic pump, a generalized equation can be developed to predict the operating pressure required in a particular well. Two pumps are analyzed to show the generality of the solution. Fig. 6.22 shows a double-acting pump with the various areas identified and the pressures labeled for upstroke and downstroke conditions. In this design, both the upper and lower rods are exposed to the power-fluid pressure, p_{pf} . At the beginning and end of each half-stroke, brief periods of deceleration and acceleration occur, but the majority of the stroke is at constant velocity. For the constant-velocity condition, the sum of the forces acting downward must equal the sum of the forces acting upward. In the case of a downstroke, the downward forces are

$$F_d = p_{pf}A_{cr} + p_{pf}(A_{cp} - A_{cr}) + p_{ps}(A_{pp} - A_{pr}), \dots (6)$$

Fig. 6.17—Manufacturer "C" pump types for Table 6.3.

Fig. 6.18—Manufacturer "D" pump types for Table 6.4.

where

- F_d = downward force, lbf,
 p_{pf} = power-fluid pressure, psi,
 A_{er} = cross-sectional area of engine rod, sq in.,
 A_{ep} = cross-sectional area of engine piston, sq in.,
 p_{ps} = pump suction pressure, psi,
 A_{pp} = cross-sectional area of pump plunger, sq in., and
 A_{pr} = cross-sectional area of pump rod, sq in.

The upward forces are

$$F_u = p_{ed}(A_{ep} - A_{er}) + p_{pd}(A_{pp} - A_{pr}) + p_{pf}(A_{pr}), \quad (7)$$

where

- F_u = upward force, lbf,
 p_{ed} = engine discharge pressure, psi, and
 p_{pd} = pump discharge pressure, psi.

Equating the upward and downward forces and solving for the power-fluid pressure at the pump gives

$$p_{pf} = p_{ed} + p_{pd}(A_{pp} - A_{pr})/(A_{ep} - A_{er}) - p_{ps}(A_{pp} - A_{pr})/(A_{ep} - A_{er}), \quad (8)$$

If $p_{ed} = p_{pd}$, as is the case in open power-fluid systems, then

$$p_{pf} = p_{pd}[1 + (A_{pp} - A_{pr})/(A_{ep} - A_{er})] - p_{ps}(A_{pp} - A_{pr})/(A_{ep} - A_{er}), \quad (9)$$

Eq. 8 can also be written as

$$p_{pf} = p_{ed} + (p_{pd} - p_{ps})(A_{pp} - A_{pr})/(A_{ep} - A_{er}), \quad (10)$$

Fig. 6.19—Pressure and force in a static plunger and cylinder assembly.

Fig. 6.20—Pressure, force, and flow in a dynamic plunger and cylinder assembly.

The same analysis for the upstroke would give the same answer because this double-acting pump is completely symmetrical.

Fig. 6.23 shows a balanced downhole unit with a single-acting pump end. First, for the downstroke, the downward forces are

$$F_d = p_{pf}(A_{ep}) + p_{ps}(A_{pp} - A_{pr}), \quad (11)$$

and the upward forces are

$$F_u = p_{pf}(A_{ep} - A_{er}) + p_{pd}(A_{er} - A_{pr}) + p_{pd}(A_{pp}). \quad (12)$$

In this pump, the areas of the engine and pump rods are half that of their respective pistons and plungers:

$$A_{er} = A_{ep}/2 \quad (13)$$

and

$$A_{pr} = A_{pp}/2. \quad (14)$$

Equating the upward and downward forces, substituting Eqs. 13 and 14, and solving for the power-fluid pressure, p_{pf} , gives

$$p_{pf} = p_{pd}(1 + A_{pp}/A_{ep}) - p_{ps}(A_{pp}/A_{ep}). \quad (15)$$

Evaluating the force balance for the upstroke gives

$$F_d = p_{ed}(A_{ep}) + p_{ps}(A_{pp} - A_{pr}) \quad (16)$$

and

$$F_u = p_{pf}(A_{ep} - A_{er}) + p_{pd}(A_{er} - A_{pr}) + p_{ps}(A_{pp}). \quad (17)$$

Eqs. 13, 14, 16, and 17 give

$$p_{pf} = 2p_{ed} - p_{pd}(1 - A_{pp}/A_{ep}) - p_{ps}(A_{pp}/A_{ep}). \quad (18)$$

Note that if $p_{ed} = p_{pd}$, which is the case in an open power-fluid installation, Eqs. 15 and 18 become the same:

$$p_{pf} = p_{pd}(1 + A_{pp}/A_{ep}) - p_{ps}(A_{pp}/A_{ep}). \quad (19)$$

Eq. 19 for the single-acting pump shown in Fig. 6.23 can be made identical to Eq. 9 for the double-acting pump shown in Fig. 6.22 by observing that, because of Eqs. 13 and 14,

$$A_{pp}/A_{ep} = (A_{pp} - A_{pr})/(A_{ep} - A_{er}). \quad (20)$$

Because it appears frequently in pressure calculations with hydraulic pumps, the term $(A_{pp} - A_{pr})/(A_{ep} - A_{er})$ is frequently simplified to P/E . This is sometimes called the “ P over E ratio” of the pump and is the ratio of the net area of the pump plunger to the net area of the engine piston. With this nomenclature, Eq. 8 for a closed power-fluid installation becomes

$$p_{pf} = p_{ed} + p_{pd}(P/E) - p_{ps}(P/E), \quad (21)$$

where $P/E = (A_{pp} - A_{pr})/(A_{ep} - A_{er})$.

Eq. 9 for an open power-fluid installation becomes

$$p_{pf} = p_{pd}[1 + (P/E)] - p_{ps}(P/E). \quad (22)$$

This approach has found widespread acceptance among the manufacturers of downhole pumps, and the ratio P/E is included in all their pump specifications (see examples in Tables 6.1 through 6.4).

P/E values greater than 1.0 indicate that a pump plunger is larger than the engine piston. This would be appropriate for shallow, low-lift wells. P/E values less than 1.0 are typical of pumps used in deeper, higher-lift wells. In some pumps, the P/E value is also the ratio of pump displacement to engine displacement, but corrections for fluid

Fig. 6.21—Pressures, forces, and flows in a hydraulic transformer.

volumes to actuate engine valves and corrections for displacement volumes on the unloaded half-stroke of some single-acting pumps are necessary. Reference to specific displacement values for the engine and pump ensures proper determination of the respective flow rates.

Fluid Friction and Mechanical Losses in Hydraulic Pumps

In deriving Eqs. 9 and 19, we assume there are no fluid friction or mechanical losses. In practice, to maintain the stroking action of the pump, an additional pressure over and above the values for p_{pf} calculated with these equations is required. The largest portion of this extra pressure is a result of fluid-friction losses in the engine and pump. Because higher stroking rates require higher fluid velocities, this friction loss increases as the pump speed increases. Because of the effect of approximately constant dead times for the pump reversals, the rate of increase in pump friction with respect to increases in stroking rate tends to be higher than expected from simple pipe friction calculations based on average velocities. It has been found through testing that, for a given pump, the friction pressure can be represented by

$$p_{fr} = 50e^{K(N/N_{\max})}, \quad (23)$$

where

p_{fr} = friction pressure, psi,

K = experimentally determined constant for the particular pump,

N = pump operating rate, strokes/min., and

N_{\max} = rated maximum pump operating rate, strokes/min.

Note that the $p_{fr(\min)}$ is 50 psi, which occurs at zero strokes per minute. The value of $p_{fr(\max)}$ occurs when $N = N_{\max}$ and is

$$p_{fr(\max)} = 50e^K, \quad (24)$$

where $p_{fr(\max)}$ = maximum friction pressure, psi.

The value of $p_{fr(\max)}$ usually falls between 500 and 1,250 psi, depending on the particular pump.

If the manufacturers' reported values for $p_{fr(\max)}$ for each of their pumps are plotted vs. the maximum total flow rate of the engine and pump ends for the units, a correlation becomes apparent. For pumps designed to fit in a specific size of tubing string, the value of $p_{fr(\max)}$ increases with the maximum rated total fluid through the engine and pump ends. The form of the equation that gives a good fit is

$$p_{fr(\max)} = Ae^{Bq_{tm}}, \quad (25)$$

Here A and B are constants that depend on the tubing size for which the pump is designed, and q_{tm} is the maximum rated total flow through the engine and pump of a particular unit.

Eqs. 24 and 25 can be used to determine the value of K , which can then be substituted into Eq. 23 to give

$$p_{fr} = 50(Ae^{Bq_{tm}}/50)^{N/N_{\max}}, \quad (26)$$

The value of A in Eq. 26 is the same for all sizes of tubing—i.e., $A = 355$. Eq. 26 can therefore be written as

$$p_{fr} = 50(7.1e^{Bq_{tm}})^{N/N_{\max}}, \quad (27)$$

The values for B for different sizes of tubing are given in Table 6.5.

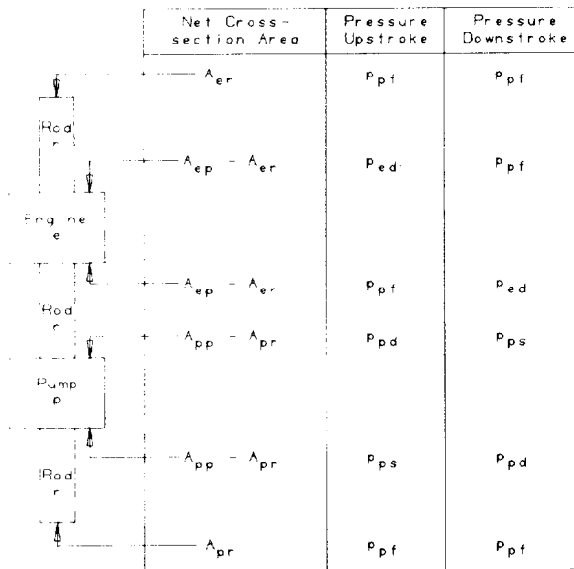

Fig. 6.22—Pressures acting on a double-acting downhole unit.

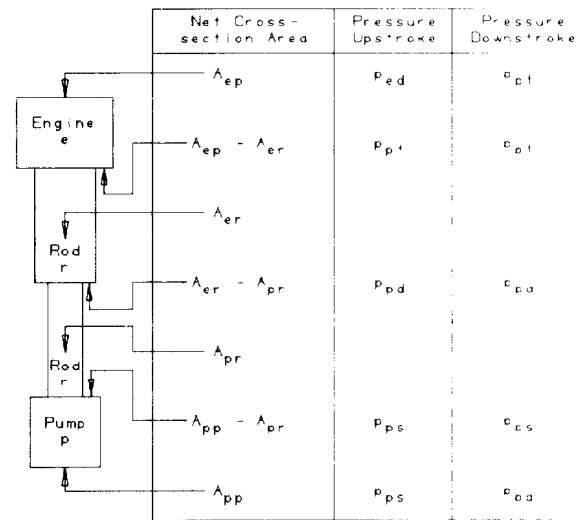

Fig. 6.23—Pressures acting on a single-acting downhole unit.

Eq. 27 is based on data accumulated from laboratory tests on water or on light test oils with viscosities less than 10 cSt and corrected to water properties. Because 75 to 80% of the losses are in the engine end of the downhole unit, specific gravity and viscosity corrections are necessary for different power fluids. To correct for density differences, the value of p_{fr} should be multiplied by the specific gravity of the power fluid, γ . A multiplying factor, F_v , which corrects for different viscosities, is given by

$$F_v = \nu_{pf}/100 + 0.99, \quad (28)$$

where ν_{pf} = power-fluid viscosity, cSt.

With both of these corrections, Eq. 27 becomes

$$p_{fr} = \gamma F_v (50) (7.1 e^{Bq_m})^{N/N_{max}}, \quad (29)$$

Curves plotted from Eq. 29 are shown in Fig. 6.24. The specific gravity of different API-gravity crudes can be determined from Table 6.6. Fig. 6.25 gives the viscosity of a variety of crudes as a function of temperature, and Fig. 6.26 gives the viscosity of water as a function of temperature with varying salt concentrations.

TABLE 6.5—TUBING SIZE VS. CONSTANT B

Tubing Size (in.)	B
2 3/8	0.000514
2 7/8	0.000278
3 1/2	0.000167
4 1/2	0.000078

Example Problem 1. Consider Manufacturer B's Type D pump—double engine, single pump end—for which the specifications are in Table 6.2. For the $2\frac{1}{2} \times 1\frac{7}{8} \times 1\frac{3}{4}$ size unit for $2\frac{1}{2}$ -in. tubing, the maximum rated engine flow rate is 1,799 B/D and the rated displacement of the pump end is 1,086 B/D for a total of 2,885 B/D. At rated speed of 100 strokes/min and using water power fluid with a specific gravity of 1.0 and a viscosity of 1 cSt, Eq. 29 gives

$$p_{fr} = (1)(1)(50) [7.1 e^{(0.000278)(2885)}]^{100/100} = 792 \text{ psi.}$$

If the pump speed is reduced to 60 strokes/min,

$$p_{fr} = 50 [7.1 e^{(0.000278)(2885)}]^{60/100} = 262 \text{ psi.}$$

These examples are shown in Fig. 6.24.

With this same unit, if the $1\frac{1}{2}$ -in. pump end is fitted, or if gas interference reduces the pump end volumetric efficiency of the $1\frac{3}{4}$ -in. pump end to 69%, the maximum rated flow through the pump end will be 744 B/D instead of 1,086 B/D, and the total flow will be reduced to 2,543 B/D. At rated speed, the friction pressure loss will then be

$$p_{fr} = 50 [7.1 e^{(0.000278)(2543)}]^{100/100} = 720 \text{ psi.}$$

If a 0.9-specific-gravity power fluid that has a viscosity of 10 cSt at bottomhole conditions was used in the last example, then

$$p_{fr} = 0.9(10/100 + 0.99)(50) [7.1 e^{(0.000278)(2543)}]^{100/100} = 706 \text{ psi.}$$

Fig. 6.24—Friction and mechanical loss in downhole pumps (specific gravity = 1.0, viscosity = 1.0 cSt).

Displacement of Downhole Pumps

Downhole pumps are normally rated by their theoretical displacement per stroke per minute on both the engine and pump ends. The theoretical displacement is the net area of the plunger times the distance traveled in a working stroke. There is also a maximum rated speed for each pump. Because of the tendency of inconsistent engine valve operation at very low stroking rates, and because of shorter pump life at very high stroking rates, downhole units are normally chosen to operate between 20 and 80% of their rated maximum speed. Choosing a pump that will meet the displacement requirements of a well at less than rated speed allows for later speed increases to offset normal pump wear. New engine efficiencies of about 95% may decline to 80% with wear. A value of 90% is often used for design purposes. New pump end efficiencies are typically high, but a worn pump end may have a volumetric efficiency as low as 70%. The specifications for downhole pumps from some major manufacturers are given in Tables 6.1 through 6.4. There are no API standards for hydraulic pumps. Consequently, there is considerable variation in designs, sizes, stroke lengths, and rated speeds, and parts are not interchangeable between brands.

At bottomhole conditions, however, the oil, water, and gas phases occupy different volumes than on the surface where flow measurements are made. Vented systems will allow significant portions of the free gas to vent to the surface, while unvented systems route all the free gas through the pump. The volume occupied by the free gas and the downhole volume of the oil with gas dissolved in it depend on several factors, including the crude gravity, gas gravity, temperature, and pressure.

The term "gas interference" has been used to describe the phenomenon of greatly reduced actual fluid displacement when gas and liquid phases are pumped at the same time. The gassy fluid is drawn into the pump suction at a low pressure and is discharged from the exhaust at a high pressure. The pump plunger, however, does not completely purge the pump barrel of fluid because of practical design and manufacturing considerations. The unswept volume is called the clearance volume. The clearance volume contains liquid and gas at pump discharge pres-

sure at the end of the discharge stroke. As the plunger reverses and moves in the suction stroke, the clearance-volume gas expands and its pressure declines. The suction valving will not open until the clearance-volume gas pressure drops below pump intake pressure. This phenomenon clearly reduces the effective stroke length of the pump, and in severe cases, the suction valves will not open for one or more pump cycles. This extreme case is referred to as "gas locking."

Hydraulic pumps usually have small clearance volumes because the engine and pump ends are very closely coupled, and control of stroke length is precise. Also, gradual leakage of power fluid or pump discharge fluid back into the pump barrel will eventually help purge clearance-volume gas. Specially designed discharge valve seats called "gas lock breakers" can be used to preclude gas lock by allowing a controlled leakage back into the pump barrel during the suction stroke. For these reasons, it is uncommon for hydraulic pumps to actually "gas lock," but the volumetric efficiency of the pump end is always reduced by the presence of gas. Even if the gas is all in solution, as when pumping above the bubblepoint of the crude, the liquid phase will occupy more volume downhole than it does in the stock tank because of dissolved gas, and this reduces the effective pump end volumetric efficiency.

Fig. 6.27, based on relationships from Standing⁹ and API Manual 14 BN,¹⁰ gives a means for determining the maximum volumetric efficiency of a pump from considerations of liquid- and gas-phase volumes. The equations used to generate Fig. 6.27 are listed in Appendix A. The gas interference effect depends on the compression ratio of the particular unit and will change with plunger size. It also depends on the ratio of intake to discharge pressure and whether the pump barrel is discharged at the top or the bottom. The magnitude of the gas interference effect is not well documented for all units. Therefore, it is common practice to assume that this effect and normal fluid leakage past fits reduces the displacement of the pump end to about 85% of the manufacturers' ratings. The pump suction rate is then

$$q_s = q_p N / N_{\max} E_{p(\max)} E_{p(\text{int})} \quad (30)$$

*First line opposite each API gravity is specific gravity at 60°F, second line is column pressure in psi/ft.

Fig. 6.25—Viscosity of oils.

Fig. 6.26—How temperature affects viscosity of salt water (these curves indicate the effect of temperature on viscosity of salt water solutions of various concentrations).

The pump displacement required to achieve a desired pump suction rate is therefore

$$q_p = q_s / [N / N_{\max} E_{p(\max)} E_{p(\text{int})}], \quad (31)$$

where

q_s = pump suction rate, B/D,

q_p = rated pump displacement, B/D,

$E_{p(\max)}$ = maximum pump efficiency from Fig. 6.27, fraction, and

$E_{p(\text{int})}$ = pump efficiency for gas interference and pump leakage (normally = 0.85), fraction.

Example Problem 2. Consider a case where one desires to produce 250 B/D of 35°API crude at a pump intake pressure of 500 psi. The gas/oil ratio (GOR) is 500:1 and the water cut is 40%. Fig. 6.27 gives 41% theoretical volumetric efficiency. The required pump displacement at 80% of rated speed is therefore given by

$$q_p = 250 / (0.8 \times 0.41 \times 0.85) = 897 \text{ B/D.}$$

When the maximum volumetric efficiency from Fig. 6.27 is below about 50%, an installation design that in-

cludes the extra cost and complexity of a gas vent should be considered. A number of factors affect the performance of gas-vent systems. However, the saturated oil-volume line in Fig. 6.27 (the upper boundary of the downhole shaded area) can be used to account for the increased downhole volume of the oil caused by gas that remains in solution. In the previous example, saturated oil at 500 psi has a downhole volume that gives a maximum pump efficiency of 95% when calculated on surface volume where the solution gas has been liberated. The required pump displacement at 80% of rated speed is therefore given by

$$q_p = 250 / (0.8 \times 0.92 \times 0.85) = 400 \text{ B/D.}$$

System Pressures and Losses in Hydraulic Installations

The flow of fluid power in a hydraulic pumping system starts with the high-pressure pump on the surface. The power fluid passes through a wellhead control valve and down the power-fluid tubing string. The power-fluid pressure increases with depth because of the increasing hydrostatic head of fluid in the tubing. At the same time, some

of the power-fluid pressure is lost to fluid friction in the tubing string. At the pump, most of the power-fluid pressure is available for work in driving the downhole unit, with the remainder lost in the friction pressure, p_{fr} . After the downhole unit is operated, the power fluid must return to the surface. The pressure of the power fluid leaving the downhole unit depends on the hydrostatic head of fluid in the return tubing above the pump. In addition to this pressure, the fluid friction pressure lost in getting to the surface and the backpressure at the wellhead must be considered. In an open power-fluid system, the produced fluid from the well will leave the downhole unit and mix with the exhaust power fluid, thereby encountering the same pressure environment as the power fluid. In a closed power-fluid system, the production will have its own unique hydrostatic head, friction pressure loss, and wellhead or flowline backpressure. In both cases, the pump suction will be at a pump intake pressure from the well that will vary with the production rate according to the IPR of the well. Fig. 6.28 shows the system pressures and losses for an open power-fluid installation, and Fig. 6.29 shows them for a closed power-fluid installation.

The relationships shown in Figs. 6.28 and 6.29 are summarized below.

Open Power-Fluid System.

$$p_{pf} = p_{so} - p_{fpt} + g_{pf}D - p_{fr}, \dots\dots\dots (32)$$

$$p_{pd} = p_{fd} + g_d D + p_{wh}, \dots\dots\dots (33)$$

$$p_{ed} = p_{pd}, \dots\dots\dots (34)$$

and

$$p_{ps} = g_s s_p, \dots\dots\dots (35)$$

Fig. 6.27—Theoretical volumetric efficiencies of unvented downhole pumps as affected by high GOR's (volume occupied by saturated oil and free gas is based on 35° API oil at 160°F BHT). Example: To determine maximum displacement of an unvented pump with 430-psi pumping bottomhole pressure, 250 gas/oil ratio, and 50% water cut. Enter chart at 430 psi down to GOR (250). From intersection, proceed horizontally to read 44+ % oil displacement. Strike a diagonal from 44+ % on Line A to Point B, from intersection with 50% water cut, read 62% maximum displacement of water and tank oil.

Note that Eq. 32 can be solved for the surface operating pressure (triplex pressure) to give

$$p_{so} = p_{pf} + p_{fpt} - g_{pf}D + p_{fr}, \dots\dots\dots (36)$$

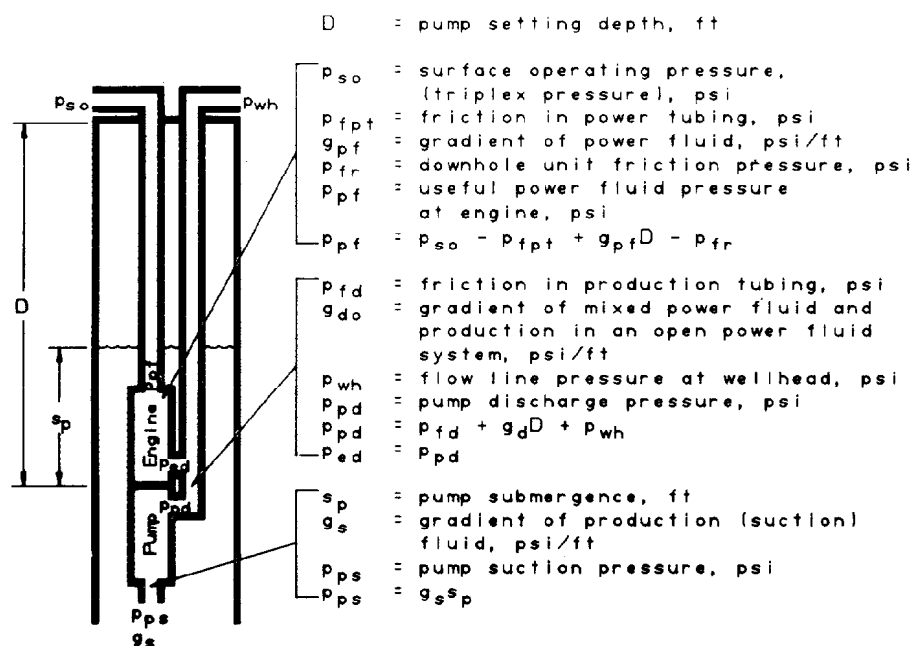

Fig. 6.28—System pressures and losses in an open power-fluid installation.

Closed Power-Fluid System.

$$p_{pf} = p_{so} - p_{fpt} + g_{pf}D - p_{fr}, \dots \dots \dots (32)$$

$$p_{ed} = p_{fet} + g_{pf}D + p_{whe}, \dots \dots \dots (37)$$

$$p_{pd} = p_{fd} + g_s D + p_{wh}, \dots \dots \dots (38)$$

and

$$p_{ps} = g_s s_p, \dots \dots \dots (35)$$

As before, solving for the surface operating pressure gives

$$p_{so} = p_{pf} + p_{fpt} - g_{pf}D + p_{fr}, \dots \dots \dots (36)$$

Calculation of Fluid Gradients. Power Fluid. Proper values for the various fluid gradients are necessary to calculate the pressures that affect the pump. The power-fluid, either oil or water, has a gradient, g_{pf} , in pounds per square inch per foot. This is also the power-fluid exhaust gradient in a closed power-fluid system. The gradient values for different-API-gravity oils are given in Table 6.6. If water is used as power fluid, its gradient may vary from the standard value of 0.433 psi/ft, depending on the amount of dissolved salt. Corrections may be made by use of the general relationship:

$$g = \gamma(0.433), \dots \dots \dots (39)$$

Produced Fluid. The gradient of the produced well fluids at the pump suction is given by

$$g_s = g_o(1 - W_c) + g_w W_c, \dots \dots \dots (40)$$

where

g_o = gradient of produced oil, psi/ft,
 g_w = gradient of produced water, psi/ft, and
 W_c = water cut (0.5 for 50% water cut),
 fraction.

This is also the value for the pump discharge gradient, g_d , in a closed power-fluid system.

Pump and Engine Discharge Gradient in an Open Power-Fluid System.

$$g_d = [(q_{pf} \times g_{pf}) + (q_s \times g_s)] / q_d, \dots \dots \dots (41)$$

where

q_{pf} = power-fluid rate, B/D,
 q_s = production (suction) fluid rate, B/D, and
 q_d = discharge fluid rate, $q_{pf} + q_s$, B/D.

Fluid Friction in Tubular and Annular Flow Passages.

Appendix B contains friction pressure-drop curves for a variety of commonly used tubing and casing sizes. Also included in Appendix B are the equations used to create the curves. Note that the pressure drops are given in pounds per square inch per 1,000 ft and that the values

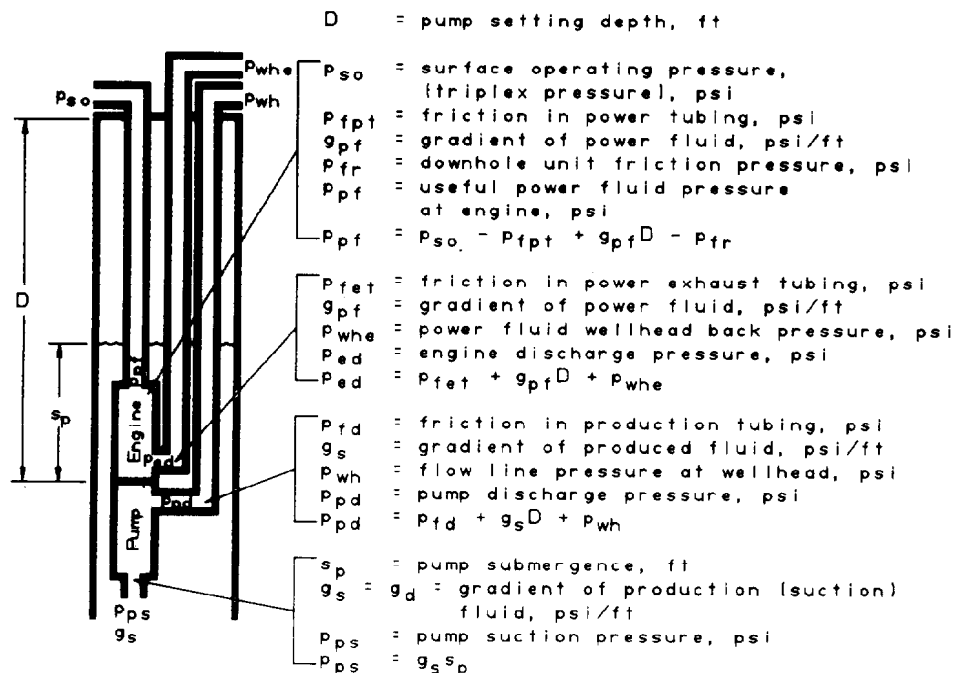

Fig. 6.29—System pressures and losses in a closed power-fluid installation.

must be multiplied by the specific gravity of the fluid. The values for the power-fluid friction pressure, p_{pft} , the power-fluid discharge pressure friction, p_{pfd} , and the production discharge friction pressure, p_{fd} , can be determined from the charts or the basic equations.

Fluid Viscosity. The viscosities of various crude oils and waters are discussed in Appendix A. The viscosity of water/oil mixtures is difficult to predict. In hydraulic pumping calculations, a weighted average is normally used. Water and oil viscosities are usually evaluated at the average temperature between surface and downhole temperatures.

$$\nu_m = (1 - W_{cd})\nu_o + W_{cd}\nu_w, \quad (42)$$

where

ν_m = mixture viscosity, cSt,

ν_o = oil viscosity, cSt,

ν_w = water viscosity, cSt, and

W_{cd} = water cut in discharge conduit to surface, fraction.

In closed power-fluid systems,

$$W_{cd} = W_c. \quad (43)$$

In open power-fluid systems using water as the power fluid,

$$W_{cd} = (q_{pf} + W_c q_s) / q_d. \quad (44)$$

For open power-fluid systems with oil as a power fluid,

$$W_{cd} = W_c q_s / q_d. \quad (45)$$

These equations do not consider the formation of any emulsions that only occasionally form in hydraulic pumping systems. Water-in-oil emulsions can cause extremely high apparent viscosities (Fig. 6.30) but the prediction of when emulsions will form is difficult. The formation of oil-in-water emulsions has been done deliberately in heavy crude wells as a means of reducing viscosity.¹¹

Multiphase Flow and Pump Discharge Pressure

Eqs. 33 and 38 for the pump discharge pressure include only the dead oil and water gradients. If the well produces significant gas, the multiphase (gas plus liquid) flow to the surface will result in pump discharge pressures lower than predicted by Eqs. 33 and 38. The magnitude of this effect on the operating pressure (and required horsepower) depends on the P/E ratio of the downhole pump. Available P/E ratios range from a low of 0.30 to a high of 2.00. By referring to Eq. 22 for open power-fluid systems, which are the most common, we can see that a change in the pump discharge pressure affects the power-fluid pressure by $(1 + P/E)$ times the change in discharge pressure. Because $(1 + P/E)$ has a range of 1.30 to 3.00, depending on the pump, a 500-psi reduction in the pump discharge pressure caused by gas effects can change the operating pressure required by 650 to 1,500 psi.

Fig. 6.30—Effect of emulsion on oil viscosity.

If the gas/liquid ratio F_{gL} is less than about 10 scf/bbl in the pump discharge flow path, the gas effects are minimal and Eqs. 33 and 38 can be used directly. For higher F_{gL} values, it is suggested that a vertical multiphase flowing gradient correlation be used to calculate the pump discharge pressure. (See Chap. 5, Gas Lift, for a detailed discussion of these calculations.) Note that in open power-fluid systems, the addition of the power fluid to the production will make the discharge F_{gl} substantially less than the formation producing GOR, R . In a closed power-fluid system,

$$F_{gL} = (1 - W_c)R. \quad (46)$$

In an open power-fluid system,

$$F_{gL} = q_s(1 - W_c)R / q_d. \quad (47)$$

The appropriate water cuts for use in vertical multiphase flowing gradient calculations are given in Eqs. 43 through 45.

Gas/Liquid Ratio in Vented Systems

Vented systems allow most of the free gas to rise to the surface without passing through the pump. The gas that is still in solution in the oil at pump intake pressure conditions, however, does pass through the pump. To determine solution GOR from Fig. 6.27, read down from the pumping BHP to the saturated oil-volume line (the upper boundary of the downhole volume shaded area). Interpolating between the intersections of the constant-GOR curves with the saturated-oil-volume line gives the solution GOR. At 500-psi pump intake pressure, the solution GOR is about 100 scf/bbl. The solution GOR should be used in Eqs. 46 and 47 when the installation includes a gas vent.

Pressure Relationships Used To Estimate Producing BHP

The pressure relationships of Eqs. 21 and 22 can be rearranged to give the pump intake pressure p_{ps} in terms of the other system pressures and the P/E ratio of the pump. For the closed power-fluid system,*

$$p_{ps} = p_{pd} - (p_{pf} - p_{ed})/(P/E). \quad (48)$$

For the open power-fluid system,

$$p_{ps} = p_{pd} - (p_{pf} - p_{pd})/(P/E). \quad (49)$$

If the appropriate relationships from Eqs. 32 through 38 are used, the equation for the closed power-fluid system becomes**

$$p_{ps} = (p_{fd} + g_s D + p_{wh}) - [(p_{so} - p_{fpt} + g_{pf} D - p_{fr}) - (p_{fet} + g_{pf} D + p_{whe})]/(P/E), \quad (50)$$

where $g_s = g_d$ in a closed power-fluid system.

For the open power-fluid system, the relationship is

$$p_{ps} = (p_{fd} + g_d D + p_{wh}) - [(p_{so} - p_{fpt} + g_{pf} D - p_{fr}) - (p_{fd} + g_d D + p_{wh})]/(P/E). \quad (51)$$

These equations can be used directly, but several problems arise. Several friction terms must be evaluated, each with a degree of uncertainty. The term p_{fr} for the losses in the pump is the least accurate number because pump wear and loading can affect it. To avoid the uncertainty in friction values, a technique called the "last-stroke method" is often used. With this method, the power-fluid supply to the well is shut off. As the pressure in the system bleeds down, the pump will continue to stroke at slower rates until it takes its last stroke before stalling out. The strokes can be observed as small kicks on the power-fluid pressure gauge at the wellhead. The power-fluid pressure at the time of the last stroke is that required to balance all the fluid pressures with zero flow and zero pump speed. At zero speed, all the friction terms are zero, except p_{fr} , which has a minimum value of 50 psi, which simplifies Eqs. 50 and 51. With the friction terms removed, the last stroke relationship for the closed power-fluid system becomes

$$p_{ps} = g_s D + p_{wh} - [(p_{so} + g_{pf} D - 50) - (g_{pf} D + p_{whe})]/(P/E). \quad (52)$$

For the open power-fluid system the relationship is

$$p_{ps} = g_d D + p_{wh} - [(p_{so} + g_{pf} D - 50) - (g_d D + p_{wh})]/(P/E). \quad (53)$$

*Eq. 48 is derived from Eq. 21 and Eq. 49 is derived from Eq. 22.

**Eq. 50 is derived from Eq. 21 and Eq. 51 is derived from Eq. 22.

These relationships have proved to be very effective in determining BHP's.¹² However, they are limited to wells that produce little or no gas for the reasons discussed in the section on Multiphase Flow and Pump Discharge Pressure. Eqs. 50 and 51 can be used in gassy wells if the hydrostatic-pressure and flowline-pressure terms are replaced by a pump discharge pressure from a vertical multiphase flowing gradient correlation. The equations for the last-stroke method, however, present a further problem because they require the gradient at a no-flow condition. The multiphase-flow correlations show a significant variation of pressure with velocity. Wilson, in Brown,⁷ suggests subtracting the friction terms from the flowing gradient for evaluating Eqs. 52 and 53 or attempting to determine p_{fr} more accurately for use in the evaluation of Eqs. 50 and 51. The method suggested here is to use a multiphase-flow correlation for determining p_{pd} at the normal operating point of the pump. With the same correlation for the same proportions of liquid and gas, determine what the p_{pd} pressure would be at a low flow rate, corresponding to the conditions when the pump is slowing down to its last stroke. By plotting the two values of p_{pd} obtained, we can extrapolate to what p_{pd} would be at zero flow. This value can be used to replace the hydrostatic-head and flowline-pressure terms.

Selecting an Appropriate P/E Ratio. As previously discussed, large values of P/E are used in shallow wells and small values in deeper wells. The larger the value of P/E , the higher the surface operating pressure to lift fluid against a given head will be. The multiplex pumps offered by the manufacturers are rated up to 5,000 psi, but few hydraulic installations use more than 4,000 psi except in very deep wells. About 80 to 90% of the installations use operating pressures between 2,200 and 3,700 psi. With the simplifying assumptions of an all-water system, no friction, 500-psi pump friction, 4,000-psi operating pressure, and a pumped-off well, Eqs. 22, 33, and 36 lead to

$$(P/E)_{\max} = 3,500/0.433L_n = 8,000/L_n, \quad (54)$$

where L_n = net lift, ft.

Eq. 54 is useful in initial selection of an appropriate P/E ratio in installation design. The actual final determination of the surface operating pressure will depend on calculation of the actual gradients and losses in the system and on the particular pump's P/E ratio.

Equipment Selection and Performance Calculations

Equipment selection involves matching the characteristics of hydraulic pumping systems to the parameters of a particular well or group of wells. A worksheet and summary of equations are given in Table 6.7.

Once a downhole unit has been selected and its power-fluid pressure and rate determined, an appropriate power supply pump must be matched to it. The section on surface equipment and pumps provides a detailed description of the types of pumps used for powering hydraulic pumping systems. Specifications for some of the pumps typically used can be found in Tables 6.1 through 6.4 (Figs. 6.15 through 6.18).

A troubleshooting guide is provided in Tables 6.8 through 6.10.

TABLE 6.7—WORKSHEET AND SUMMARY OF EQUATIONS FOR RECIPROCATING PUMPS

Well Identification Example Problem 3

Vertical setting depth, ft	9,000	Water specific gravity	1.03
Tubing length, ft	9000	Power fluid gradient, psi/ft	0.357
Tubing ID, in.	2.441	Produced oil gradient, psi/ft	0.357
Tubing OD, in.	2.875	Water gradient, psi/ft	0.446
Return ID, in.	4.892	Oil viscosity, cSt	2
Wellhead pressure, psi	100	Water viscosity, cSt	0.485
Gas specific gravity	0.75	GOR, scf/bbl	100
Oil gravity, °API	40	Water cut, %	70
Power fluid specific gravity	0.82	Surface temperature, °F	100
Produced oil specific gravity	0.82	Bottomhole temperature, °F	200

Expected net lift, ft	7,800	Vented?	Yes _____ No <input checked="" type="checkbox"/>
Desired production, B/D	250		
Pump intake pressure at above rate, psi	500		
Installation: Casing <input checked="" type="checkbox"/> Parallel _____			
OPF <input checked="" type="checkbox"/> CPF _____			

Step 1— $(P/E)_{\max} = 8,000/L_n = 1.03$ (Eq. 54)**Step 2**—Maximum pump efficiency $E_{p(\max)}$ (Fig. 6.27) _____ % (Vented)
97 % (Unvented)**Step 3**—Minimum recommended pump displacement (Eq. 31):

$$q_p = q_s / \frac{N}{N_{\max}} \times E_{p(\max)} \times E_{p(\text{int})} = 250 / (0.8 \times 0.97 \times 0.85) = 379 \text{ B/D.}$$

Step 4—Select pump from Tables 6.1 through 6.4 with P/E less than or equal to value from Step 1 and a maximum rated pump displacement equal to or greater than the value from Step 3.

Pump designation: Manufacturer B Type A 2½ × 1¼-1¼ in.

P/E	1.00
Rated displacement, B/D	492
Pump, B/D/strokes/min	4.92
Engine, B/D/strokes/min	5.02
Maximum rated speed, strokes/min	100

Step 5—Pump speed:

$$N = \frac{q_s / [(E_{p(\max)} \times E_{p(\text{int})})]}{q_p / N_{\max}} = \frac{250 / (0.97 \times 0.85)}{492 / 100} = 61.6 \text{ strokes/min.}$$

Step 6—Calculate power-fluid rate (assume 90% engine efficiency, E_e)

$$q_{pf} = N(q_e / N_{\max}) / E_e = 61.6(502 / 100) / 0.90 = 344 \text{ B/D.}$$

Step 7—Return fluid rate and properties—OPF system

- a. Total fluid rate: power fluid rate, q_{pf} = 344 B/D
+ production rate, q_s = 250 B/D
= total rate, q_d = 594 B/D

b. Water cut:

Water power fluid (Eq. 44)

$$W_{cd} = (q_{pf} + W_c q_s) / q_d = \text{_____}$$

Oil power fluid (Eq. 45)

$$W_{cd} = W_c q_s / q_d = 0.7 \times 250 / 594 = 0.29$$

c. Viscosity (Eq. 42)

$$\nu_m = (1 - W_{cd})\nu_o + W_{cd}\nu_w = (1 - 0.29)2 + 0.29 \times 0.485 = 1.56 \text{ cSt.}$$

d. Suction gradient (Eq. 40)

$$g_s = g_o(1 - W_c) + g_w W_c = 0.357(1 - 0.7) + 0.446 \times 0.7 = 0.419 \text{ psi/ft.}$$

e. Return gradient (Eq. 41)

$$g_d = [(q_{pf} \times g_{pf}) + (q_s \times g_s)] / q_d = [(344 \times 0.357) + (250 \times 0.419)] / 594 = 0.383 \text{ psi/ft.}$$

f. Gas/liquid ratio (Eq. 47)

$$F_{gL} = q_s(1 - W_c)R / q_d = 250(1 - 0.7)100 / 594 = 12.6 \text{ scf/bbl.}$$

Note: For vented installations, use solution GOR (Fig. 6.27).

TABLE 6.7—WORKSHEET AND SUMMARY OF EQUATIONS FOR RECIPROCATING PUMPS (continued)

Step 8—Return fluid rates and properties—closed power-fluid systems. Because the power fluid and produced fluid are kept separate, the power return conduit carries the flow rate from Step 6, with power-fluid gradient and viscosity. The production return conduit carries the desired production rate with production gradient, water cut, viscosity, and GOR.

- a. Power-fluid return rate _____ B/D
- b. Production return rate _____ B/D

Step 9—Return friction: If a gas lift chart or vertical multiphase flowing gradient correlation (see Chap. 5) is used for return flow calculations, it will already include friction values and the flowline backpressure. Use of gas lift charts or correlations is suggested if the gas/liquid ratio from Step 7 is greater than 10. The value from such a correlation can be used directly in Step 11c without calculating friction values. If a gas-lift chart or vertical flow correlation is not used, then with the values from Steps 7 and 8, as appropriate, determine the return conduit friction(s) from the charts or equations in Appendix B.

1. Open power-fluid friction $p_{fd} = \text{_____}$ psi.
2. Closed power-fluid friction

- a. power return $p_{fet} = \text{_____}$ psi.
- b. production return $p_{fd} = \text{_____}$ psi.

Step 10—Power-fluid friction: With the power-fluid rate from Step 6, use the appropriate charts or equations in Appendix B to determine the power-fluid friction loss.

Power fluid friction $p_{fpt} = 4.4$ psi.

Step 11—Return pressures:

- a. Open power-fluid system (Eq. 33)

$$p_{pd} = p_{fd} + g_d D + p_{wh} = \text{_____} \text{ psi.}$$

- b. Closed power-fluid system (Eqs. 37 and 38)

$$1. p_{ed} = p_{fet} + g_{pf} D + p_{whe} = \text{_____} \text{ psi.}$$

$$2. p_{pd} = p_{fd} + g_s D + p_{wh} = \text{_____} \text{ psi.}$$

- c. If a vertical multiphase flowing gradient correlation is used instead of Eqs. 33, 37, or 38, then $p_{pd} = 3,500$ psi.

Step 12—Required engine pressure p_{pf} :

- a. Open power-fluid system (Eq. 22)

$$p_{pf} = p_{pd} [1 + (P/E)] - p_{ps} (P/E) = 3,500[1 + 1] - 500(1) = 6,500 \text{ psi.}$$

- b. Closed power-fluid system (Eq. 21)

$$p_{pf} = p_{ed} + p_{pd} (P/E) - p_{ps} (P/E) = \text{_____} \text{ psi.}$$

Step 13—Calculate pump friction

- a. Rated pump displacement, $q_p = 492$ B/D
- b. Rated engine displacement, $q_e = 502$ B/D
- c. Total displacement, $q_{tm} = 994$ B/D
- d. "B" value (Table 6.5) = 0.000278
- e. $N/N_{max} = 61.6/100 = 0.616$
- f. $F_v = \nu/100 + 0.99 = 2/100 + 0.99 = 1.01$ (Eq. 28)
- g. Pump friction (Eq. 29 or Fig. 6.24)

$$p_{fr} = \gamma F_v (50) (7.1 e^{B q_{tm}^{N/N_{max}}})^{N/N_{max}}$$

$$p_{fr} = 0.82(1.01)(50)[7.1 e^{0.000278(994)}]^{0.616} = 164 \text{ psi.}$$

Step 14—Required surface operating pressure p_{so} (Eq. 36):

$$p_{so} = p_{pf} + p_{fpt} - g_{pf} D + p_{fr} = 6,500 + 4.4 - 0.357(9,000) + 164 = 3,455 \text{ psi.}$$

Step 15—Required surface horsepower, assuming 90% surface efficiency (Eq. 5):

$$P_h = q_{pf} \times p_{so} \times 0.000017/E_s = 344 \times 3,455 \times 0.000017/0.9 = 22.4 \text{ hp.}$$

Step 16—Summary:

Pump designation—Manufacturer B Type A 2½ × 1¼-1¼ in.	
Pump speed, strokes/min	61.6
Production rate, B/D	250
Power fluid rate, B/D	344
Power fluid pressure, psi	3,455
Surface horsepower	22.4

Step 17—Triplex options (from manufacturer specification sheet, Tables 6.16 through 6.18):

Type	J-30	D-323-H	
Plunger size, in.	1⅞	1⅞	
Revolutions/min	450	300	
Flow rate at revolutions/min (B/D)	400	399	
Maximum pressure rating, psi	3,590	4,000	
Horsepower	26	26	

TABLE 6.8—SUBSURFACE TROUBLESHOOTING GUIDE—RECIPROCATING PUMP

Indication	Cause	Remedy
1. Sudden increase in operating pressure—pump stroking.	(a) Lowered fluid level, which causes more net lift. (b) Paraffin buildup or obstruction in power-oil line, flow line, or valve. (c) Pumping heavy material, such as salt water or mud. (d) Pump beginning to fail.	(a) If necessary, slow pump down. (b) Run soluble plug or hot oil, or remove obstruction (c) Keep pump stroking—do not shut down. (d) Retrieve pump and repair.
2. Gradual increase in operating pressure—pump stroking.	(a) Gradually lowering fluid level. Standing valve or formation plugging up. (b) Slow buildup of paraffin. (c) Increasing water production.	(a) Surface pump and check. Retrieve standing valve. (b) Run soluble plug or hot oil. (c) Raise pump strokes/min and watch pressure.
3. Sudden increase in operating pressure—pump not stroking.	(a) Pump stuck or stalled. (b) Sudden change in well conditions requiring operating pressure in excess of triplex relief valve setting. (c) Sudden change in power-oil emulsion, etc. (d) Closed valve or obstruction in production line.	(a) Alternately increase and decrease pressure. If necessary, unseat and reseat pump. If this fails to start pump, surface and repair. (b) Raise setting on relief valve. (c) Check power-oil supply. (d) Locate and correct.
4. Sudden decrease in operating pressure—pump stroking. (Speed could be increased or reduced.)	(a) Rising fluid level—pump efficiency up. (b) Failure of pump so that part of power oil is bypassed. (c) Gas passing through pump. (d) Tubular failure—downhole or in surface power-oil line. Speed reduced. (e) Broken plunger rod. Increased speed. (f) Seal sleeve in BHA washed or failed. Speed reduced.	(a) Increase pump speed if desired. (b) Surface pump and repair. (d) Check tubulars. (e) Surface pump and repair. (f) Pull tubing and repair BHA.
5. Sudden decrease in operating pressure—pump not stroking.	(a) Pump not on seat. (b) Failure of production unit or external seal. (c) Bad leak in power-oil tubing string. (d) Bad leak in surface power-oil line. (e) Not enough power-oil supply at manifold.	(a) Circulate pump back on seat. (b) Surface pump and repair. (c) Check tubing and pull and repair if leaking. (d) Locate and repair. (e) Check volume of fluid discharged from triplex. Valve failure, plugged supply line, low power-oil supply, excess bypassing, etc., all of which could reduce available volume.
6. Drop in production—pump speed constant.	(a) Failure of pump end of production unit. (b) Leak in gas-vent tubing string. (c) Well pumped off—pump speeded up. (d) Leak in production return line. (e) Change in well conditions. (f) Pump or standing valve plugging. (g) Pump handling free gas.	(a) Surface pump and repair. (b) Check gas-vent system. (c) Decrease pump speed. (d) Locate and repair. (f) Surface pump and check. Retrieve standing valve. (g) Test to determine best operating speed.
7. Gradual or sudden increase in power oil required to maintain pump speed. Low engine efficiency.	(a) Engine wear. (b) Leak in tubulars—power-oil tubing, BHA seals, or power-oil line.	(a) Surface pump and repair. (b) Locate and repair.
8. Erratic stroking at widely varying pressures.	(a) Caused by failure or plugging of engine.	(a) Surface pump and repair.
9. Stroke "downkicking" instead of "upkicking."	(a) Well pumped off—pump speeded up. (b) Pump intake or downhole equipment plugged. (c) Pump failure (balls and seats). (d) Pump handling free gas.	(a) Decrease pump speed. Consider changing to smaller pump end. (b) Surface pump and clean up. If in downhole equipment, pull standing valve and backflush well. (c) Surface pump and repair.
10. Apparent loss of, or unable to account for, system fluid.	(a) System not full of oil when pump was started due to water in annulus U-tubing after circulating, well flowing or standing valve leaking. (b) Inaccurate meters or measurement.	(a) Continue pumping to fill up system. Pull standing valve if pump surfacing is slow and cups look good. (b) Recheck meters. Repair if necessary.

TABLE 6.9—SUBSURFACE TROUBLESHOOTING GUIDE—JET PUMPS

Indication	Cause	Remedy
1. Sudden increase in operating pressure—pump taking power fluid.	(a) Paraffin buildup or obstruction in power-oil line, flowline, or valve. (b) Partial plug in nozzle.	(a) Run soluble plug or hot oil, or remove obstruction. Unseat and reseat pump. (b) Surface pump and clear nozzle.
2. Slow increase in operating pressure—constant power-fluid rate or slow decrease in power-fluid rate, constant operating pressure.	(a) Slow buildup of paraffin. (b) Worn throat or diffuser.	(a) Run soluble plug or hot oil. (b) Retrieve pump and repair.
3. Sudden increase in operating pressure—pump not taking power fluid.	(a) Fully plugged nozzle.	(a) Retrieve pump and clear nozzle.
4. Sudden decrease in operating pressure—power-fluid rate constant or sudden increase in power-fluid rate, operating pressure constant.	(a) Tubular failure. (b) Blown pump seal or broken nozzle.	(a) Check tubing and pull and repair if leaking. (b) Retrieve pump and repair.
5. Drop in production—surface conditions normal.	(a) Worn throat or diffuser. (b) Plugging of standing valve or pump. (c) Leak or plug in gas vent. (d) Changing well conditions.	(a) Increase operating pressure. Replace throat and diffuser. (b) Surface pump and check. Retrieve standing valve. (c) Check gas-vent system. (d) Run pressure recorder and resize pump.
6. No production increase when operating pressure is increased.	(a) Cavitation in pump or high gas production. (b) Plugging of standing valve or pump.	(a) Lower operating pressure or install larger throat. (b) Surface pump and check. Retrieve standing valve.
7. Throat worn—one or more dark, pitted zones.	(a) Cavitation damage.	(a) Check pump and standing valve for plugging. Install larger throat. Reduce operating pressure.
8. Throat worn—cylindrical shape worn to barrel shape, smooth finish.	(a) Erosion wear.	(a) Replace throat. Install premium-material throat. Install larger nozzle and throat to reduce velocity.
9. New installation does not meet prediction of production.	(a) Incorrect well data. (b) Plugging of standing valve or pump. (c) Tubular leak. (d) Side string in parallel installation not landed.	(a) Run pressure recorder and resize pump. (b) Check pump and standing valve. (c) Check tubing and pull and repair if leaking. (d) Check tubing and restab if necessary.

TABLE 6.10—POWER OIL PLUNGER PUMPS TROUBLESHOOTING GUIDE

Possible Cause	Correction
<u>Knocking or Pounding in Fluid End and Piping</u>	
Suction line restricted by	
a. Trash, scale build-up, etc.	Locate and remove.
b. Partially closed valve in suction line.	Locate and correct.
c. Meters, filters, check valves, non-full-opening, cut-off valves or other restrictions.	Rework suction line to eliminate.
d. Sharp 90° bends or 90° blind tees.	Rework suction line to eliminate.
Air entering suction line through valve stem packing.	Tighten or repack valve stem packing.
Air entering suction line through loose connection or faulty pipe.	Locate and correct.
Air or vapor trapped in suction.	Locate rise or trap and correct by straightening line, providing enough slope to permit escape and prevent buildup.
Low fluid level.	Increase supply and install automatic low-level shutdown switch.
Suction dampener not operating.	Inspect and repair as required.
Worn pump valves or broken spring.	Inspect and repair as required.
Entrained gas or air in fluid.	Provide gas boot or scrubber for fluid.
Inadequate size of suction line.	Replace with individual suction line or next size larger than inlet of pump.
Leaking pressure relief valve that has been piped back into pump suction.	Repair valve and rework piping to return to supply tank—not suction line.
Bypass piped back to suction.	Rework to return bypassed fluid back to supply tank—not supply line.
Broken plunger.	Inspect when rotating pump by hand and replace as required.
Worn crosshead pin or connecting rod.	Locate and replace as required.
<u>Knock in Power End</u>	
Worn crosshead pin or connecting rod.	Locate and replace as required. Check oil quality and level.
Worn main bearings.	Replace as required. Check oil quality and level.
Loose plunger—intermediate rod—crosshead connection.	Inspect for damage—replace as required and tighten.
<u>Rapid Valve Wear or Failure</u>	
Cavitation.	Predominant cause of short valve life and is always a result of poor suction conditions. This situation can be corrected by following appropriate recommendations as listed under No. 1.
Corrosion.	Treat fluid as required.
Abrasives in fluid.	Treat to remove harmful solids.
<u>Fluid Seal Plunger Wear, Leakage, or Failure</u>	
Solids in power oil.	This is likely to cause greatest amount of wear. Power oil should be analyzed for amount and type of solids content. Proper treating to remove solids should be instigated.
Improper installation.	Follow written instructions and use proper tools. Remember, plunger and liner are matched sets. Ensure proper lubrication at startup. (Be sure air is bled out of fluid end before starting up.)
<u>Reduced Volume or Pressure</u>	
Bypassing fluid.	Locate and correct.
Air in fluid end of triplex.	Bleed off.
Inaccurate meter or pressure gauge.	Check and correct.
Pump suction cavitation due to improper hook-up, suction restriction or entrained gas.	Locate and correct.
Valves worn or broken.	Replace.
Plungers and liners worn.	Replace.
Reduced prime mover speed because of increased load, fuel or other conditions.	Determine cause and correct. (May be increased pressure caused by paraffin, temperature change, etc.)

Jet Pumps

Jet pumps are a type of downhole pump that can be used in hydraulic pumping systems instead of the reciprocating pumps previously discussed. They can be adapted to fit interchangeably into the BHA's designed for the stroking pumps. In addition, special BHA's have been designed for jet pumps to take advantage of their short length and their high-volume characteristics. Because of their unique characteristics under different pumping conditions, jet pumps should be considered as an alternative to the conventional stroking pumps.

Although technical references to jet pumps can be found as far back as 1852,¹³ it was not until 1933¹⁴ that a consistent mathematical representation was published, which included suggestions for pumping oil wells.¹⁵ Angier and Crocker¹⁶ applied for a patent on an oil well jet pump in 1864 that looked very much like those currently marketed.¹⁶ Jacuzzi¹⁷ received a patent in 1930 for jet pumps that were subsequently used in shallow water wells very successfully. McMahon¹⁸ also received the first of six patents on oilwell jet pumps in 1930. Apparently McMahon built and marketed pumps in California in the late 1930's, but they did not achieve widespread usage. Hardware improvements and the advent of computer models for correct application sizing in oil wells led to the successful marketing of jet pumps in 1970.^{1,2} Use of jet pumps has grown steadily since then. More recent publications on hydraulic pumping that describe the use of jet pumps in oil wells include those by Wilson,¹ Bell and Spisak,² Christ and Zublin,⁶ Nelson,¹⁹ Brown,²⁰ Clark,²¹ Bleakley,²² and Petrie *et al.*²³ Much of the following discussion derives from Refs. 20, 23, and 24.

An example of the simplest downhole jet free-pump completion, the single-seal style, is shown in Fig. 6.31. The most significant feature of this device is that it has no moving parts. The pumping action is achieved through energy transfer between two moving streams of fluid. The high-pressure power fluid supplied from the surface passes through the nozzle where its potential energy (pressure) is converted to kinetic energy in the form of a very-high-velocity jet of fluid. Well fluids surround the power-fluid jet at the tip of the nozzle, which is spaced back from the entrance of the mixing tube. The mixing tube, usually called the throat, is a straight, cylindrical bore about seven diameters long with a smoothed radius at the entrance. The diameter of the throat is always larger than the diameter of the nozzle exit, allowing the well fluids to flow around the power-fluid jet and be entrained by it into the throat. In the throat, the power fluid and produced fluid mix, and momentum is transferred from the power fluid to the produced fluid, causing an energy rise in it. By the end of the throat, the two fluids are intimately mixed, but they are still at a high velocity, and the mixture contains significant kinetic energy. The mixed fluid enters an expanding area diffuser that converts the remaining kinetic energy to static pressure by slowing down the fluid velocity. The pressure in the fluid is now sufficient to flow it to the surface from the downhole pump.

With no moving parts, jet pumps are rugged and tolerant of corrosive and abrasive well fluids. The nozzle and throat are usually constructed of tungsten carbide or ceramic materials for long life. Jet pumps are compact and can even be adapted to TFL completions that require the

pump to be circulated around a 5-ft-radius loop in the power-fluid tubing at the wellhead. Successful jet-pump adaptations have also been made for sliding side doors (see Fig. 6.5) in both the normal and reverse flow configurations. These are normally run in on wireline or as a fixed or conventional installation on continuous coiled tubing, and have been successful in offshore drillstem testing (DST) of heavy-crude reservoirs. Other applications include the dewatering of gas wells.²⁵

With different sizes of nozzles and throats, jet pumps can produce wells at less than 50 B/D or up to rates in excess of 10,000 B/D. As with all hydraulic pumping systems, a considerable range of production is possible from a particular downhole pump by controlling the power-fluid supply at the surface. In a given size tubing, the maximum achievable rates are usually much higher than those possible with stroking pumps. Significant free-gas volumes can be handled without the problems of pounding or excessive wear associated with positive-displacement pumps, or the inlet choking encountered in centrifugal pumps. The lack of vibration and the free-pump feature make them ideal for use with pumpdown pressure recorders to monitor BHP's at different flow rates.

Because they are high-velocity mixing devices, there is significant turbulence and friction within the pump, leading to lower horsepower efficiencies than can be achieved with positive-displacement pumps. This often leads to higher surface horsepower requirements, although some gassy wells may actually require less power. Jet pumps are prone to cavitation at the entrance of the throat at low pump intake pressures, and this must be considered in design calculations. Also, because of the nature of their performance curves, the calculations used for installation design are complex and iterative in nature and are best handled by programmable calculators or computers. Despite these limitations, their reliability and volume capability make them attractive in many wells, and their use has become widespread since commercial introduction in the early 1970's.

Performance Characteristics

Intuitively, larger-diameter nozzles and throats would seem to have higher flow capacities, and this is the case. The ratio of the nozzle area to the throat area is an important variable, however, because this determines the tradeoff between produced head and flow rate. Fig. 6.32 shows a schematic of the working section of a jet pump. If, for a given nozzle, a throat is selected such that the area of the nozzle, A_n , is 60% of the area of the throat, A_t , a relatively high-head, low-flow pump will result. There is a comparatively small area, A_s , around the jet for well fluids to enter. This leads to low production rates compared to the power-fluid rate, and because the energy of the nozzle is transferred to a small amount of production, high heads will develop. Such a pump is suited for deep wells with high lifts. Substantial production rates can be achieved if the pump is physically large, but the production rate will always be less than the power-fluid rate.

If a throat is selected such that the area of the nozzle is only 20% of the area of the throat, much more flow area around the jet is available for the production. How-

ever, because the nozzle energy is transferred to a large amount of production compared to the power-fluid rate, lower heads will be developed. Shallow wells with low lifts are candidates for such a pump.

Any number of such area combinations are possible to match different flow and lift requirements best. Attempting to produce small amounts of production compared to the power-fluid rate with a nozzle/throat-area ratio of 20% will be inefficient as a result of high turbulent mixing losses between the high-velocity jet and the slow-moving production. Conversely, attempting to produce high production rates compared to the power-fluid rate with a nozzle/throat-area ratio of 60% will be inefficient because of high friction losses as the produced fluid moves rapidly through the relatively small throat. Optimal ratio selection involves a tradeoff between these mixing and friction losses.

As a type of dynamic pump, jet pumps have characteristic performance curves similar to electric submersible pumps. An example is shown in Fig. 6.33. A family of performance curves is possible, depending on the nozzle pressure supplied to the pump from the surface. Different sizes of throats used in conjunction with a given nozzle give different performance curves. If the nozzle and throat areas of the pumps represented in Fig. 6.33 were doubled, the nozzle flow rates would double, and the production rates would double for each value of the pressure rise, Δp . The maximum Δp at zero production rate would remain the same. The curves are generally fairly flat, especially with the larger throats, which makes the jet pump sensitive to changes in intake or discharge pressure. Because variable fluid mixture densities, gas/liquid ratios, and viscosities affect the pressures encountered by the pump, the calculations to simulate performance are complex and iterative in nature, and lend themselves to a computer solution.

Cavitation in Jet Pumps

Because the production must accelerate to a fairly high velocity (200 to 300 ft/sec) to enter the throat, cavitation is a potential problem. The throat and nozzle flow areas define an annular flow passage at the entrance of the throat. The smaller this area is, the higher the velocity of a given amount of produced fluid passing through it. The static pressure of the fluid drops as the square of the

Fig. 6.31—Typical single-seal jet pump.

Fig. 6.32—Jet-pump nomenclature.

Fig. 6.33—Typical jet-pump performance.

velocity increases and will decline to the vapor pressure of the fluid at high velocities. This low pressure will cause vapor cavities to form, a process called cavitation. This results in choked flow into the throat, and production increase are not possible at that pump-intake pressure, even if the power-fluid rate and pressure are increased. Subsequent collapse of the vapor cavities as pressure is built up in the pump may cause erosion known as cavitation damage. Thus, for a given production flow rate and pump intake pressure, there will be a minimum annular flow area required to keep the velocity low enough to avoid cavitation. This phenomenon has been the subject of numerous investigations. Notable is that of Cunningham and Brown,²⁶ who used actual oilwell pump designs at the high pressures used in deep wells.

The description of the cavitation phenomenon previously discussed suggests that if the production flow rate approaches zero, the potential for cavitation will disappear because the fluid velocities are very low. Under these conditions, however, the velocity difference between the power-fluid jet and the slow-moving production is at a maximum, which creates an intense shear zone on the boundary between them. Such a shear zone constantly generates vortices, the cores of which are at a reduced pressure. Vapor cavities may form in the vortex cores, leading to erosion of the throat walls as the bubbles collapse because of vortex decay and pressure rise in the pump. Although no theoretical treatments of this phenomenon have been published, it has been the subject of experimental work. This has led to the inclusion of potential damage zones on performance prediction plots by some suppliers. This experimental correlation predicts cavitation damage at low flow rates and low pump-intake pressures before the choked flow condition occurs. Field experience has shown, however, that in most real oil wells, the erosion rate in this operating region is very low, probably because of produced gas cushioning the system by reducing the propagation velocity of the bubble-collapse shock waves. It is generally agreed that this phenomenon is of concern only in very-high-water-cut wells with virtually no gas present. Under these conditions, cavitation erosion has been observed even at very low pro-

duction rates. If a jet pump is operated near its best efficiency point, the shear vortices are a distinctly second-order effect in the cavitation process.

Mathematical Presentation

The manufacturers of oilfield jet pumps offer a large number of nozzle and throat combinations for various pumping conditions. For each nozzle size, five or more throats can be used to give different head-flow characteristics. There is no standardization of sizes, however, leading to a very large number of performance curves. Because each curve is really a family of curves that depend on the nozzle pressure, selection of the proper pump for a particular well is confusing. This problem can be greatly simplified with a unifying mathematical representation.

Cunningham^{27,28} has expanded on the original Gosline-O'Brien presentation¹⁴ in writing a set of equations describing the performance of geometrically similar pumps. If the equations are written nondimensionally, they will apply to all sizes of pumps as long as the operating Reynolds numbers are close or sufficiently high that viscosity effects are negligible. Because oilwell jet pumps necessarily require high pressures and velocities because of the large lifts involved, this latter condition is usually met.

By considering the energy and momentum equations for the nozzle, suction passage, throat (mixing tube), and diffuser, the following equations can be derived for a jet pump of the configuration shown in Fig. 6.32.

Nozzle Flow Rate (B/D).

$$q_n = 832 A_n \sqrt{(p_n - p_{ps})/g_n}, \dots \dots \dots (55)$$

where p_n = nozzle pressure, psi, and g_n = nozzle flow gradient, psi/ft.

Dimensionless Area Ratio.*

$$F_{aD} = A_n/A_1, \dots \dots \dots (56)$$

Dimensionless Mass Flow Ratio.*

$$F_{mD} = (q_s \times g_s)/(q_n \times g_n), \dots \dots \dots (57)$$

where q_s = suction flow rate, B/D, and g_s = suction gradient, psi/ft.

Dimensionless Pressure Ratio.*

$$F_{pD} = (p_{pd} - p_{ps})/(p_n - p_{pd}); \dots \dots \dots (58)$$

$$F_{pD} = \{2F_{aD} + [(1 - 2F_{aD})(F_{mD}^2 F_{aD}^2)/(1 - F_{aD})^2] - (1 + K_{td})F_{aD}^2(1 + F_{mD})^2\} / \{(1 + K_n) - \{2F_{aD} + [(1 - 2F_{aD})(F_{mD}^2 F_{aD}^2)/(1 - F_{aD})^2] - (1 + K_{td})F_{aD}^2(1 + F_{mD})^2\}\} \dots \dots \dots (59)$$

*Ref. 14 uses R_m , M , and N and Ref. 27 uses b , ϕ , and N , respectively.

Fig. 6.34—Typical dimensionless performance curves.

Note that Eq. 59 is of the form

$$F_{pD} = \frac{\text{Numerator}}{(1 + K_n) - \text{Numerator}} \quad (60)$$

Efficiency.

$$E_p = F_{mD} \times F_{pD} = \frac{(p_{pd} - p_{ps})(q_s \times g_s)}{(p_n - p_{pd})(q_n \times g_n)} \quad (61)$$

Cavitation area, sq in.

$$A_{cm} = \frac{q_s}{691 \sqrt{\frac{p_{ps}}{g_s}}} \quad (62)$$

Eq. 55 for the nozzle flow rate can be recognized as the expression for flow through an orifice with a power fluid whose gradient is g_n psi/ft. This nozzle flow gradient is the same variable as g_{pf} used earlier for the gradient of the power fluid supplied to the engine of a stroking hydraulic pump. Eq. 56 defines F_{aD} as the dimensionless ratio of the nozzle area to that of the throat. Eq. 57 defines a dimensionless mass flow ratio equal to the production or suction flow rate divided by the nozzle flow rate times the ratio of the suction gradient divided by the nozzle fluid gradient. Eq. 58 defines a dimensionless pressure ratio. Physically, it is the ratio of the pressure rise imparted to the produced fluid to the pressure lost by the power fluid in the pump. Eq. 59 is a formulation for the dimensionless pressure of Eq. 58 in terms of the area ratio, F_{aD} , the mass flow ratio, F_{mD} , and two loss coefficients, K_{td} and K_n . These loss coefficients are experimentally

determined and are similar to orifice and pipe friction loss coefficients. Eqs. 57 and 58 can be combined to give the efficiency expressed in Eq. 61. Because hydraulic power is the product of pressure differential times flow rate, Eq. 61 is interpreted as the ratio of the power added to the produced fluid to the power lost from the power fluid. Eq. 62, derived from the orifice flow equation for the annular production flow area, A_s , at the entrance of the throat, defines the minimum flow area required to avoid cavitation if the suction flow rate is q_s and is at a pressure p_{ps} . This equation includes the assumption that the pressure at the entrance of the throat is zero at cavitation.

A slightly different formulation of these equations can be found in Brown,⁷ following the method of Gosline and O'Brien.¹⁴ The two methods give comparable results, although the formulation in Eq. 59 is more complex algebraically in the Gosline-O'Brien method. Also, the empirical loss coefficients (K_{td} and K_n) will be slightly different numerically when experimental results are correlated with the equations. The dimensionless cavitation prediction equation found in Brown will reduce to Eq. 62 if the power fluid and production have the same gradient and the dimensions from a particular size pump are used.

A representative set of dimensionless performance curves based on Eq. 59 is shown in Fig. 6.34 for typical nozzle/throat-area ratios of 0.50, 0.40, 0.30, 0.25, 0.20, and 0.15. The power fluid and produced fluid are of the same density. A nozzle loss coefficient K_n of 0.03 was used, which is typical of a well-shaped and smoothed design. A throat-diffuser loss coefficient, K_{td} , of 0.20 was used. Lower values can be obtained in laboratory tests, but this conservative value compensates for average losses in routing fluids through the rest of the pump and BHA. The peak efficiencies of about 33% shown in Fig. 6.34 can be achieved with commercially available pumps producing typical well fluids at around a 700-B/D rate.

Fig. 6.35—GOR for gas-vented production.

Much larger or smaller pumps producing fluids of very low or high viscosity can result in pumps with somewhat higher or lower efficiencies, respectively. Note that each area-ratio curve has an associated efficiency curve, and that there is a most-efficient ratio for a given value of the dimensionless mass flow ratio, F_{mfD} . These curves represent the type of noncavitating performance obtainable from the jet pumps available for oilwell production. Fig. 6.34 shows that the jet pumps with area ratios, F_{aD} , of 0.30 and 0.25 have the highest peak efficiencies. Pumps with an F_{aD} value greater than 0.50 or less than 0.10 will have noticeably reduced peak efficiencies. This effect is predicted by Eq. 59. Operating under cavitating conditions will result in deviations from these curves.

By presentation of jet-pump performance in the dimensionless form of Fig. 6.34, a significant simplification has been achieved. Any jet pump, regardless of its size, will have a performance curve that corresponds to the standard one for the particular area ratio of the pump. If the pressure environment the pump encounters leads to a calculated value for F_{pD} of 0.50, the mass ratio the unit will deliver can be read from Fig. 6.34. For power and produced fluids of equal density (or gradient), the mass ratio is also the volume ratio of produced fluid to power fluid. If $F_{aD}=0.5$, then $F_{mfD}=0.47$. This means that if a nozzle size is used that supplies 100 B/D of power fluid, 47 B/D of production will be obtained. If $F_{aD}=0.4$, then $F_{mfD}=0.60$, and 60 B/D production could be obtained with 100 B/D power fluid. If $F_{aD}=0.3$, then $F_{mfD}=0.62$, and 62 B/D production would be pumped. If $F_{aD}=0.25$, then F_{mfD} drops to 0.52, and the production to only 52 B/D. This illustrates that the pump with an area ratio of $F_{aD}=0.3$ is the most efficient for this

value of F_{pD} and will produce the most fluid. If a much larger nozzle were used that supplies 1,000 B/D of power fluid, a jet pump with an area ratio of $F_{aD}=0.3$ would produce 620 B/D of production if the system pressures were such that $F_{pD}=0.50$. The many ratios available from the suppliers are not always the same as those shown in Fig. 6.34. Therefore, a calculation scheme that will consider all the possible available ratios should be based on the basic equations. This will become more apparent when the effects of gas are considered.

Approximations for Handling Gas

The equations previously presented are for liquids. The free gas present in many oil wells affects pump performance. A rigorous treatment of the pumping of multiphase and compressible fluids is outside the scope of this chapter. It has been found, however, that simple but useful approximations can be made. Cunningham²⁷ found that if the free-gas volume is added to the liquid volume as if it were liquid, pump performance follows the standard curves reasonably well. Eq. 57 then becomes

$$F_{mfD} = \frac{q_s + q_g}{q_n} \left(\frac{g_s}{g_n} \right), \dots \dots \dots (63)$$

where q_g is the flow rate of free gas in B/D at pump-intake pressure conditions.

A review of Standing's⁹ work by F.C. Christ for a variety of bottomhole conditions results in an empirical correlation for the gas-plus-liquid FVF. When this is substituted into Eq. 63, the following relationship is obtained:*

$$F_{mfD} = q_s \left\{ \left[1 + 2.8 \left(\frac{R}{p_{ps}} \right)^{1.2} \right] (1 - W_c) + W_c \right\} \times \left(\frac{g_s}{q_n \times g_n} \right), \dots \dots \dots (64)$$

where R =producing GOR, scf/bbl.

The relationship expressed in Eq. 64 is similar to that used to generate Fig. 6.27 for the stroking-pump volumetric efficiency. This simplified expression is suggested for use with jet pump calculations, however, because its simplicity is helpful if the relationships are fitted into the limited memory of hand-held programmable calculators. It was found to give very reasonable results in conjunction with the other jet pump equations in over 8 years of comparisons between predicted jet pump performance and the actual field results.

A cavitation correction for gas is also required.* If the assumption of choked flow into the throat annulus around the power fluid jet is made and the downhole fluid properties are typical, the additional area required to pass the gas is

$$A_g = \frac{q_s(1 - W_c)R}{24,650 p_{ps}}, \dots \dots \dots (65)$$

*Personal communication with F.C. Christ, Natl. Supply Co.

Eq. 62 considering gas then becomes

$$A_{cm} = q_s \left[\frac{1}{691} \sqrt{\frac{g_s}{p_{ps}}} + \frac{(1 - W_c)R}{24,650 p_{ps}} \right] \dots \dots \dots (66)$$

If provisions for venting free gas are made, the solution GOR at pump suction conditions rather than the total GOR should be used in Eqs. 64 through 66. Fig. 6.35 shows the appropriate solution GOR for different values of p_{ps} and various API gravities in vented systems. Fig. 6.35 is based on Muskat's work²⁹ and shows higher GOR values at low pump-intake pressures than does Fig. 6.27, which is based on Standing's⁸ work. It has been found from field testing that the Muskat correlation gives better results in conjunction with the other approximations used in the jet-pump equations. If the total GOR is less than the value from Fig. 6.35, it indicates that all the gas is in solution (p_{ps} is above the bubblepoint) and the total GOR should be used. A vent system is not necessary in such a case. As mentioned previously, parallel installations automatically provide a gas vent unless a packer has been set or the casing outlet is shut off.

Nozzle and Throat Sizes

Each manufacturer has different sizes and combinations of nozzles and throats. Manufacturers A and B increase the areas of nozzles and throats in a geometric

progression—i.e., the flow area of any nozzle or throat is a constant multiple of the area of the next smaller size. Manufacturer B's factor is $10^{1/9} = 1.29155$ and Manufacturer A's factor is $4/\pi = 1.27324$. The system of sizes offered by Manufacturer C uses a similar geometric progression concept, but does not use the same factor over the total range. In the smaller sizes, where the change in horsepower per size is small, the rate of increase in area is more rapid than in the systems of Manufacturers A and B. In the larger, higher-horsepower sizes, the percent increase in size is less rapid than in the other systems to limit the incremental increase in horsepower. The sizes offered by Manufacturer C cover a slightly larger range than those of Manufacturers A and B. The sizes from these manufacturers are listed in Table 6.11. The maximum sizes of nozzles and throats that are practical in pumps for a given tubing size depend on the fluid passages of the particular pump, BHA, swab nose, and standing valve. Single-seal pumps cannot use nozzles as large as those practical in higher-flow, multiple-seal pumps. In general, nozzles larger than 0.035 sq in. in flow area are used only in pumps for 2½- and 3½-in. tubing.

The strict progression used by Manufacturers A and B establishes fixed area ratios between the nozzles and different throats. A given nozzle matched with the same number throat will always give the same area ratio: 0.380 in Manufacturer A's system, and 0.400 in Manufacturer B's system (Table 6.11). This is called the A ratio. Successively larger throats matched with a given nozzle give

the B, C, D, and E ratios. In the systems of Manufacturers A and B, the size of a pump is designated by the nozzle size and ratio. Examples are 11-B, which is a No. 11 nozzle and a No. 12 throat, and 6-A, which is a No. 6 nozzle and a No. 6 throat.

Because the size progression for the nozzles and throats in Manufacturer C's system is not constant over the whole range, the nozzle/throat combinations do not yield fixed ratios. However, the ratios that result cover the same basic range as the other two systems. The actual ratios are listed in Table 6.12. In Manufacturer C's system, the nozzle and mixing tube (throat) sizes designate the size of a pump. An example is C-5, which is the size C nozzle and the No. 5 throat. This combination has an area ratio of 0.32. The annular flow areas of Manufacturer C's jet pumps used in cavitation calculations are also included in Table 6.12. The annular areas for Manufacturers A and B's jet pumps are listed in Tables 6.13 and 6.14.

The most commonly used area ratios fall between 0.400 and 0.235. Area ratios greater than 0.400 are sometimes used in very deep wells with high lifts or when only very low surface operating pressures are available and a high head regain is necessary. Area ratios less than 0.235 are used in shallow wells or when very low BHP's require a large annular flow passage to avoid cavitation. Referring to Fig. 6.34, we see that the performance curves for the higher area ratios show higher values of the dimensionless parameter, F_{pD} , within their regions of maximum efficiency. Because F_{pD} is a measure of the pressure rise in the produced fluid, the higher area ratios are suited for high net lifts, but this is achieved only with production rates substantially less than the power-fluid rate ($F_{mD} < 1.0$). The smaller area ratios develop less head, but may produce more fluid than is used for power fluid ($F_{mD} > 1.0$). Where the curves for different area ratios cross, the ratios will have equal production and efficiency. However, different annular flow areas (A_s) may give them different cavitation characteristics.

Jet Pump Application Sizing

The current use of jet pumps can be credited to the advent of computer programs capable of making the iterative calculations necessary for application design. Jet-pump performance depends largely on the pump discharge pressure, which in turn is strongly influenced by the gas/liquid ratio, F_{gL} , in the return column to the surface. With the range of return F_{gL} seen in hydraulic pumping, higher values of F_{gL} lead to reduced pump discharge pressure. Because the jet pump is inherently an open power-fluid device, F_{gL} depends on the formation GOR and on the amount of power fluid mixed with the production. The amount of power fluid depends on the size of the nozzle and the operating pressure. As the power-fluid pressure is increased, the lift capability of the pump increases, but the additional power-fluid rate decreases F_{gL} , thereby increasing the effective lift. Finding a match between the power-fluid rate (Eq. 55), the pump performance curve (Eq. 59), and the pump discharge pressure, p_{pd} , is an iterative procedure involving successive refined guesses.

Refs. 23 and 24 provide a listing of the sequence of steps necessary in the iterative procedure and program listings for programmable calculators. This procedure has proved to be quite successful in accurately predicting the performance of oilfield jet pumps in a variety of wells. The various suppliers of jet pumps also have developed in-house computer programs for application design that are faster than the calculator routines and incorporate more correlations for fluid properties and the pump discharge pressure. The following procedure is a variation on that presented in Refs. 23 and 24 and is more suitable for hand calculations. The object of the calculation sequence will be to superimpose a jet pump performance curve on the IPR curve of the well and to note the intersections that represent the pump performance in the particular well. Therefore, a plot of the best estimate of the IPR (or PI)

curve of the well is the starting point. An example of a completed performance plot in this format is shown in Fig. 6.36.

Calculation Sequence and Supplemental Equations

Fig. 6.37 shows a typical jet pump installation with the appropriate pressures that determine pump operation. Although a parallel installation is shown for clarity of nomenclature, the same relationships hold for the casing-type installation.

Power-Fluid Flow Through the Nozzle.

Step 1—Calculate the pump suction gradient, g_s , from Eq. 40,

$$g_s = g_o(1 - W_c) + g_w W_c.$$

Step 2—For the desired production, q_s , and pump-intake pressure, p_{ps} , calculate the minimum suction area needed to avoid cavitation (A_{cm} from Eq. 66).

Step 3—Referring to Tables 6.11 through 6.14, find a nozzle and throat combination with area ratio, F_{ad} , close to 0.4 that has an annular flow area, A_s , greater than the value of A_{cm} from Step 2. Note that this ensures that larger throats matched with this nozzle (lower values of F_{ad}) will also have annular flow areas greater than A_{cm} .

Step 4—Pick a value of the surface operating pressure, p_{so} . This is usually between 2,000 and 4,000 psi, with higher values needed in deeper wells. A good starting point is 3,000 psi.

Step 5—Determine the pressure at the nozzle, p_n . This relationship is the same as Eq. 32 without the p_{fr} term. For the first approximation, the friction term p_{fpt} can be neglected.

$$p_n = p_{so} + g_n D - p_{fpt}, \quad (67)$$

where p_{fpt} = power-fluid tubing friction pressure, psi.

Step 6—Determine the nozzle flow, q_n , from Eq. 55 for a desired pump-intake pressure, p_{ps} .

Step 7—Determine the friction in the power-fluid tubing from the charts and equations in Appendix B.

Step 8—Return to Step 5, and recalculate the pressure at the nozzle and then recalculate the nozzle flow at Step 6. This return to Steps 5 and 6 need be done only once unless the nozzle flow changed by more than 15%. Because the power-fluid rate through the nozzle depends only on the power-fluid pressure at the nozzle, p_n , and the pump-intake pressure, p_{ps} , this portion of the flow circuit has been defined and will not change with variations in the pump flow rate or pump discharge pressure so long as the pump intake pressure is held constant in the calculations.

Pump Performance and Return Flow.

Step 1—Determine the values needed to predict the pump discharge pressure, p_{pd} .

Total return flow: for a desired production rate, q_s , at a point on the IPR curve of the well,

$$q_d = q_s + q_n. \quad (68)$$

The value of q_s will be adjusted during the iteration process.

Return flow fluid gradient:

$$g_d = [(q_n \times g_n) + (q_s \times g_s)] / q_d. \quad (69)$$

Return flow water cut: for water as power fluid,

$$W_{cd} = \frac{q_n + W_c q_s}{q_d}. \quad (70)$$

For oil as power fluid,

$$W_{cd} = \frac{W_c q_s}{q_d}. \quad (45)$$

Return flow gas/liquid ratio:

$$F_{gL} = q_s(1 - W_c)R / q_d. \quad (47)$$

Return flow viscosity:

$$\nu_m = (1 - W_{cd})\nu_o + W_{cd}\nu_w. \quad (42)$$

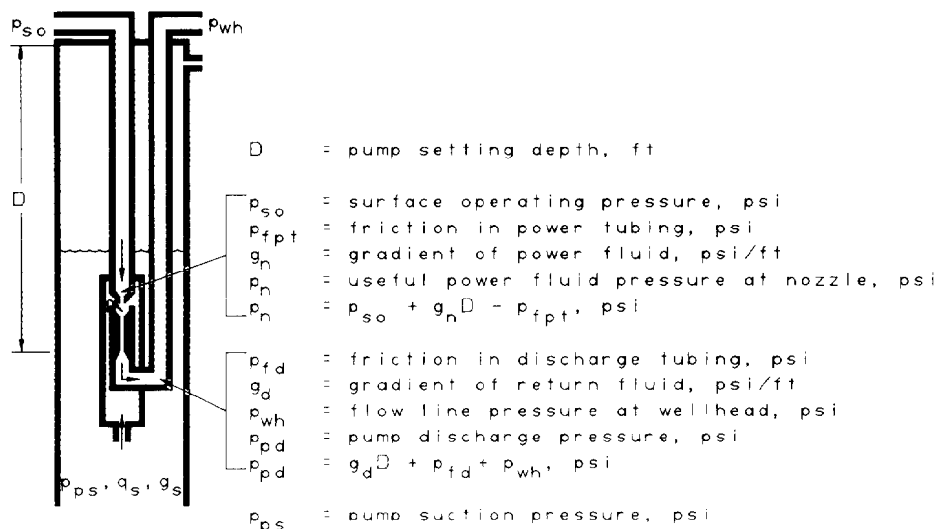

Fig. 6.37—Typical jet-pump installation.

Step 2—If F_{gL} is less than 10, it is suggested that the pump discharge pressure be calculated without considering the gas effects, particularly in casing-type installations. In such a case, the pump discharge pressure, p_{pd} , is given by

$$p_{pd} = p_{fd} + g_d D + p_{wh} \quad (33)$$

The value for the return friction can be determined from the equations or figures in Appendix B.

Step 3—If F_{gL} is greater than 10, determine the pump discharge pressure from a vertical multiphase flowing gradient correlation or from gas-lift charts.

Step 4—From the values for p_n , p_{ps} , and p_{pd} , determine the value of F_{pD} from Eq. 58.

Step 5—Calculate the value of F_{mD} from Eq. 64. Note that if the GOR is zero, F_{mD} is given by Eq. 57.

Step 6—Referring to Fig. 6.34, check whether the values of F_{mD} and F_{pD} from Steps 4 and 5 fall on one of the standard curves. Starting with the value of F_{pD} on the vertical axis, move across to the farthest curve intercepted. This will be the most-efficient-ratio curve for that value of F_{pD} . Read down to the value of F_{mD} . If this value of F_{mD} does not agree with the one from Step 5, a correction is needed in the value of q_s selected in Step 2 under Power-Fluid Flow Through the Nozzle. If the F_{mD} values do agree (within 5%), a solution has been found. The nozzle size selected in Step 3 under Power-Fluid Flow Through the Nozzle is to be used with a throat that gives a value of F_{aD} as close as possible to that found by reading across from the value of F_{pD} . The solution obtained is for the amount of production possible for the originally assumed surface operating pressure and for the originally assumed pump-intake pressure. If only one iteration was made, the value of q_s will be the originally assumed value. This solution point can be plotted on the graph of the IPR curve of the well, as shown in Fig. 6.36.

Step 7—If the values of F_{mD} did not agree closely enough, correct the value of q_s by the following method:

$$q_{s(\text{new})} = q_{s(\text{old})} \times F_{mD_6} / F_{mD_5} \quad (71)$$

where F_{mD_6} = value of F_{mD} from Step 6 and F_{mD_5} = value of F_{mD} from Eq. 64 in Step 5. By using this value of q_s , go back to Step 1 and repeat the procedure until the value of F_{mD} from Fig. 6.34 and the calculated value from Step 5 agree within about 5%.

Step 8—Determine the cavitation-limited flow rate, q_{sc} , at this particular pump intake pressure, p_{ps} .

$$q_{sc} = q_{si} (A_t - A_n) / A_{cm} \quad (72)$$

where q_{si} = initial assumed value. This value of q_{sc} can be plotted on the IPR plot for the particular value of p_{ps} under consideration.

Step 9—Because the value of q_s has been changed in the above procedure when more than one pass through the equations has been made, the combination of this value of q_s and the assumed value of p_{ps} will probably not be on the IPR curve of the well. In this case, return to Step 5 under Power-Fluid Flow Through the Nozzle with a new value of the pump-intake pressure, p_{ps} . If the solution point was below and to the left of the IPR curve, select a value of p_{ps} higher than the first one. If the solution point was above and to the right of the IPR curve, select a lower value of p_{ps} . Repeating all the remaining steps for the same area ratio, F_{aD} , will give a new solution point that can be plotted on the same graph used for the IPR curve, as shown in Fig. 6.36. The two solution points define a portion of the constant-operating-pressure curve for the particular pump. If the curve intersects the IPR curve, a match between pump performance and well performance has been found. It may be necessary to calculate a third point to extend the pump performance curve

TABLE 6.15—WORKSHEET AND SUMMARY OF EQUATIONS FOR JET PUMPS

Part A—Nozzle choice and power fluid iteration**Step 1**—Pump suction gradient (Eq. 40)

$$g_s = g_o(1 - W_c) + g_w W_c \quad g_s = 0.381$$

Step 2—Minimum suction area (Eq. 66)

$$A_{cm} = q_s \left[\frac{1}{691} \sqrt{g_s / \rho_{ps}} + \frac{(1 - W_c)R}{24,650 \rho_{ps}} \right] \quad A_{cm} = 0.0163$$

Step 3—Nozzle size from Table 6.11 with $F_{aD} \approx 0.4$ such that throat annulus area (Tables 6.12, 6.13, or 6.14) is $> A_{cm}$ from Step 2.

$$\text{size} = 7 \text{ (Manufacturer A)} \\ A_n = 0.0103$$

Step 4—Operating pressure chosen.

$$p_{so} = 2,500$$

Step 5—Nozzle pressure (Eq. 67)—neglect friction on first iteration.

$$\rho_n = p_{so} + g_n D - p_{tpi} \quad \rho_n = 4,265 \quad 4,232$$

Step 6—Nozzle flow (Eq. 55)

$$q_n = 832 A_n \sqrt{(\rho_n - \rho_{ps}) / g_n} \quad q_n = 824 \quad 820$$

Step 7—Friction from Appendix B.

$$p_{tpi} = 33 \quad 33$$

Step 8—Return to Step 5 until successive values are within 15%. Then go to Part B.**Part B—Iteration on production rate****Step 1**—a. Return flow (Eq. 68)

$$q_d = q_s + q_n \quad q_d = 1,320 \quad 1,477 \quad 1,490$$

b. Return gradient (Eq. 69)

$$g_d = [(q_n \times g_n) + (q_s \times g_s)] / q_d \quad g_d = 0.364 \quad 0.365 \quad 0.366$$

c. Return water cut (Eqs. 45 and 70)

for water power fluid

$$W_{cd} = (q_n + W_c q_s) / q_d \quad W_{cd} = \quad \quad$$

for oil power fluid

$$W_{cd} = W_c q_s / q_d \quad W_{cd} = 0.113 \quad 0.133 \quad 0.139$$

d. Return gas/liquid ratio (Eq. 47)

$$F_{gL} = q_s(1 - W_c)R / q_d \quad F_{gL} = 40 \quad 47 \quad 49$$

e. Return viscosity (Eq. 42)

$$\nu_m = (1 - W_{cd})\nu_o + W_{cd}\nu_w \quad \nu_m = 2.3 \quad 2.3 \quad 2.3$$

TABLE 6.15—WORKSHEET AND SUMMARY OF EQUATIONS FOR JET PUMPS (continued)

Step 2—Discharge pressure (Eq. 31) if $F_{gL} < 10$

$$p_{fd} \text{ from Appendix B.} \quad p_{fd} = \underline{\hspace{2cm}} \quad \underline{\hspace{2cm}} \quad \underline{\hspace{2cm}}$$

$$p_{pd} = p_{fd} + g_d D + p_{wh} \quad p_{pd} = \underline{\hspace{2cm}} \quad \underline{\hspace{2cm}} \quad \underline{\hspace{2cm}}$$

Step 3—Use vertical multiphase flow correlation if $F_{gL} > 10$ to determine p_{pd}

$$p_{pd} = 1,780 \quad 1,756 \quad 1,746$$

Step 4—Calculate pressure ratio (Eq. 58)

$$F_{pD} = (p_{pd} - p_{ps}) / (p_n - p_{pd}) \quad F_{pD} = 0.318 \quad 0.305 \quad 0.300$$

Step 5—Calculate mass flow ratio (Eq. 64)

$$F_{mD} = \frac{q_s \left\{ \left[1 + 2.8 \left(\frac{R}{p_{ps}} \right)^{1.2} \right] (1 - W_c) + W_c \right\} g_s}{q_n \times g_n} \quad F_{mD_5} = 0.791 \quad 1.04 \quad 1.09$$

Step 6—Use value of F_{pD} in Fig. 6.34 to find F_{mD} from farthest curve to right at that value of F_{pD} . Note value of F_{aD} .

$$\begin{array}{ccc} F_{aD} = 0.25 & 0.25 & 0.25 \\ F_{mD_6} = 1.04 & 1.06 & 1.10 \end{array}$$

Step 7—Compare F_{mD_5} from Step 5 with F_{mD_6} from Step 6. If within 5%, go to Step 8. If not, correct q_s by Eq. 71.

$$q_{s(\text{new})} = q_{s(\text{old})} F_{mD_6} / F_{mD_5} \quad q_{s(\text{new})} = 657 \quad 670 \quad 676$$

then return to Step B.1.a.

Part C—Hardware and final calculations**Step 1**—Pick throat size closest to

$$A_t = \frac{A_n}{F_{aD}} = 0.0412 \text{ sq in.} \quad \text{Actual throat area} = 0.0441 \text{ size} = 9$$

Step 2—Cavitation limited flow (Eq. 72)

$$q_{sc} = q_{si} \times \frac{A_t - A_n}{A_{cm}} \quad q_{sc} = 1,037$$

Step 3—Hydraulic horsepower (Eq. 5)

$$P_h = q_n \times p_{so} \times 0.000017 \quad P_h = 35$$

Step 4—Triplex power at 90% efficiency = 39**Summary**

$$\begin{array}{lll} A_n = 0.0103 & p_{so} = 2,500 & q_s = 676 \\ A_t = 0.0441 & q_n = 820 & p_{ps} = 1,000 \\ F_{aD} = 0.235 & P_h = 39 & \end{array}$$

Triplex options (from manufacturer specification sheet, Tables 6.16 through 6.18)

Type	D-323-H	J-60	K-100
Plunger size, in.	1 1/2	1 1/2	1 3/4
rev/min	400	400	221
Flow rate at rev/min, B/D	945	945	945
Maximum pressure rating, psi	2,690	2,690	2,740
Horsepower	44.6	44.6	44.6

until it intersects the IPR curve. Note that in Step 8, a new value of A_{cm} will have to be calculated because p_{ps} has changed.

Step 10—Other constant-operating-pressure curves can be constructed in the same manner by assuming a different value for p_{so} in Step 4 under Power-Fluid Flow Through the Nozzle. If the intersection of a particular constant operating pressure curve with the IPR curve is at a lower-than-desired production, try a higher value of the operating pressure.

Example Problem 4. Table 6.15 can be used to aid in organizing jet pump calculations. A sample set of calculations is shown in the worksheet of Table 6.15 for one point on the 2,500-psi operating line of Fig. 6.36. Manufacturer A's jet pump sizes are used for this example. In the example calculation, the initial estimate of 500 B/D production at 2,500-psi operating pressure became 676 B/D as a result of the iterative process. This indicates that an operating pressure less than 2,500 psi is required to produce 500 B/D. Fig. 6.36 shows that the desired 500 B/D can be pumped with an operating pressure slightly more than 2,000 psi and a power-fluid rate of about 750 B/D, which is about 30 triplex hp. Higher operating pressures lead to greater production rates. For example, the 2,500-psi operating-pressure curve intersects the well PI line at about 590 B/D. The maximum production from the well with Pump 7-C is at the intersection of the cavitation line with the well's PI line at 830 B/D. The operating pressure would be about 4,000 psi.

Considering Other Sizes. In this relatively shallow well with a modest lift requirement, the selection procedure leads to a pump that is larger than necessary for 500 B/D production. This is evident from the intersection of the cavitation curve with the PI line at about 830 B/D, which is well beyond the 500-B/D production target. In a low-lift well, the value of F_{pD} will be low and area ratios less than 0.4 can be used efficiently. The No. 7 nozzle was chosen because it has sufficient annular area to avoid cavitation with an area ratio of 0.4. Ref. 24 shows that Sizes 6-B, 5-C, and 4-D are also reasonable choices in this well and that size 4-D requires the least power (23 hp), although at a higher operating pressure (2,849 psi). This suggests that when the calculation sequence leads to $F_{aD} < 0.4$, trying a smaller nozzle is warranted.

In some cases, the value of F_{aD} found by the selection procedure will be greater than 0.4. It is then necessary to check whether the throat annular area of that combination is still greater than the value of A_{cm} calculated in Step 2 under Power-Fluid Flow Through the Nozzle. If it is not, a larger nozzle size must be tried, or a higher operating pressure specified. The use of a higher operating pressure will lower the value of F_{pD} and permit the use of a throat giving a lower value of F_{aD} with a larger throat-annulus area. Larger nozzles and throats of the same area ratio will have larger throat-annulus areas.

Programming Considerations. As mentioned, Refs. 23 and 24 contain programs for hand-held programmable calculators. The method presented here can also be pro-

grammed on calculators or computers to avoid manual calculations and the use of reference charts. If Eq. 59 is solved for F_{mfd} , the following expressions emerge:

$$F_{mfd}^2(B_2 - C_2) - F_{mfd}(2C_2) + \left[(A_2 - C_2) - \frac{F_{pD}D_2}{F_{pD} + 1} \right] = 0, \quad (73)$$

where

$$A_2 = 2F_{aD}, \quad (74)$$

$$B_2 = (1 - 2F_{aD}) \frac{F_{aD}^2}{(1 - F_{aD})^2}, \quad (75)$$

$$C_2 = (1 + K_{td})F_{aD}^2, \quad (76)$$

and

$$D_2 = (1 + K_n), \quad (77)$$

Eq. 73 can then be solved by means of the familiar expression for the root of a quadratic equation:

$$F_{mfd} = \frac{2C_2 - \sqrt{(-2C_2)^2 - 4(B_2 - C_2) \left[(A_2 - C_2) - \frac{F_{pD}D_2}{F_{pD} + 1} \right]}}{2(B_2 - C_2)} \quad (78)$$

With this calculated value of F_{mfd} from Eq. 78, Eq. 71 becomes

$$q_{s(\text{new})} = q_{s(\text{old})} \frac{F_{mfd1}}{F_{mfd2}}, \quad (79)$$

where

$$F_{mfd1} = \text{dimensionless mass flow rate from Eq. 78, and}$$

$$F_{mfd2} = \text{dimensionless mass flow rate from Eq. 64.}$$

Iterating through the pump performance and return flow equations will refine the value of q_s until the desired degree of convergence is achieved. With the same value for the surface operating pressure, p_{so} , but a new value of the pump suction pressure, p_{ps} , the values for a constant operating pressure line on an IPR plot can be obtained.

Application Range

Experience in using the procedures previously described to predict jet pump performance in field applications indicates that the algorithm has a broad range of applicability. Simplifications of assumptions in the performance

equations and in correlations for liquid and gas properties, however, have been made to reduce the number of calculations during the iteration process. The IPR curve of the well is often not well known, and the gas production of an individual well may be uncertain. Jet-pump performance is strongly affected by the pump intake pressure (determined by the IPR curve) and by the pump discharge pressure (significantly determined by the GOR). For every psi error in the pump intake pressure or pump discharge pressure, the effect on surface operating pressure will be from 3 to 5 psi if the same production rate is to be obtained (see Ref. 7 for the relationships that demonstrate this effect). Higher discharge pressures or lower pump intake pressures require higher operating pressures. This multiplier effect is greater with the larger throats (low values of F_{ad}). Fluid friction losses through the passages of the particular downhole completion hardware can affect these pressures as well.

Even when accurate well data are available, the performance predictions may not always match field performance. When the volume of free gas at producing bottomhole conditions is very large, performance will probably deviate from that predicted by the equations. Current jet pump designs have been optimized for liquid production, not for pumping gas. Accuracy of prediction begins to suffer at above five parts of gas to one part liquid, and at 90% gas, the predictions are very questionable. In the case of a 42° API crude, 150 GOR, and a 30% water cut, the FVF of gas plus oil and water phases is about 1.2 RB/STB at 1,000-psi pump intake pressure, p_{ps} . If the GOR were about 2,000, the FVF would be about 5.5, which is on the boundary of the region of decreasing correlation accuracy. At higher GOR's or lower pump intake pressures or water cuts, prediction accuracy would begin to suffer. With a 500-psi pump intake pressure, a GOR of 2,000 leads to an FVF of about 11.3, which is outside the working region of the model.

If the algorithm presented here is used to evaluate wells in which the gas/liquid volume ratio is large at the downhole pumping conditions, it is suggested that the expression within the brackets in Eq. 64 be checked. This expression is the FVF for the oil, water, and gas phases in RB/STB. Up to a value of 5 or 6, the model correlates well with actual performance. Above this point, prediction accuracy diminishes, and a gas-vent system is suggested as a conservative design procedure, using the GOR value from Fig. 6.35.

Jet-pump performance with high-viscosity fluids is not modeled in these routines. Heavy crudes with viscosities above about 500 cp will cause significant deviations from predictions unless produced water is the dominant phase. Oil power fluids of less than about 22° API will also introduce losses that are not properly modeled.

A troubleshooting guide for subsurface jet pumps is given in Table 6.9.

Downhole Pump Accessories

Swab Cups. A number of accessories are available for downhole pumping systems. Free-pump systems require swab cups and a standing valve to accomplish the pump-in and pump-out operations. The swab cups are carried on a mandrel extending above the pump. The mandrel assembly may contain a check valve to limit the amount of fluid bypassing the pump as it is circulated to the surface.

Fig. 6.38—Swab noses.

Fig. 6.39—Standing valves.

If the pump does not enter a lubricator on the wellhead, the check valve may include a check-valve bypass that is actuated when the pump enters the wellhead catcher to prevent excessive pressure buildup. Two examples of swab cup assemblies are shown in Fig. 6.38. Jet pumps usually use the simpler system.

Standing Valves. Standing valves are necessary in free-pump systems to create a "U" tube and prevent the circulating fluid from flowing back into the reservoir. During pumping operations, the standing valve is opened by flow from the formation to the pump suction, as shown in Fig. 6.3. Whenever the pump is shut down, the standing valve closes. In some cases, the standing-valve ball is held open by a small magnet to prevent it from cycling during reciprocating pump-stroking reversals. When the downhole pump is unseated, fluid attempting to flow back into the formation washes the ball off the magnet and onto the seat. The standing valve is wireline-retrievable and includes a provision for draining the tubing before attempting to pull it. In most cases, the standing valve forms the no-go and bottom seal for the pump. Some jet-pump installations, however, use high-flow designs that do not serve as a pump seat. An example of each type is shown in Fig. 6.39.

Pressure Recorders. To obtain producing BHP's at several different withdrawal rates, downhole pressure recorders are often run in conjunction with hydraulic pumps. With all hydraulic pumps, a pressure recorder can be hung below the standing valve. While this arrangement provides not only pressure drawdown but also pressure-buildup data, it has the disadvantage of requiring wireline operations to run and retrieve the recorder. Some reciprocating pumps can be run with a pressure recorder attached, which eliminates the wireline operations but does not permit observation of pressure buildup because the recorder is above the standing valve. Virtually all jet pumps can be run with recorders attached, and very smooth recordings are obtained because the jet pump is pulsation free.

Dummy Pumps. Dummy pumps are sometimes run to blank off one or more tubing strings so that they may be checked for leaks. If the dummy pump has a fluid passage in it, the terms "flow-through dummy" or "blanking tool" are often used. These tools are useful for acidizing or steaming.

Screens and Filters. To protect the downhole pump from trash in the well, various types of screens and filters are sometimes run. Because circulating pumps in and out of a well may dislodge scale and corrosion products in the tubing, a starting filter can be attached to the swab-cup assembly to filter the power fluid. Because this must be a relatively small filter, it will eventually plug up and an automatic bypass arrangement is provided. This system collects foreign material during the crucial start-up phase with a newly installed pump. For long-term operation, power-fluid and pump intake screens or strainers are used in some units. These will exclude large-diameter objects that could damage or plug the pump.

Safety Valves. In some areas, subsurface safety valves are required. When a packer is set and the BHA is above it, a wireline-retrievable safety valve can be installed be-

tween the standing valve and the packer to isolate the formation. The safety valve is normally closed unless high-pressure fluid is supplied by a small tubing line run from the main power-fluid tubing just above the pump. The pump discharge pressure provides the reference pressure to the safety valve. When the pump is on bottom and power-fluid pressure is applied to it, the safety valve opens to allow well fluid to enter the pump. Most safety valves will not hold pressure from above, so the standing valve is still necessary for circulating the pump in and out of the well. Fig. 6.40 illustrates this type of installation.

Surface Equipment

Surface Pumps

Hydraulic pumping systems have evolved toward the use of relatively high pressures and low flow rates to reduce friction losses and to increase the lift capability and efficiency of the system. Surface operating pressures are generally between 2,000 and 4,000 psi, with the higher pressures used in deeper wells. Power-fluid rates may range from a few hundred to more than 3,000 B/D. While some surface multistage centrifugal pumps are rated to this pressure range, they are generally quite inefficient at the modest flow rates associated with single-well applications. Multistage centrifugals can be used effectively when multiple wells are pumped from a central location.⁵ The surface pump for a single well or for just a few wells must be a high-head and low-specific-speed pump. Wide experience in the overall pumping industry has led to the use of positive-displacement pumps for this type of application. The vast majority of hydraulic pump installations are powered by triplex or quintiplex pumps driven by gas engines or electric motors. The multiplex pumps used for hydraulic pumping range from 30 to 625 hp. An example of a surface triplex pump is shown in Fig. 6.41. Specification sheets for multiplex pumps commonly used in hydraulic pumping systems are available from the manufacturers (Tables 6.16 through 6.18).

Multiplex pumps consist of a power end and a fluid end. The power end houses a crankshaft in a crankcase. The connecting rods are similar to those in internal combustion engines, but connect to crossheads instead of pistons. The fluid end houses individual plungers, each with intake and discharge check valves, usually spring loaded. The fluid end is attached to the power end by the spacer block, which houses the intermediate rods and provides a working space for access to the plunger system. Most units being installed in the oil field are of the horizontal configuration shown in Fig. 6.41. This minimizes contamination of the crankcase oil with leakage from the fluid end. Vertical installations are still found, however, particularly with oil as the pumped fluid or when space is at a premium, as in townsite leases.

Multiplex pumps applied to hydraulic pumping usually have stroke lengths from 2 to 7 in. and plunger diameters between 1 and 2½ in. The larger plungers provide higher flow rates, but are generally rated at lower maximum pressure because of crankshaft loading limitations. The normal maximum rating of multiplexes for continuous duty in hydraulic pumping applications is 5,000 psi, with lower ratings for the larger plungers. Actual applications above 4,000 psi are uncommon. Multiplex pumps are run at low speed to minimize vibration and wear and to avoid dynamic problems with the spring-loaded intake and dis-

Fig. 6.40—Downhole pump with wireline-retrievable safety valve.

Fig. 6.41—Triplex pump.

charge valves. Most applications fall between 200 and 450 rev/min. Because this is below the speeds of gas engines or electric motors, some form of speed reduction is usually required. Belt drives are found on some units, although gear reduction is more common. Gear reduction units are integral on some multiplexes and separate on others. A variety of reduction ratios are offered for each series of pumps.

Because a positive-displacement pump has an essentially constant discharge flow rate for a given prime mover speed, bypass of excess fluid is normally used to match a particular pressure and flow demand. Another option that has been used successfully is to drive the multiplex pump through a four-speed transmission, which greatly enhances the flexibility of the system. This allows much closer tailoring of the triplex output to the demand, thereby decreasing or eliminating the bypassing of fluid and increasing efficiency. The ability to run the multiplex pump at reduced speed when needed also tends to increase the life of such components as packing and valving.

Each plunger pumps individually from a common intake manifold and into a common discharge manifold. Because discharge occurs only on the upstroke, there is some pulsation to the discharge flow. For this reason, pulsation dampeners are commonly used.

Two types of plunger systems are in common use. For oil service, a simple and effective plunger-and-liner system is used that consists of a closely fitted metallic plunger that runs inside a metallic liner. Sprayed metal coatings or other hardfacing means are often used to extend the life of the plunger and liner. When pumping water, the metal-to-metal system is not practical because the fit would have to be extremely close to keep leakage to an acceptable level. Galling and scoring are problems with close fits and the low lubricity of water. To solve this problem, spring-loaded packing systems are used that do not require adjusting. The advent of high-strength aramid

fibers for packing, in conjunction with other compounds to improve the friction characteristics, has resulted in a pronounced improvement in the ability of the pump to handle high-pressure water for extended periods of time. Water still presents a more severe challenge than oil, however, and water systems show much better life if operated at or below 3,500 psi.

Suction conditions are important to multiplex operation. Friction losses in piping, fluid end porting, and across the suction valving reduce the pressure available to fill the pumping chamber on the plunger downstroke. If these losses are sufficiently great, cavitation may result. When pumping oil with dissolved gas, the reduction in pressure will liberate free gas and cause knocking. For these reasons, it is necessary to have a positive head on the suction side to overcome the friction losses. In addition, another phenomenon known as "acceleration head" must be considered. The flow in the suction piping must accelerate and decelerate a number of times for each crankshaft revolution. For the fluid (which has inertia) to follow the acceleration, energy must be supplied, which is then returned to the fluid on deceleration. The energy supplied during acceleration comes from a reduction in the pressure in the fluid, and if this drops too low, cavitation or gas liberation will result. The standards of the Hydraulic Inst.³⁰ provide the following relationship:

$$h_a = L_s \times \bar{v}_{sl} \times N_c \times C_3 / (K_2 \times g), \dots \dots \dots (80)$$

where

- h_a = acceleration head, ft,
- L_s = actual length of suction line, ft.
- \bar{v}_{sl} = average velocity in suction line, ft/sec,
- N_c = speed of pump crankshaft, rev/min,
- C_3 = constant depending on type of pump,
- K_2 = constant depending on fluid compressibility, and
- g = gravitational constant, 32.2 ft/sec².

For a triplex, $C_3 = 0.066$, and for a quintiplex, $C_3 = 0.040$. For water, $K_2 = 1.4$, and for oil, $K_2 = 1.5$.

The minimum suction head for the multiplex pump is then the sum of the friction losses and the acceleration head. Although the pump can draw a vacuum, this will flash gas and may tend to suck air across valve or plunger packing. Manufacturers of multiplex pumps will recommend appropriate suction charging pressures for their products. It is worth noting that Eq. 80 predicts that long, small-diameter suction lines will increase the acceleration head loss. Such lines also increase the friction loss. It is therefore recommended that suction lines be short and of large diameter, with no high spots to trap air or gas. Suction stabilizers or pulsation dampeners that tend to absorb the pulsations from the pump will also reduce acceleration head.

In many cases, sufficient hydrostatic head is not available to provide the necessary suction pressure. Charge pumps are used to overcome this problem. Positive displacement pumps of the vane or crescent-gear type driven from the triplex have been used extensively. These pumps require a pressure control valve to bypass excess fluid and match the multiplex displacement. Where electric power is available, centrifugal charge pumps have given excellent service. Centrifugal pumps generally need to run at speeds considerably above the multiplex speed. Driving them from the multiplex presents problems, particularly with gas engine drive where prime mover speed variations cause significant variations in the charge-pump output pressure.

While good charging pressures are necessary to ensure proper loading and smooth operation, there are problems associated with very high charge pressures. High charge pressures add to the crankshaft loading, and for charge pressures above about 250 psi it is advisable to derate the maximum discharge pressure by one third of the charge pressure. Also, high charge pressures can adversely affect the lubrication of bearings, particularly in the cross-head wristpin. In addition, the mechanical efficiency of multiplex pumps is some 3 to 5% lower on the suction side compared to the discharge side.³¹ Consequently, the combination of a charge pump and multiplex pump will be most efficient with low charging pressures and a high boost by the multiplex pump. Charging pressures should therefore be limited to that necessary to give complete filling of the multiplex pump with a moderate safety allowance for variations in the system parameters.

In some cases, it is desirable to inject corrosion inhibitors or lubricants into the multiplex suction. Fresh water is sometimes injected to dissolve high salt concentrations. In severe pumping applications with low-lubricity fluids, a lubricating oil is sometimes injected or dripped onto the plungers in the spacer block area to improve plunger life. Injection pumps are often driven from the multiplex drive for these applications. A troubleshooting guide for multiplex pumps is given in Table 6.10.

Fluid Controls

Various types of valves are used to regulate and to distribute the power-fluid supply to one or more wellheads. Common to all free-pump systems is a four-way valve or wellhead control valve. This valve is mounted at the wellhead, as shown in Fig. 6.42. Its function is to provide for different modes of operation. To circulate the

Fig. 6.42—Wellhead control valve.

pump in the hole, as shown in Fig. 6.3, power fluid is directed down the main tubing string. The power fluid begins to operate the pump once it is on bottom and seated on the standing valve. In the pump-out mode, power fluid is directed down the return tubing or casing annulus to unseat the pump and to circulate it to the surface. When the pump is on the surface, putting the valve in the bypass and bleed position permits the well to be bled down and the pump to be removed and replaced. The various functions can all be accomplished by moving the valve to different positions.

Most systems include a constant-pressure controller, as shown in Fig. 6.43. This valve maintains a discharge-pressure load on the multiplex pump by continuously bypassing the excess discharge fluid. These valves operate on the principle of an adjustable spring force on a piston-and-valve assembly that is pressure compensated. If the pressure rises on the high-pressure side, which is being controlled because of changing system loads, the pressure forces on the various areas within the valve will cause the valve to open and to bypass more fluid. This restores the high-pressure side to the preset condition. Jet pumps are frequently operated with a constant-pressure valve as the only surface control valve. The constant-pressure controller can be used to regulate the pressure on a manifold assembly serving multiple wells.

Reciprocating downhole pumps are usually regulated with a constant-flow control valve, shown in Fig. 6.44. The downhole unit can be maintained at a constant stroking rate if a constant volume of power fluid is supplied to it. The constant-flow control valve is designed to provide a preset flow rate even if the downhole operating pressure fluctuates because of changing well conditions. Because this valve does not bypass fluid, it must be used in conjunction with a constant-pressure controller on the higher-pressure or inlet side.

Fig. 6.43—Constant-pressure controller.

Control Manifolds

Where a number of wells are to be pumped from a central battery, a control manifold is used to direct the flows to and from the individual wells. Control manifolds are designed to be built up in a modular fashion to match the number of wells pumped and are generally rated for a 5,000-psi working pressure. Fig. 6.45 shows a power control manifold module. A constant-pressure control valve regulates the pressure on the common power-fluid side of the manifold. This pressure is generally a few hundred pounds per square inch greater than the highest pressure demanded by any well to allow proper operation of the individual well control valves. Individual constant-flow control valves regulate the amount of power fluid going to each well in the case of reciprocating pumps. Constant-pressure control valves or manual throttling valves are often used to regulate those wells on jet pumps. Meter loops or individual meters for each station can be integrated into the manifold.

Lubricator

Some wells will flow or kick back when the operator is attempting to remove or to insert a pump in the wellhead. Also, the presence of H_2S may make it inadvisable to open up the entire tubing string for pump insertion and removal. The use of a lubricator allows the master valve below the wellhead to be closed and the entire lubricator with the pump in it to be removed from the wellhead. The lubricator is essentially an extended piece of tubing with a side line to allow fluid flow when the pump is circulated up into it. A latch mechanism at the bottom prevents the pump from falling out when the lubricator is removed from the wellhead. An example of a lubricator is shown in Fig. 6.46.

Power-Fluid Systems

The function of the surface treating system is to provide a constant supply of suitable power fluid to be used to operate the subsurface production units. The successful and economical operation of any hydraulic pumping system is to a large extent dependent on the effectiveness of the treating system in supplying high-quality power fluid.

The presence of gas, solids, or abrasive materials in the power fluid will seriously affect the operation and wear life of the surface and downhole units. Therefore, the primary objective in treating crude oil or water for use as power fluid is to make it as free of gas and solids as possible. In addition, chemical treatment of the power fluid may be beneficial to the life of the engine end or pump end of the production unit.

On the basis of an analysis of more than 50 power-oil samples from the Permian Basin, the maximums in Table 6.19 have been established as ideal for a quality power oil in the 30 to 40°API range.³²

It has been observed, however, that acceptable performance has been achieved in many instances where these limits were exceeded moderately. Because leakage past close fits in the downhole unit is often the limiting factor, heavier power oils can perform satisfactorily with more solids because the resulting wear does not increase leakage to the same degree. The periodic analysis of power oil indicates the steps to be taken for improved operations. For example, if the power oil analysis shows that iron sulfide or sulfate compounds make up the bulk of the total solids, then a corrosion or scale problem exists that would require the use of chemical inhibitors to correct the problem.

Water is being used more frequently as a power fluid, particularly in congested locations such as townsite leases and offshore platforms where the safety and environmental advantages of water are important. Water, however, usually requires that a lubricant be added for use with

reciprocating downhole pumps, that corrosion inhibitors be added, and that all oxygen be scavenged. Because of these costly considerations, the closed power-fluid system is often used with water power fluid to minimize the amount of water treated. Filtering of water power fluid to 10 μ m is recommended, particularly with reciprocating downhole pumps.

Other considerations in the choice of water or oil as a power fluid include the following.

1. Maintenance on surface pumps is usually less with oil power fluid. The lower bulk modulus of oil also contributes to reduced pressure pulsations and vibrations, which can affect all the surface equipment.

2. Well testing for oil production is simpler with water power fluid because all the oil coming back is produced oil. With oil power fluid, the power oil rate must be metered and subtracted from the total oil returning to the surface. This can be a source of considerable error in

Fig. 6.44—Constant-flow control valve.

HOW IT WORKS

As illustrated at left, there are three separate pressures involved in the operation of a constant flow controller—inlet, intermediate, and outlet. The spring acts on the diaphragm with a force equivalent to 100-psi pressure; therefore the diaphragm is in equilibrium when the intermediate pressure is 100 psi greater than the outlet pressure. The outlet valve thus has a 100-psi pressure drop maintained across it at all times, which ensures a constant flow rate. The characterized outlet valve is shaped to allow, at this 100-psi pressure drop, the rate of flow selected by the handwheel.

high-water-cut wells where the power-oil rate is large compared with the net oil production. This particular objection to oil power fluid does not hold, however, with the single-well power units to be discussed later.

3. In high-friction systems, as sometimes occur with jet pumps in restricted tubulars, the lower viscosity of water can increase efficiency. With no moving parts, the jet pump is not adversely affected by the poor lubricating properties of water.

4. In deep casing-type installations, particularly with jet pumps, water power fluid can "load up" in the casing annulus return, negating any beneficial gas-lifting effects from produced gas.

The use of filters with oil power fluid has not been found to be practical unless heat and chemicals are used to eliminate waxing and emulsion plugging, and a settling process is normally used. The basic purpose of the settling process is to remove foreign particles from lease crude oil by gravity separation or settling in a continuous-flow system. All the tanking and piping specifications for an adequate power-oil system are dictated by this settling requirement. In a tank of static fluid, all the foreign particles contained in the oil would fall or settle to the bottom. Some of the particles, such as fine sand and small water droplets, will fall slowly. Heavier solids and larger water drops will fall more rapidly. This difference in rate of fall is partially because of the difference in density of the oil, water, and solids. The density, or specific gravity, of most of the solids is considerably greater than that of the oil and they will tend to settle quickly in oil. The densities of water and oil are much closer, and gravity separation will be slower. Other factors that influence the rate of separation are related to the resistance the particles encounter in dropping through oil and depend on both the size of the particles and the viscosity of the oil.

Gravity separation of small bubbles of gas, drops of water, or sand grains follows Stokes' law when the Reynolds number is less than or equal to 1.85. Stokes' law is given by

$$v_s = 4.146 \frac{d_p^2 (\gamma_{sp} - \gamma_L)}{\mu_L} \quad (81)$$

where

v_s = settling velocity, ft/hr,

d_p = diameter of particles, thousandths of an inch,

μ_L = viscosity of liquid, cp,

γ_{sp} = specific gravity of suspended particles, and

γ_L = specific gravity of liquid.

Fig. 6.45—Power control manifold module.

If the Reynolds number is greater than 1.85, a correction to Stokes' law is required and is given by

$$v_s = \frac{19.1 d_p^{1.14} (\gamma_{sp} - \gamma_L)^{0.71} F_s}{\mu_L^{0.43} \gamma_{sp}^{0.29}}, \dots\dots\dots (82)$$

where F_s = shape factor; spheres = 1.0, sand = 0.65.

Table 6.20 gives the velocity of separation of gas bubbles, water drops, and sand grains in oil having a viscosity of 10 cp and a specific gravity of 0.87.

In an actual oil system, it is neither practical nor necessary to furnish space that will provide settling under perfectly still conditions. It is necessary to provide a tank where clean crude oil can be continuously and automatically withdrawn. Proper settling under these conditions then is accomplished only if the upward flow through the settling tank is maintained at a rate that is slower than the foreign-particle fallout rate. If the upward rate of the fluid is even slightly greater than the rate at which the particles will fall, the particles will be carried upward by the fluid. Even though they may move upward very slowly, they will eventually be carried through the tank. It has been found by experience that in most cases an upward velocity of 1 ft/hr is low enough to provide sufficient gravity separation of entrained particles to clean crude oil to power-oil requirements.

Power-Oil Tank and Accessories

Open Power-Fluid System. A typical power-oil treating system that has proven adequate for most open power-fluid systems when stock-tank quality oil is supplied is shown in Fig. 6.47. This system has the general characteristic that all return fluids from the well, both production and power fluid, must pass through the surface treating facility. The power-oil settling tank in this system (shown in Fig. 6.48) is usually a 24-ft-high, three-ring, bolted steel tank. A tank of this height generally will provide adequate head for gravity flow of oil from the tank to the multiplex pump suction. If more than one multiplex pump is required for the system, individual power-oil tanks can be set for each pump, or a single large tank can be used, whichever is more economical and best meets the operating requirements. If a single large tank supplies the suction for several pumps, individual suction lines are preferred.

The gas boot is essentially a part of the power-oil tank. The purpose of the boot is to provide final gas/oil separation so that the oil will be stable at atmospheric pressure. If the gas is not sufficiently separated from the oil, entrained free gas can enter the power-oil tank and destroy the settling process by causing the fluid in the tank to roll. The following piping specifications for the gas boot are necessary to ensure undisturbed settling.

1. The gas boot inlet height should be 4 ft above the top of the power-oil tank to allow the incoming fluid to fall, and so that the agitation will encourage gas/oil separation.
2. The top section of the gas boot should be at least 3 ft in diameter and 8 ft higher than the top of the power-oil tank. These two factors will provide a reservoir that should absorb the volume of the surges.

*For this table, the density of gas is assumed to be 0.0.

3. The gas line out of the top of the boot should be tied into the power-oil tank and stock-tank vent line with a riser on the top of the power-oil tank. In the event the gas boot does become overloaded and kicks fluid over through the gas line, this arrangement will prevent the raw or unsettled fluid from being dumped in the top of the power-oil tank where it may contaminate the oil drawn off to the multiplex. A minimum diameter of 3 in. is recommended for the gas line.

4. The line connecting the gas boot to the power-oil tank should be at least 4 in. in diameter. This is necessary to minimize restrictions to flow during surge loadings of the boot.

Oil entering a large tank at the bottom and rising to be drawn off the top tends to channel from the tank inlet to the outlet. The purpose of the spreader is to reduce the velocity of the incoming fluid by distributing the incoming volume over a large area. This allows the fluid to rise

upward at a more uniform rate. The recommended spreader consists of a round, flat plate, approximately half the diameter of the tank, with a 4-in. skirt that has 60°, triangular, saw-tooth slots cut in it. The slots provide automatic opening adjustment for varying amounts of flow. It is essential that they be cut to uniform depth to obtain an even distribution of flow. This type of spreader must be installed with the tops of all the slots in a level plane to prevent fluid from dumping out under a high side. The spreader should be mounted about 2 ft above the bottom rim of the tank.

The location of the stock-tank take-off and level control is important because it establishes the effective settling interval of the power-oil tank and controls the fluid level. All fluid coming from the spreader rises to the stock take-off level where stock-tank oil is drawn off. Fluid rising above this level is only that amount required to replace the fluid withdrawn by the multiplex pump, and it is in

Fig. 6.47—Surface facilities for open power-fluid system.

this region that the power-oil settling process takes place. The light solids settled out are carried with the production through the stock-tank takeoff, and the heavier particles settle to the bottom where they must be periodically removed. The location of the stock take-off point should be within 6 ft of the spreader. The height to which the stock oil must rise in the piping to overflow into the stock tank determines the fluid level in the power-oil tank. For this reason, the level control should be placed a minimum of 18 in. from the top of the power-oil tank and the diameter of piping used should be sufficient to provide negligible resistance for the required volume of flow (4-in. minimum diameter recommended). The extension at the top of the level control is connected to the gas line to provide a vent that keeps oil in the power-oil tank from being siphoned down to the level of the top of the stock tank.

The power-oil outlet should be located on the opposite side of the power-oil tank from the stock take-off outlet to balance the flow distribution within the tank. Because the fluid level in the tank is maintained approximately 18 in. from the top of the tank, the upper outlet should be located 3 ft below the top of the tank to ensure an oil level above it at all times. The second, or emergency, power-oil outlet should be located below the upper outlet for use in starting up or filling tubing strings. The location of this outlet will depend on estimated emergency requirements and the capacity per foot of tank. A distance of 7 ft from the top of the tank is usually sufficient. This lower outlet line contains a shutoff valve that is to be kept closed during normal operations so that the full settling interval will be used.

Closed Power-Fluid Systems. In the closed power-fluid system, the power fluid returns to the surface in a separate conduit and need not go through the surface treating facilities. The reduction in surface treating facilities can tend to offset the additional downhole cost of the system. Virtually all closed power-fluid systems are in California because of the large number of townsite leases and offshore platforms, and water is usually the power fluid. The sur-

Fig. 6.48—Recommended gas-boot/settling-tank system.

face facilities for a closed power-fluid central system are shown in Fig. 6.49. Note the addition of a power-fluid tank, which is part of a closed loop including the multiplex pump and the engine end of the downhole production unit. Gravity settling separation in the power-fluid tank ensures that the power fluid remains clean despite the addition of solids from power-fluid makeup, corrosion products, and contamination during pump-in and pump-out operations. The power-fluid makeup is required to replace the small amount of fluid lost through fits and seals in the downhole pump and wellhead control valve. A certain amount of power fluid is lost during circulating operations as well. As before, if gravity separation is used, the upward velocity of the fluid in the tank should be kept below 1 ft/hr. If filtration of power water is used, the power-fluid tank size can be reduced considerably. It should be remembered that this system is not possible with the downhole jet pump because it is inherently a power-fluid and production mixing device.

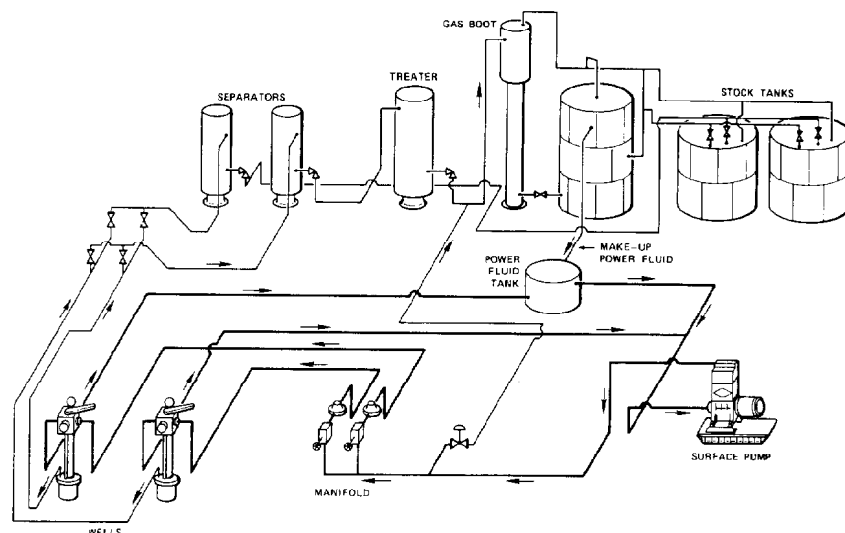

Fig. 6.49—Surface facilities for closed power-fluid system.

Single-Well Systems

The central battery systems previously discussed have been used successfully for years and provide a number of benefits. The use of lease fluid treating facilities as part of the hydraulic system ensures good, low-pressure separation of the gas, oil, water, and solid phases present in any system. Good triplex charging of clean, gas-free oil and consistently clean power fluid supplied to the down-hole pump are desirable features of this system. The lease treating facilities, however, must have sufficient capacity to process both the well production and the return power fluid. When the wells are closely spaced, the clustering of power generation, fluid treating, and control functions in one location is very efficient and allows good use of the installed horsepower. Because the system is not limited by production variations on any one well, an adequate supply of the desired power fluid is ensured by the size of the system. A further benefit associated with use of the lease separation facilities is the option of a closed power-fluid system. When well spacing is large, however, long, high-pressure power-fluid lines must be run. Also, individual well testing is complicated by the need to meter the power-fluid rate to each well, which can introduce measurement errors. As a final consideration, only a few wells in a field may be best suited to artificial lift by hydraulic pumping, and the installation of a central system is difficult to justify.

To address the limitations of the central battery system, single-well systems have been designed.^{33,34} Many of the requirements of a single-well system are the same as for a central battery. The oil, water, gas, and solid phases must be separated to provide a consistent source of power fluid. Hydraulic power to run the system must be generated. A choice of water or oil power fluid should be possible, and the fluid used as power fluid must be sufficiently clean to ensure reliable operation and be gas-free

at the multiplex suction to prevent cavitation and partial fluid end-loading. An adequate reservoir of fluid must be present to allow continuous operation and the various circulating functions associated with the free-pump procedures. Finally, a means of disposing of and measuring the well production to the lease treating and storage facilities must be provided.

To achieve these objectives, several of the manufacturers of hydraulic pumping units offer packaged single-well systems that include all the control, metering, and pumping equipment necessary. All components are skid-mounted on one or two skids to facilitate installation at the well and to make the system easily portable if the unit needs to be moved to a different well. Usually, the only plumbing required at the wellsite is for power-fluid and return-line hookup at the wellhead, and connection of the vessel outlet to the flowline.

An example of a typical single-well power unit is shown in Fig. 6.50. All units of this type share certain design concepts, with small variations depending on manufacturer preference. Two other designs are shown in Figs. 6.51 and 6.52. Either one or two pressure vessels are located at the wellsite. The size of the main reservoir vessel depends on the nature of the well and the tubular completion. The reservoir size should ensure that if the well heads and partially empties the return conduit to the flowline, adequate capacity remains to operate the down-hole unit until production returns re-enter the vessel. Even if the well does not head, extra capacity is needed. When the unit is shut down for maintenance or pump changeout, that portion of the return conduit occupied by gas will need to be filled from the vessel to unseat the pump and to circulate it to the surface. The vessel sizes normally used range from 42 × 120 to 60 × 240 in. In some wells, even the largest vessel may not be able to compensate fully for heading. In these cases, it is common to backpressure the well to stabilize heading. The vessels themselves

Fig. 6.50—Schematic flow diagram, single-well power unit.

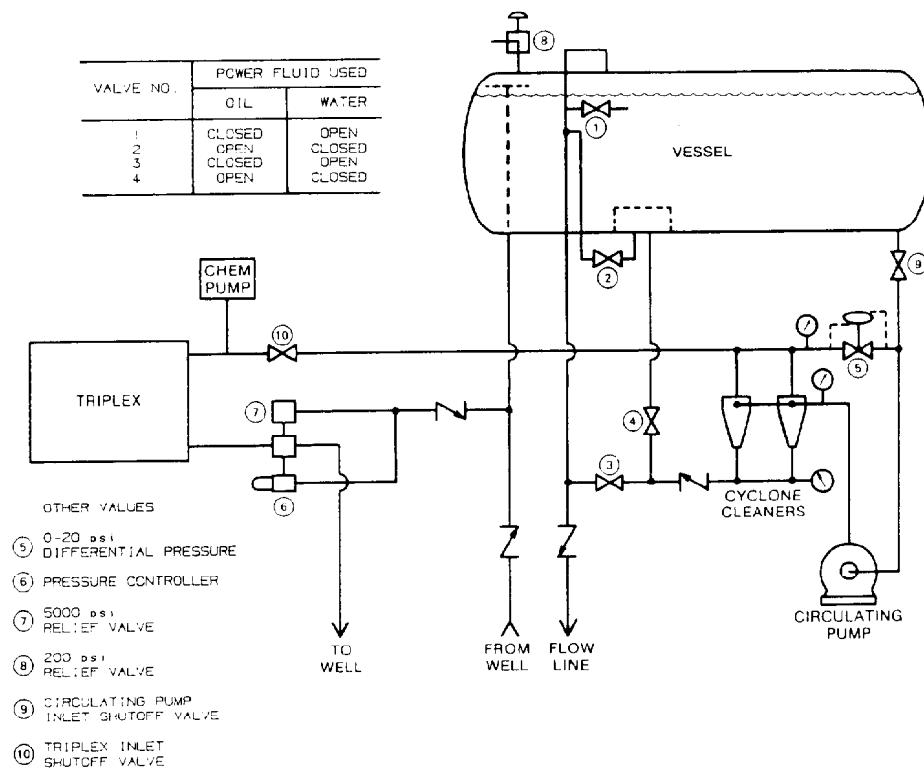

Fig. 6.51—Schematic flow diagram, single-well power unit.

Fig. 6.52—Schematic flow diagram, dual-vessel, single-well power unit.

Fig. 6.53—Hydrocyclone.

are normally rated in the 150- to 175-psi range, with higher ratings available for special applications. Coal tar epoxy internal coatings are common, with special coatings available for CO_2 service.

The return power fluid and production from the well enter the vessel system where basic separation of oil, water, and gas phases take place. Free gas at vessel pressure is discharged to the flowline with a vent system that ensures a gas cap in the vessel at all times. The oil and water separate in the vessel, and the desired fluid is withdrawn for use as power fluid. The power fluid passes through one or more cyclone desanders to remove solids before entering the multiplex suction where it is pressurized for reinjection down the power-fluid tubing. Any excess multiplex output that is bypassed for downhole pump control is returned to the vessel. The underflow from the bottom of the cyclone desanders contains a high solids concentration and is discharged either into the flowline or back into the vessel system. Once the system is stabilized on the selected power fluid, the well production of oil, water, and gas is discharged into the flowline from the vessel, which is maintained at a pressure above the flowline. Because the flowline is carrying only what the well makes, additional treating and separating facilities are not needed as they are in the central battery system that encounters mixed well production and power fluid. This feature also facilitates individual well testing.

Overall fluid level in the vessel system is controlled by simple gravity dump piping that consists of a riser on the outside of the vessel. The height of the riser determines the fluid level within. To prevent siphoning of the vessel, the gas-vent line is tied into the top of the riser as a siphon breaker. The choice of oil or water power fluid is made by selection of the appropriate take-off points on the vessel so that the production goes to the flowline and

the power fluid goes to the multiplex pump. If the multiplex suction is low in the vessel and the flowline outlet is high in the vessel, water will tend to accumulate in the vessel and will be the power fluid. If the multiplex suction is high in the vessel and the flowline outlet is low, oil will tend to accumulate in the vessel and will be the power fluid. Opening and closing appropriate valves will set the system up for the chosen power fluid. The multiplex suction outlets are positioned with respect to the overall fluid level in the vessel to avoid drawing power fluid from the emulsion layer between the oil and water because this layer generally contains a significantly higher concentration of solids and is not easily cleaned in the cyclones.

The fluid cleaning is accomplished with cyclone desanders that require a pressure differential across them. In the two-vessel system, this is accomplished by a differential pressure valve between the two vessels that stages the pressure drop from the wellhead. The energy to maintain this staged pressure drop is supplied by the multiplex pump through the downhole pump. In the single-vessel system, a charge pump and a differential pressure control valve are necessary to maintain the appropriate pressures. The charge pumps are of either the positive displacement type with a pressure-relief valve, or a centrifugal pump. The centrifugal pumps are generally practical only with separate electric drive because the speed variation with gas engine drives causes excessive variations in the pump discharge pressure.

The flow path through a cyclone cleaner is shown in Fig. 6.53. Fluid enters the top of the cone tangentially through the feed nozzle and spirals downward toward the apex of the cone. Conservation of angular momentum dictates that the rotational speed of the fluid increases as the radius of curvature decreases. It is the high rotational

speed that cleans the fluid by centrifugal force. The clean fluid, called the overflow, spirals back upward through the vortex core to the vortex finder, while the dirty fluid exits downward at the apex through the underflow nozzle. The cones are usually constructed of cast iron with an elastomer interior. Different feed-nozzle and vortex-finder sizes and shapes are available to alter the performance characteristics of the cyclone. Different sizes of cyclones are available, with the smaller sizes having lower flow rates but somewhat higher cleaning efficiencies.

Maintaining the proper flows through the cyclone to ensure good cleaning depends on correctly adjusting the pressures at the feed nozzle, overflow, and underflow. At the design flow rates, a 40-to-50-psi drop normally occurs from the feed nozzle to the overflow. In a single-vessel system, the pressure is supplied by a charge pump. In a dual-vessel system, the pressure is supplied by higher backpressure on the returns from the well. Because of the centrifugal head, the cyclone overflow pressure is generally 5 to 15 psi higher than the underflow pressure. An underflow restrictor is commonly used to adjust the amount of underflow from 5 to 10% of the overflow. This ensures good cleaning without circulating excessive fluid volumes. It should be noted that the volume flow rates through a cyclone vary inversely with the specific gravity of the fluid, and that within the range of normal power fluids, increased viscosity leads to increased flow rates. This latter effect is caused by the viscosity that suppresses the internal vortex action. Therefore, proper cyclone sizing to match the charge and multiplex pump characteristics must be done carefully and with knowledge of the fluid to be processed. The manufacturers of the packaged systems will supply appropriate cyclones for the installation. Moving the portable unit to another well may require resizing of the cyclone system. A discussion of field experience and proper cyclone sizing is given by Justus.³⁵

The routing of the dirty underflow varies with different systems, and may be an adjustable option in some systems. Two basic choices are available: return of underflow to the vessel or routing of the underflow to the flowline. In a dual-vessel system, the underflow must be returned to the flowline downstream of the backpressure valve to provide sufficient pressure differential to ensure underflow. Discharging the solids to the flowline is attractive because they are disposed of immediately and are excluded from possible entry into the power fluid. Under some conditions, however, continuous operation may not be possible. If, for any length of time, the net well production is less than the underflow from the cyclone, the level of fluid in the vessel will drop. Over an extended period of time, this can result in shutdown of the system. Shutting off the cyclone underflow during these periods will stop the loss of fluid, but apex plugging may occur during the shutoff period. Returning the underflow to the vessel eliminates the problem of running the vessel dry, but does potentially reintroduce some of the solids into the power fluid. In single-vessel units, the underflow is generally plumbed back to the vessel in a baffled section adjacent to the flowline outlet. This provides for the maximum conservation of fluid, but requires a differential pressure valve between the cyclone overflow and the vessel. This valve is normally set at about 20 psi to ensure a positive pressure to the underflow fluid.

As mentioned previously, the vessel pressure is held above the flowline pressure to ensure flow into the flowline. A differential-pressure control valve is sometimes used for this purpose. This will keep the vessel pressure, which is backpressure on the well, at a minimum during flowline pressure changes that may occur during normal field operation. When water is the power fluid, ridding the flowline in this manner is acceptable. However, when oil is the power fluid, changing vessel pressures will cause flashing of gas in the power oil and will adversely affect the multiplex suction. When oil is used as power fluid, it is recommended that a pressure-control valve be used to keep the vessel at a steady pressure some 10 to 15 psi above the highest expected flowline pressure.

Although the single-well system was developed for applications involving widely spaced wells, two- or three-well installations have been successfully operated from a single-vessel system. This installation design is very attractive on offshore platforms. With a large number of highly deviated wells, offshore production is well-suited to hydraulic pumping with free pumps, but the extra fluid treating facilities required with an open power-fluid system are a drawback when severe weight and space limitations exist. The closed power-fluid system answers this problem, but the extra tubulars in deviated holes create their own set of problems and expense. Furthermore, the use of jet pumps, which are quite attractive offshore, is not possible with the closed power-fluid system. For safety and environmental reasons, water is almost always the power fluid of choice offshore. A single large vessel of the type used for single-well installations can receive the returns from all the wells and separate the power water necessary for reinjection to power downhole units. Full 100% separation of the oil from the power water is not necessary, and, in fact, some minor oil carryover will contribute to the power fluid lubricity. The platform separation facilities then have to handle only the actual production from the wells. A compact bank of cyclone cleaners completes the power fluid separation and cleaning unit.

Nomenclature

- A = pump friction constant
- A_{cm} = minimum cavitation cross-sectional area, sq in.
- A_{ep} = cross-sectional area of engine piston, sq in.
- A_{er} = cross-sectional area of engine rod, sq in.
- A_n = cross-sectional area of nozzle, sq in.
- A_{pp} = cross-sectional area of pump plunger, sq in.
- A_{pr} = cross-sectional area of pump rod, sq in.
- A_s = cross-sectional area of annulus between throat and jet, sq in.
- A_t = cross-sectional area of throat, sq in.
- A_2 = constant defined by Eq. 74
- B = pump friction constant depending on tubing-size pump designed for
- B_t = total FVF, RB/STB
- B_2 = constant defined by Eq. 75
- C_2 = constant defined by Eq. 76

- C_3 = constant depending on type of multiplex pump, Eq. 80
 d = diameter of tubing, in.
 d_p = diameter of particles, thousandths of an in.
 d_1 = ID of outer tube, in.
 d_2 = OD of inner tube, in.
 d_3 = OD of coupling, in.
 D = pump setting depth, ft
 D_2 = constant defined by Eq. 77
 e = eccentricity; also base of natural logarithm
 E_e = efficiency of engine, fraction
 E_p = efficiency of pump, fraction
 $E_{p(\text{int})}$ = pump efficiency for gas interference and pump leakage, fraction
 $E_{p(\text{max})}$ = maximum pump efficiency under downhole conditions, fraction
 E_s = efficiency of surface pump, fraction
 f = weighted average friction factor
 F_{aD} = dimensionless area ratio
 F_d = downward forces, lbf
 F_{gL} = gas/liquid ratio, scf/bbl
 F_{mFD} = dimensionless mass flow ratio
 F_{pD} = dimensionless pressure ratio
 F_s = shape factor
 F_u = upward forces, lbf
 F_v = multiplying factor correcting for viscosity
 g = gravitational constant
 g_d = gradient of discharge fluid, psi/ft
 g_n = nozzle flow gradient, psi/ft
 g_o = gradient of produced oil, psi/ft
 g_{pf} = gradient of power fluid, psi/ft
 g_s = gradient of production (suction) fluid, psi/ft
 g_w = gradient of produced water, psi/ft
 h_a = acceleration head, ft
 K = experimentally determined constant for particular pump
 K_n = nozzle loss coefficient
 K_{td} = throat-diffuser loss coefficient
 K_2 = constant depending on fluid compressibility
 L = length of annulus or tubing, ft
 L_n = net lift, ft
 L_s = actual length of suction line, ft
 N = pump rate, strokes/min
 N_c = speed of pump crankshaft, rev/min
 N_{max} = rated maximum pump rate, strokes/min
 N_{Re} = Reynolds number
 p = pressure, psi
 p_{ed} = engine discharge pressure, psi
 p_{fd} = friction pressure in discharge tubing, psi
 p_{fet} = friction pressure in power exhaust tubing, psi
 p_{fpt} = friction pressure in power tubing, psi
 p_{fr} = pump friction pressure, psi
 $p_{fr(\text{max})}$ = maximum friction pressure, psi
 p_n = pressure at the nozzle, psi
 p_{pd} = pump discharge pressure, psi
 p_{pf} = power fluid pressure, psi
 p_{ps} = pump suction pressure, psi
 p_r = reduced pressure, psi
 p_{so} = surface operating pressure, psi
 p_{wh} = flowline pressure at wellhead, psi
 p_{whe} = power-fluid exhaust wellhead backpressure, psi
 Δp = pressure rise, psi
 Δp_f = friction pressure drop, psi
 P = power, ft-lbf/sec
 P_h = horsepower, hp
 q = flow of oil, B/D
 q_d = discharge-fluid rate, B/D
 q_e = maximum rated engine displacement, B/D
 q_n = nozzle flow rate, B/D
 q_p = maximum rated pump displacement, B/D
 q_{pf} = power-fluid rate, B/D
 q_s = production (suction) fluid rate, B/D
 q_{sc} = cavitation limited flow rate, B/D
 q_{si} = initial assumed value of q_s
 q_{im} = maximum rated total flow through engine and pump, B/D
 R = producing GOR, scf/bbl
 R_s = solution GOR, scf/bbl
 R_{si} = initial solution GOR, scf/bbl
 s_p = pump submergence, ft
 T = temperature, °F
 T_r = reduced temperature, °F
 v_s = settling velocity, ft/hr
 \bar{v}_{sl} = average velocity in suction line, ft/sec
 V_s = surface volume
 V_D = downhole volume
 W_c = water cut, fraction
 W_{cd} = water cut in discharge conduit to surface
 z_g = gas compressibility factor
 γ_{sp} = specific gravity of suspended particles
 $\bar{\gamma}$ = weighted average specific gravity
 γ_{API} = API specific gravity
 γ_g = gas specific gravity
 γ_L = liquid specific gravity
 γ_o = oil specific gravity
 μ_L = viscosity of liquid, cp
 $\bar{\mu}$ = weighted average viscosity, cp
 ν_m = mixture viscosity, cSt
 ν_o = oil viscosity, cSt
 ν_{pf} = power-fluid viscosity, cSt
 ν_w = water viscosity, cSt
 $\bar{\rho}$ = weighted average density, g/cm³

and

$$p_r = \frac{p_a}{4,830 - 324\gamma_g}, \dots\dots\dots (A-13)$$

where p_r = reduced pressure, kPa, and T_r = reduced temperature, K.

$$v = 14.73 \frac{q}{d^2}, \dots\dots\dots (B-1)$$

where

- v = fluid viscosity, m/s,
- q = quantity of oil flowing, m³/d, and
- d = diameter of tubing, mm.

$$\Delta p_f = 4.71 \times 10^5 \frac{\bar{\mu} L q}{d^4}, \dots\dots\dots (B-2)$$

and

$$\Delta p_f = 1.084 \times 10^5 \bar{\gamma} \bar{f} L \frac{q^2}{d^5}, \dots\dots\dots (B-3)$$

where

- Δp_f = friction pressure drop, kPa,
- $\bar{\mu}$ = weighted average of viscosity, Pa·s,
- $\bar{\mu}/\bar{\rho}$ = weighted average kinematic viscosity, cSt,
- $\bar{\gamma}$ = weighted average specific gravity,
- $\bar{f} = \phi(dv\bar{\rho}/\bar{\mu})$, weighted average friction factor,
- $\quad = \frac{0.0555(\bar{\mu}/\bar{\rho})^{0.21}}{(dv)^{0.21}}$, and
- L = length of tubing or annulus, m.

$$N_{Rc} = 1,000 \frac{dv}{\bar{\mu}/\bar{\rho}}, \dots\dots\dots (B-4)$$

$$v = 14.73 \frac{q}{d_1^2 - d_2^2}, \dots\dots\dots (B-5)$$

and

$$\Delta p_f = \frac{4.71 \times 10^5 \bar{\mu} L q \left(\frac{d_1}{d_1 - d_2} \right)^{0.1}}{(d_1 - d_2)^2 (d_1^2 - d_2^2) (1 + 1.5e^2)}, \dots\dots (B-6)$$

where d_1 = ID of outer tube, mm, and d_2 = OD of inner tube, mm.

$$\Delta p_f =$$

$$\frac{1.084 \times 10^5 \bar{\gamma} \bar{f} q^2 L}{(d_1 - d_2)(d_1^2 - d_2^2)^2 \left(\frac{d_1}{d_1 - d_2} \right)^{0.1} (1 + 1.5e^2)^{0.25}}, \dots\dots\dots (B-7)$$

where d_3 = OD of coupling (inner tube), mm, and e = eccentricity.

Appendix A—Fluid Properties

A detailed analysis of a hydraulic pumping system would include the properties of all the fluids under the different temperature, pressure, dissolved-gas, and emulsion conditions that can exist in different parts of the well and pumping system. Important properties that would vary include the density (or specific gravity), viscosity, and bulk modulus (or compressibility) of the various phases present. An excellent discussion of this subject as applied to hydraulic pumping is given by Brown and Coberly.³⁶

In many cases, however, the well fluid data available are not sufficiently reliable to justify detailed analysis. It has also been noted that the parameters of interest to the production engineer and foreman—notably the surface operating pressure, flow rate, and the predicted pump performance—are not sensitive to small variations in fluid properties. The deviations from expected performance can usually be compensated for readily with the inherent flexibility of the system. For these reasons, average or typical properties are often used in design calculations.

Fig. 6.54—Specific gravity of 24.6°API and 44.0°API oil at 0 to 10,000 psi.

Gravity

The values of specific gravity and gradient (pounds per square inch per foot) for different API crude gravities are given in Table 6.6. The specific gravity of oils varies with temperature and pressure, as shown in Fig. 6.54. Particularly in deep wells, variations in the specific gravity of fluids can have a significant effect on the calculated pressures. It can be seen, however, that the temperature and pressure effects are somewhat compensating. As the well gets deeper, the pressures increase, but so do the temperatures. It is usually sufficient to use reported water specific gravity and an oil specific gravity based on the API gravity from Table 6.6.

Viscosity

The viscosity of water varies with temperature as shown in Fig. 6.26. At oilfield temperatures, it is sufficiently low that variations in viscosity have a negligible effect on friction calculations unless very large volumes are being produced in restricted tubulars, as occasionally occurs with large jet pumps or turbopumps.

At normal temperature (usually 100°F for viscosity determinations), the viscosity of oils increases with specific gravity quite consistently, even though the compositions of the oils may differ. Paraffinic oils generally have somewhat higher viscosities than asphaltic crudes. Fig. 6.55 is a plot of a large number of oils (paraffinic, asphaltic, and mixed-base) from widely scattered fields, which show a good correlation with gravity. This figure has the log-log scale for kinematic viscosity as used for the ordinate of ASTM viscosity charts, and specific gravity as the abscissa. For oils on which actual viscosity determinations are not available, this figure may be used to obtain viscosities at 100°F for estimating friction losses.

Oil viscosity decreases with temperature and is represented by a straight-line relation for most oils when plot-

Fig. 6.55—Viscosity of oil vs. specific gravity (viscosity at 100°F).

ted on ASTM viscosity sheets having log-log of viscosity as the ordinate and log of absolute temperature as the abscissa. Fig. 6.25 is a useful plot of the variation of viscosity with temperature of 13 oils from 10 to 50° API.

Emulsion viscosity depends on several factors, most notably whether water or oil is the continuous phase. Emulsions only rarely occur in hydraulic pumping systems, and can usually be treated chemically with additives to the power fluid. Despite the vigorous turbulent mixing action of jet pumps, they have not been observed to aggravate emulsion tendencies. When water is the continuous phase, it wets the wall of the tubing, and the viscosity effects for friction calculations will be determined principally by the water properties. Fig. 6.30 shows the pronounced effect water-in-oil emulsions can have on the apparent viscosity of the fluid.

The effect of dissolved gas on oil viscosity can be significant, particularly with heavy crudes having high viscosities. The effect of dissolved gas is to decrease the viscosity of the crude. As can be seen from Fig. 6.56 (after Ref. 37), the effect is greatest with fluids of high viscosity.

Gas and Liquid FVF's

The downhole pumps must handle formation volumes of oil, water, and gas, which will change when brought to the surface. Fig. 6.27 provides a means for determining the estimated pump-end volumetric efficiency with reciprocating pumps considering these changes. The equations used for Fig. 6.27 follow.^{9,10}

The FVF equations include

$$B_o = 0.972 + 0.000147F^{1.175}, \dots \dots \dots (A-1)$$

$$B_g = 0.0283 \frac{z_g(T+460)}{p_a}, \dots \dots \dots (A-2)$$

Fig. 6.56—Effect of solution gas on crude viscosity.

and

$$B_t = B_o + B_g(R_{si} + R_s) \frac{1}{5.615}, \dots \dots \dots (A-3)$$

where

$$F = R_s \left(\frac{\gamma_g}{\gamma_o} \right)^{0.5} + 1.25T, \dots \dots \dots (A-4)$$

and

$$R_s = \gamma_g \left(\frac{p_a}{18} \times \frac{10^{0.01257 \gamma_{API}}}{10^{0.000917}} \right)^{1/0.83}, \dots \dots \dots (A-5)$$

where

- B_o = oil FVF, RB/STB,
- B_g = gas FVF, RB/STB,
- z_g = gas compressibility factor,
- T = temperature, °F,
- p = pressure, psia,
- B_t = total (oil plus gas) FVF, RB/STB,
- R_s = solution GOR, scf/bbl,

R_{si} = initial solution GOR, scf/bbl,

γ_g = gas specific gravity,

γ_o = oil specific gravity, and

γ_{API} = API gravity.

The pump efficiency equations involve the ratio of the surface oil and water volume to the downhole oil, water, and gas volume.

$$E_p = \frac{V_s}{V_D} \dots \dots \dots (A-6)$$

and

$$E_p = \left[\frac{1}{W_c + (1 - W_c)B_t} \right], \dots \dots \dots (A-7)$$

where

- E_p = pump efficiency, fraction,
- V_s = surface (oil and water) volume,
- V_D = downhole (oil, water, and gas) volume,
- and
- W_c = water cut, fraction.

The compressibility of gas is a function of three variables—gas specific gravity, temperature, and pressure.

$$z_g = f(\gamma_g, T, p). \quad \text{..... (A-8)}$$

A gas compressibility equation programmed for the computer relates these variables as follows:

$$z_g = A + Bp_r + (1-A)e^{-C} - H(p_r/10)^4, \quad \text{..... (A-9)}$$

where

$$A = -0.101 - 0.36T_r + 1.3868(T_r - 0.919)^{0.5}, \quad \text{(A-10)}$$

$$B = 0.021 + 0.04275/(T_r - 0.65), \quad \text{..... (A-11)}$$

$$T_r = (T + 460)/(175 + 307\gamma_g), \quad \text{..... (A-12)}$$

$$p_r = p_a/(701 - 47\gamma_g), \quad \text{..... (A-13)}$$

$$C = p_r(D + Ep_r + Fp_r^4), \quad \text{..... (A-14)}$$

$$D = 0.6222 - 0.224T_r, \quad \text{..... (A-15)}$$

$$E = 0.0657/(T_r - 0.86) - 0.037, \quad \text{..... (A-16)}$$

$$F = 0.32e^{[-19.53(T_r - 1)]}, \quad \text{..... (A-17)}$$

and

$$H = 0.122e^{[-11.3(T_r - 1)]}, \quad \text{..... (A-18)}$$

where

p_r = reduced pressure, and
 T_r = reduced temperature.

Appendix B—Friction Relationships

Because hydraulic pumping systems require greater circulating volumes of fluid than other artificial lift systems, the proper determination of friction losses is important. This subject is thoroughly covered by F.B. Brown and C.J. Coberly³⁸ and includes the effect of viscosity gradients, laminar to turbulent transitions, proper equivalent diameters for annulus passages, and tubing eccentricity in casing/tubing annular flow passages. Their results are summarized in the following equations.

Circular Sections—Tubing

$$v = 0.01191 \frac{q}{d^2}, \quad \text{..... (B-1)}$$

where

v = velocity, ft/sec,
 q = quantity of oil flowing, B/D, and
 d = diameter of tubing, in.

$$\Delta p_f = 7.95 \times 10^{-6} \frac{\bar{\mu} L q}{d^4} \quad \text{..... (B-2)}$$

for laminar flow and

$$\Delta p_f = 11.46 \times 10^{-6} \bar{\gamma} \bar{f} L \frac{q^2}{d^5} \quad \text{..... (B-3)}$$

for turbulent flow, where

Δp_f = friction pressure drop, psi,
 $\bar{\mu}$ = weighted average viscosity, cp,
 $\bar{\mu}/\bar{\rho}$ = weighted average kinematic viscosity, cSt,
 L = length of tubing, ft,
 q = quantity of oil flowing, B/D,
 d = ID of tubing, in.,
 $\bar{\gamma}$ = weighted average specific gravity,
 \bar{f} = weighted average friction factor
 $= \phi(dv\bar{\rho}/\bar{\mu})$
 $= 0.0361 (\bar{\mu}/\bar{\rho})^{0.21} / (dv)^{0.21}.$

Transition from laminar to turbulent flow occurs when the Reynolds number (N_{Re}) is greater than 1,200.

$$N_{Re} = 7.742 \times 10^3 \frac{dv}{\bar{\mu}/\bar{\rho}}, \quad \text{..... (B-4)}$$

Annular Sections—Flow Between Tubing and Casing

Laminar flow:

$$v = 0.01191 \frac{q}{d_1^2 - d_2^2} \quad \text{..... (B-5)}$$

and

$$\Delta p_f = \frac{7.95 \times 10^{-6} \bar{\mu} L q \left(\frac{d_1}{d_1 - d_2} \right)^{0.1}}{(d_1 - d_2)^2 (d_1^2 - d_2^2) (1 + 1.5e^2)}, \quad \text{..... (B-6)}$$

where

Δp_f = friction pressure drop, psi,
 $\bar{\mu}$ = weighted average viscosity, cp,
 L = length of annulus, ft,
 q = flow, B/D,
 d_1 = ID of outer tube, in.,
 d_2 = OD of inner tube, in.,
 e = eccentricity of tubes = $2d_3/(d_1 - d_2)$, and
 d_3 = distance inner tube is off center, in.

Turbulent Flow:

$$\Delta p_f = \frac{11.46 \times 10^{-6} \bar{\gamma} \bar{f} q^2 L}{(d_1 - d_2)(d_1^2 - d_2^2)^2 \left(\frac{d_1}{d_1 - d_2} \right)^{0.1} (1 + 1.5e^2)^{0.25}}, \quad \text{..... (B-7)}$$

where

Δp_f = friction pressure drop, psi,
 q = flow, B/D,
 L = length of annulus, ft,
 $\bar{\gamma}$ = weighted average specific gravity
 (water = 1.0),
 d_1 = ID of outer tube, in.,
 d_2 = OD of inner tube, in.,
 d_3 = OD of coupling (inner tube), in.,
 e = eccentricity = $(d_1 - d_3)/(d_1 - d_2)$,
 $\bar{f} = \phi(dv\bar{\rho}/\bar{\mu}) = 0.0361 (\bar{\mu}/\bar{\rho})^{0.21} / (dv)^{0.21}$, and
 $\bar{\mu}/\bar{\rho}$ = weighted average kinematic viscosity, cSt.

In calculating Reynolds numbers, N_{Re} , for annular sections, the characteristic diameter becomes $(d_1 - d_2)$ in Eq. B-4. However, the velocity, v , is calculated from the actual annular cross-sectional area between d_1 and d_2 .

These relationships have been used to construct Figs. 6.57 and 6.58. The viscosity in these figures refers to the weighted average viscosity of Eq. 42 and are for liquid flow only. Vertical or horizontal multiphase flowing gradient calculations or curves should be used when significant gas is present. Figs. 6.57 and 6.58 were constructed with values of the eccentricity, e , of one-half of its maximum value, which occurs when the tubing is against the casing.

Chapter 7

Electric Submersible Pumps

W.J. Powers, TRW Reda Pump Div.

Introduction

The electric submersible pump (ESP), sometimes called "submergible," is perhaps the most versatile of the major oil-production artificial lift methods. This chapter provides the reader with a broad understanding of the key factors in selection, installation, and operation of electric submersible pumps. ESP topics covered include the ESP system; applications; ESP system components; selection data and methods; handling, installation, and operation; and troubleshooting.

ESP System

The ESP system comprises a downhole pump, electric power cable, and surface controls. In a typical application, the downhole pump is suspended on a tubing string hung on the wellhead and is submerged in the well fluid (see Fig. 7.1). The pump is close-coupled to a submersible electric motor that receives power through the power cable and surface controls.

The ESP has the broadest producing range of any artificial lift method. The standard 60-Hz producing range of the ESP extends from a low of 100 B/D of total fluid up to 90,000 B/D. Variable-speed drives can extend the producing range beyond these rates. Although most operators tend to associate ESP's with "high volume" lift rates, the average ESP produces less than 1,000 B/D of total fluid in continuous operation.

ESP's are used to produce a variety of fluids and the gas, chemicals, and contaminants commonly found in these fluids. Currently ESP's are operated economically in virtually every known oil field environment. The WOR is, in general, not significant in assessing an application. Relatively high gas/fluid ratios can be handled using "tapered" design pumps and a special gas separator pump intake. Aggressive fluids (those containing H_2S , CO_2 , or similar corrosives) can be produced with special materials and coatings. Sand and similar abrasive contaminants can be produced with acceptable pump life by using specially modified pumps and operation procedures.

ESP's usually do not require storage enclosures, foundation pads, or guard fences. An ESP can be operated in a deviated or directionally drilled well, although the recommended operating position is in a straight section of the well. Because the ESP can be up to 200 ft long, operation in a bend or dogleg could seriously impact unit run-life and performance by causing hot spots where the motor rests against the casing. The ESP can operate in a horizontal position. In this case, run-life will be determined by the protector's ability to isolate well fluid from the motor.

ESP's are currently operated in wells with bottomhole temperatures (BHT's) up to 350°F. Operation at elevated ambient temperatures requires special components in the motor and power cables capable of sustained operation at high ambient temperature.

ESP's have efficiently lifted fluids in wells deeper than 12,000 ft. The pumps can be operated in casing as small as 4.5 in. OD. Many studies indicate that ESP's are the most efficient lift method and the most economical on a cost per lifted barrel basis. System efficiency ranges from 18 to 68%, depending on fluid volume, net lift, and pump type.

The major disadvantage of the ESP is that it has a narrow producing rate range compared with other artificial lift forms. It does handle free gas well, but the impact of large volumes of gas can be destructive to the pump. Run life can be adversely affected by a poor quality electric power supply, but this is not limited to the ESP.

Applications

The ESP historically has been applied in lifting water or low oil-cut wells that perform similar to water wells. However, within this seemingly narrow segment there are many types of installations and equipment configurations. This section covers typical installation, booster and injection, bottom intake/discharge, cavern storage/shrouded configuration, and offshore platforms.

Fig. 7.1—Typical submersible pump application.

Typical Installation

A typical ESP installation is shown in Fig. 7.1. The ESP system's major surface and downhole equipment is shown. In this installation, the available surface power is transformed to the downhole power requirements by three single-phase transformers. The transformed power is supplied by a power cable to a switchboard and then through a junction box and wellhead/tubing support. The power cable is run in with the production tubing string and is banded to the tubing to prevent mechanical damage during installation and removal. The power cable is spliced to a motor flat cable, which is banded to the exterior of the pump-protector motor unit. The centrifugal pump is located at the top of the downhole unit. The pump is hung on the tubing string by the discharge head. Below the pump is a standard intake, which provides for fluid entry to the pump. The center component is the protector. The protector both equalizes external and internal pressure and isolates the motor from the well fluid. The lowest component is the motor, which drives the centrifugal pump. Note that the downhole unit is landed above the perforations. This is necessary so that fluid entering the well flows past the motor. This flow cools the motor, which is otherwise likely to overheat and fail.

These and other accessory products and system components are discussed in detail later.

Booster and Injection

Fig. 7.2 displays a booster application. In this application, a standard pump-protector motor unit is used to lift fluid from a flowline or other source and simultaneously provide injection pressure for a waterflood, pipeline, or other purpose. In a booster application, the unit is set in a short piece of casing, usually near the surface. This configuration can be used for water injection, power fluid, fluid transfer, water disposal, or as a tailgate booster.

Injection applications usually lift fluids from an aquifer at normal depths and inject the produced water into a producing zone in the same well or a second well. Injection systems can provide pressure greater than 3,000 psi. The production rate of the pump can be designed to closely match the injectivity characteristics of a reservoir during fillup.

Bottom Intake and Bottom Discharge

Fig. 7.3 displays a bottom intake configuration. In bottom intake applications, the well fluid enters the pump through a stinger landed in a permanent packer. The pump and motor sections are inverted from typical positions. The well fluid is produced up the annulus instead of the conventional tubing string. This configuration is used where casing clearance limits production volume because of tubing friction loss or pump diameter interference. Because the bottom intake pump can be suspended by small-diameter, high-tensile-strength tubing, output and efficiency are significantly improved.

Fig. 7.4 shows a bottom discharge configuration. The bottom discharge pump typically is used to inject water from a shallow aquifer into a deeper producing zone. This eliminates surface flowlines and pumping equipment completely. In this configuration, the pump and motor sections are inverted from a typical position. The pump produces the fluid through a tubing stinger landed in a permanent packer in the injection zone. Thus, the injection pressure is the sum of the interzonal hydrostatic head and the output pressure of the pump.

Shrouded Configuration/Cavern Storage

Fig. 7.5 displays a standard downhole unit that has been fitted with a shroud. Depending on the exact configuration, a shroud can serve two purposes: (1) direct fluid past the motor for cooling and (2) allow free gas to separate from the fluid before entering the pump intake. This configuration is useful in low-volume, high-gas/fluid-ratio wells where drawdown is critical. A shroud allows the pump to be set below the perforations or producing formation. Other examples are cavern or platform leg storage where a unit is suspended in the fluid on tubing and the shroud provides the necessary motor cooling-fluid flow.

Offshore Platforms

Both drilling and production platforms include ESP equipment. Typical applications are mud mixing, washdown, fire protection, sump pumps, water supply, and off-loading crude oil from storage. The major reason for the use of ESP's in these applications is its space savings when compared with conventional pump products.

Fig. 7.2—Booster service application.

Fig. 7.3—Bottom intake application.

ESP System Components

Motor

The ESP system's prime mover is the submersible motor (see Fig. 7.6). The motor is a two-pole, three-phase, squirrel-cage induction type. Motors run at a nominal speed of 3,500 rev/min in 60-Hz operation. Motors are filled with a highly refined mineral oil that provides dielectric strength, bearing lubrication, and thermal conductivity. The standard motor thrust bearing is a fixed-pad Kingsbury type. Its purpose is to support the thrust load of the motor rotors. Other types are used in high-temperature applications above 250°F.

Heat generated by motor operation is transferred to the well fluid as it flows past the motor housing. A minimum fluid velocity of 1 ft/sec is recommended to provide adequate cooling. Because the motor relies on the flow of well fluid for cooling, a standard ESP should never be set at or below the well perforations or producing zone unless the motor is shrouded (Fig. 7.5).

Motors are manufactured in four different diameters (series) 3.75, 4.56, 5.40, and 7.38 in. Thus, motors can be used in casing as small as 4.5 in. Sixty-Hz horsepower capabilities range from a low of 7.5 hp in 3.75-in. series to a high of 1,000 hp in the 7.38-in. series. Motor construction may be a single section or

several "tandems" bolted together to reach a specific horsepower. Motors are selected on the basis of the maximum OD that can be run easily in a given casing size.

The standard motor housing material is heavy-wall, seamless, low-carbon steel tubing. The motor-shaft material is carbon steel. The rotors are supported by sleeve bearings made of Nitralloy and bronze. The squirrel cage rotor is made of one or more sections depending on motor horsepower and length. The motor stator is wound as a single unit in a fixed housing length.

Pump

The ESP is a multistage centrifugal type pump (Fig. 7.7). The type of stage used determines the design volume rate of fluid production. The number of stages determines the total design head generated and the motor horsepower required.

The materials used in manufacturing an impeller are Ni-Resist, Rytan, and bronze. Diffusers are universally manufactured of Ni-Resist. The standard shaft material is K-Monel®. Optional, high-strength shaft materials (Inconel® and Hastalloy®) are used in deep-setting applications where conventional shaft material horsepower limits are exceeded. "Bolt-on" design makes it possible to vary the capacity and total head of a pump by using

Fig. 7.4—Bottom discharge application.

Fig. 7.5—Shrouded application.

Fig. 7.6—Motor.

Fig. 7.7—Pump with standard intake.

more than one pump section. However, large-capacity pumps typically have integral heads and bases. The nominal OD of a pump will range from 3.38 to 11.25 in.

Protector

The protector's primary purpose is to isolate the motor oil from the well fluid while balancing bottomhole pressure (BHP) and the motor's internal pressure. There are two types of protector design—the positive seal (Fig. 7.8) and the labyrinth path (Fig. 7.9). The positive seal design relies on an elastic, fluid-barrier bag to allow for the thermal expansion of motor fluid in operation, and yet still isolate the well fluid from the motor oil. The labyrinth path design uses differential specific gravity of the well fluid and motor oil to prevent the well fluid from entering the motor. This is accomplished by allowing the well fluid and motor oil to communicate through tube paths connecting segregated chambers.

The protector performs four basic functions. The protector (1) connects the pump to the motor by connecting both the housing and drive shafts, (2) houses a thrust bearing to absorb pump shaft axial thrust, (3) isolates motor oil from well fluid while allowing wellbore-motor pressure equalization, and (4) allows thermal expansion of motor oil resulting from operating heat rise and thermal contraction of the motor oil after shutdown.

Pump Intake

Two types of intakes are used to allow fluid to enter the pump. These are the standard intake shown in Fig. 7.7 and the gas separator intake shown in Figs. 7.10 and 7.11. A gas separator intake is used when the gas/liquid ratio (GLR) is greater than can be handled by the pump. If the gas remains in solution, the pump will perform normally. However, once the GLR exceeds a value of about 0.1, the pump may produce less head than normal. As the GLR increases above 0.1 and free gas increases, the pump will eventually "gas lock," which usually drastically reduces fluid production and in extreme cases can damage the pump.

There are two types of gas separator intakes—the static type (Fig. 7.10) and the rotary type (Fig. 7.11). The static type induces gas separation by reversing the fluid flow direction. At the fluid entry ports, the reversal of fluid flow direction creates lower pressure that allows the gas to separate. The separated gas moves up the annulus and vents at the wellhead. The fluid, which still contains some gas, enters the separator and moves downward into the stand tube. The fluid is picked up by the rotating pickup impeller. The impeller creates a vortex, which forces dense, gas-free fluid to the outside and causes gas to break out and move up the shaft. This provides the first stage of the pump with a higher density of fluid than if the gas broke out in the pump.

Fig. 7.8—Positive seal protector.

Fig. 7.9—Labyrinth path protector.

Fig. 7.10—Static type gas separator.

The rotary gas separator in Fig. 7.11 includes a rotary inducer-centrifuge to separate the gas and produced liquids. The well fluid enters the intake ports and moves into the inducer. The inducer increases the fluid pressure discharging into the centrifuge. The centrifuge forces the denser fluid to the outside. Gas rises from the center of the centrifuge through the flow divider into the crossover section where gas vents to the annulus and fluid is directed into the first stage of the pump.

Power Cable

Electric power is supplied to the downhole motor by a special submersible cable. There are two cable configurations: flat (or parallel) and round (Fig. 7.12). Round construction is used except where casing clearance requires the lower profile of flat construction. The standard range of conductor sizes is 1/0 to 6 AWG (American wire gauge). This range meets virtually all motor amperage requirements. Almost all conductors are copper.

Mechanical protection is provided by armor made from galvanized steel or, in extremely corrosive environments, Monel™. Unarmored cable is used in low-temperature (<180°F) wells with a static BHP of less than 1,500 psi.

Cable is constructed with three individual conductors—one for each power phase. Each conductor is

enclosed by insulation and sheathing material. The thickness and composition of the insulation and sheathing determines the conductor's resistance to current leakage, its maximum temperature capability, and its resistance to permeation by well fluid and gas. Electric power cable is rated to operate up to 400°F at 1,500 psi.

Round cable is also manufactured with an "I-wire." The I-wire serves as an electrical link between a downhole instrument and surface reading/processing equipment.

Motor Flat Cable

The motor flat cable is the lowest section of the power cable string. The motor flat cable has a lower profile than standard flat power cable so that it can run the length of the pump and protector in limited clearance situations (Fig. 7.1). The motor flat cable is manufactured with a special terminal called a "pothead." The function of the pothead is to allow entry of electric power into the motor while sealing the connection from well fluid entry.

Switchboard

The switchboard is basically a motor control device (Fig. 7.13). Voltage capability ranges from 600 to 4,900 V on standard switchboards. All enclosures are NEMA-3R

Fig. 7.11—Rotary gas separator.

Fig. 7.12—Round and parallel power cable.

(Natl. Electrical Manufacturers Assn.), which is suitable for virtually all outdoor applications. The switchboards range in complexity from a simple motor starter/disconnect switch to an extremely sophisticated monitoring/control device.

There are two major construction types—electromechanical and solid state. Electromechanical construction switchboards provide overcurrent/overload protection through three magnetic inverse time-delay contact relays with pushbutton, manual reset. Undercurrent protection is provided by silicone-controlled rectifier (SCR) relays. These features provide protection against downhole equipment damage caused by conditions such as pumpoff, gas lock, tubing leaks, and shutoff operation.

The solid state switchboards incorporate the highly sophisticated Redalert™ motor controller. The purpose of the motor controller is to protect the downhole unit by sensing abnormal power service and shutting down the power supply if current exceeds or drops below preset limits. This is accomplished by monitoring each phase of the input power cable to the downhole motor.

The monitoring function applies to both overload and underload conditions. When a fault condition occurs, the controller shuts down the unit. It can be programmed to automatically restart the downhole motor following a user-selected time delay if the fault condition is caused by an underload. The programmed time delay can be from 1 minute up to 20 hours. Overload condition shutdown must be restarted manually, but this should be done only after the fault condition has been identified and corrected.

A valuable switchboard option is the recording ammeter. Its function is to record, on a circular strip chart, the input amperage to the downhole motor. The ammeter chart record shows whether the downhole unit is performing as designed or whether abnormal operating conditions exist. Abnormal conditions can result when a well's inflow performance is not matched correctly with pump capability or when electric power is of poor quality. Abnormal conditions that are indicated on the ammeter chart record are primary line voltage fluctuations, low amps, high amps, and erratic amps. Specific examples of typical problems encountered and the associated ammeter chart pattern are discussed later.

Transformer

The ESP system involves three different transformer configurations. These are three single-phase transformers (Fig. 7.14), one three-phase standard transformer, and one three-phase autotransformer. Transformers generally are required because primary line voltage does not meet the downhole motor voltage requirement. Oil-immersed self-cooled (OISC) transformers are used in land-based applications. Dry type transformers are sometimes used in offshore applications that exclude oil-filled transformers.

Wellhead

The ESP wellhead or tubing support is used as a limited pressure seal (Fig. 7.15). The wellhead provides a pressure tight pack-off around the tubing and power cable. High-pressure wellheads, up to 3,000 psi, use an

Fig. 7.13—Switchboard.

Fig. 7.14—Single-phase transformer.

electrical power feed to prevent gas migration through the cable. Wellheads are manufactured to fit standard casing sizes from 4.5 to 10% in.

Junction Box

A junction box connects the power cable from the switchboard to the well power cable (Fig. 7.16). The junction box is necessary to vent to the atmosphere any gas that may migrate up the power cable from the well. This prevents accumulation of gas in the switchboard that can result in an explosive and unsafe operating condition. *A junction box is required on all ESP installations.*

Accessory Options

The following covers two major accessory options—the pressure-sensing instrument and the variable-speed drive.

Pressure-Sensing Instrument (PSI). The PSI provides the operator with precise downhole pressure and temperature data. The PSI has two components: (1) a

Fig. 7.15—Hercules HHS wellhead.

Fig. 7.16-Junction box.

Fig. 7.17—Pressure- and temperature-sensing instrument.

downhole transducer/sending unit and (2) a surface readout unit (Fig. 7.17). The downhole transducer/sending unit connects electrically and bolts to the base of the motor. Both pressure and temperature data are transmitted from the transducer/sending unit to the surface readout through the motor windings and the power cable on a DC carrier signal. The transducer receives operating power from the motor's neutral winding. This allows the operation of the PSI even when the motor is not running.

The major use of the PSI unit is in determining the producing potential of a well. This is accomplished by determining both static and dynamic reservoir pressures. By correlating the change in pressure with a given producing rate, a well's inflow performance can be accurately quantified. This in turn will allow equipment selection, which optimizes well production.

Variable-Speed Drive. The variable-speed drive (VSD) is a highly sophisticated switchboard-motor controller (see Fig. 7.18). A VSD performs three distinct functions. It varies the capacity of the ESP by varying the

Fig. 7.18--500KVA variable-speed drive.

motor speed, protects downhole components from power transients, and provides "soft-start" capability. Each of these functions is discussed.

A VSD changes the capacity of the ESP by varying the motor speed. By changing the voltage frequency supplied to the motor and thus motor rev/min, the capacity of the pump is changed also in a linear relationship. Thus, well production can be optimized by balancing inflow performance with pump performance. This applies to both long-range reservoir changes as well as short-term transients such as those associated with high-GOR wells. This may eliminate the need to change the capacity of a pump to match changing well conditions or it may mean longer run life by preventing cycling problems. This capability is also useful in determining the productivity of new wells by documenting pressure and production values over a range of drawdown rates. The change in voltage frequency can be made manually or automatically. The VSD can operate automatically in a "closed loop" mode with a programmable controller and PSI instrument.

The VSD also protects the downhole motor from poor-quality electric power. The VSD is relatively insensitive to incoming power balance and regulation while providing closely regulated and balanced output. The VSD will not put power transients out to the downhole motor but it can be shut down or damaged by such transients. Given the choice, most operators prefer to repair surface installation equipment rather than pull and run downhole equipment. Within limits, the VSD upgrades poor-quality electric power by "rebuilding." The VSD takes a given frequency and voltage AC input, converts the AC to DC, and then rebuilds the DC to an AC

waveform. The shape of the waveform is a six-step square wave.

The soft-start capability of a VSD provides two major benefits. First, it reduces the startup drain on the power system. Second, the strain on the pump shaft is significantly reduced when compared with that of a standard start. This capability is valuable in gassy or sandy wells. In some cases, slowly ramping a pump up to operating speed may avoid pump damage.

Selection Data and Methods

This section covers the data requirements and calculation procedures required for pump selection in a typical ESP application. The single most important factor in selection of an ESP is the input data. The data used in sizing an ESP must be accurate and reliable to ensure that the unit is properly matched to the well's inflow performance.

The data requirements for selection of an ESP are categorized as mechanical data, production data, fluid data, and power supply.

Mechanical Data

The mechanical data include: (1) casing size and weight, (2) tubing size, weight, and thread, (3) well depth—both measured and true vertical, (4) perforations depth—both measured and true vertical, and (5) unusual conditions such as tight spots, doglegs, and deviation from true vertical at desired setting depth.

The casing size and weight determine the maximum diameter of the motor, pump, and protector components that will fit in the well. In general, the most efficient installation is obtained when the largest possible diameter pump, in the target flow range, is selected.

The depth of the well and the perforations determine the maximum setting depth of the ESP. If the motor is to be set below the perforations, a motor shroud must be used to provide a flow of well fluid past the motor for cooling (Fig. 7.5).

Production Data

The production data include: (1) current and desired production rate, (2) oil-production rate, (3) water-production rate, (4) GOR—free gas and solution gas or gas bubblepoint, (5) static BHP and fluid level, (6) producing BHP and stabilized fluid level, (7) BHT, and (8) system backpressure from flowlines, separator, and wellhead choke.

The inflow performance of a well establishes the maximum economical and efficient rate at which it can be produced. Liquid-level data may be used as a substitute for producing pressures and rates in water wells or in low-oil-cut wells with no gas. In these cases, a straight line PI may be used as a reasonable approximation of well capacity.

Most oil wells do not exhibit a straight-line PI because of interference caused by gas. The Vogel technique¹ yields a downward-sloping curve that corrects for gas interference. The IPR curve (Fig. 7.19) applies when wellbore pressure in the producing zone drops below the bubblepoint, which results in two-phase flow as the gas breaks out of the fluid. Again, the data obtained for this approach in sizing an ESP must be both accurate and reliable to ensure proper equipment selection.

Fig. 7.19—Inflow performance relationships curve.

Fluid Data

The fluid data include: (1) oil API gravity, viscosity, pour point, paraffin content, sand, and emulsion tendency; (2) water specific gravity, chemical content, corrosion potential, and scale-forming tendency; (3) gas specific gravity, chemical content, and corrosive potential; and (4) reservoir FVF, bubblepoint pressure, and viscosity/temperature curve.

The specific gravity of the produced fluid has a direct impact on the horsepower required to turn a given size pump. Although relatively few applications encounter fluid viscosities high enough to influence pump performance, it is important to be aware that capacity, head, and horsepower correction factors may be required. In wells with a water cut of 65% or higher, the fluid will not require viscosity correction factors (except for emulsions).

The PVT data are required when gas is present. A computer program for pump selection (discussed later in this section) contains a subroutine that uses Standing's correlations² in approximating the PVT values when actual data are not available. In high-GOR applications, PVT data are very desirable because the three standard correlation estimates—Standing,² Lasater³, and Vasquez and Beggs⁴—yield large differences in calculated downhole gas volume (see Chap. 22).

Electric Power Supply

The electric power supply includes: (1) voltage available and frequency, (2) capacity of the service, and (3) quality of service (spikes, sags, etc.).

TABLE 7.1—PUMP SELECTION TABLE (60 Hz, 3,500 rpm)

Series	OD (in.)	Pump Type	Maximum BHP Rating For Pump Shaft	Capacity Range Recommended Limits	
				(B/D)	(m ³ /D)
338	3.38	A400	94	280 to 500	45 to 80

950	9.50	N1050	1000	24000 to 47500	3816 to 7552
1000	10.00	N1500	1000	35000 to 59000	5564 to 9380
1125	11.25	P2000	1000	53600 to 95800	8521 to 15240

The power data are important because they partially determine transformer and switchboard requirements. Frequency influences pump rotation speed, capacity, and head.

Once the required data have been gathered and analyzed, the next ESP selection step is to determine the well's production capacity at a given pump-setting depth. This involves analysis of the inflow performance data as well as desired production rate. Two key factors that must be considered are the minimum pump intake pressure (net positive suction head), which the well will permit without pumpoff or gas lock, and the producing rate, which draws the fluid level down to an optimal level.

The next selection step is to determine the total dynamic head (TDH). TDH is the sum of: (1) the true vertical lift distance from the producing fluid level to the surface, (2) friction loss in the tubing string, and (3) discharge pressure head at the wellhead. The design TDH determines the number of stages required in a pump.

Selection of a specific pump involves identifying a pump of the largest possible diameter that can be run in the well. The pump should have the target capacity

within its recommended operating range and close to its peak efficiency. The initial pump capacity selection can be made from Table 7.1.

The individual pump curve should then be reviewed to determine the optimal producing range and the proximity of the design producing rate to the pump's peak efficiency (see Fig. 7.20 for a typical pump performance curve). It is very important to choose a producing rate that is in the recommended capacity range of the specific pump. When a pump operates outside this range, premature failure can result.

Once a pump is chosen, the number of stages required can be calculated using the lift-feet-per-stage data from the performance curve.

$$n_s = \frac{Z}{L_s},$$

where

n_s = number of design stages,
 Z = total dynamic head, ft, and
 L_s = lift per stage, ft.

Fig. 7.20—Typical pump performance curve.

The horsepower required by the pump design then can be calculated. To accomplish this, the horsepower required per stage is read from the specific pump performance curve. The required motor horsepower is determined by multiplying the horsepower required per stage by the number of design stages. The performance curve horsepower data apply only to liquids with a specific gravity of 1.0. For other liquids (other specific gravities), the water horsepower also must be multiplied by the specific gravity of the fluid pumped. Thus we have the following equation for the motor horsepower calculation.

$$P_{hm} = P_{hs} \times n_s \times \rho_f,$$

where

$$\begin{aligned} P_{hm} &= \text{motor horsepower,} \\ P_{hs} &= \text{horsepower per stage,} \\ n_s &= \text{number of design stages, and} \\ \rho_f &= \text{specific gravity of fluid.} \end{aligned}$$

Once the design motor horsepower is determined, specific motor selection is based on setting depth, casing size, and motor voltage. Although the cost of the motor is generally unrelated to voltage, overall ESP system cost may be lowered by using higher-voltage motors in deep applications. This lower cost can sometimes occur because a higher voltage can lower the cable conductor size required. A smaller-conductor-size, lower-cost cable can more than offset the increased cost of a higher-voltage switchboard. Setting depth is a major variable in motor selection because of starting and voltage drop losses that are a function of the motor amperage and cable conductor size.

Cable selection variables are amperage, voltage drop, annulus clearance, ambient well temperature, and corrosion conditions. The standard maximum voltage drop is limited to 30V/1000 ft. If voltage drop exceeds this value, a larger conductor size should be used. Round cable normally is used unless tubing collar/annulus clearance dictates flat or parallel construction. The maximum operating temperature of a cable in relation to the specific well's ambient temperature determines the specific type of cable. Armor and lead sheathing may be recommended for wells with mechanical or clearance problems or corrosive gas such as H_2S .

The surface electrical equipment (switchboard and transformers) selection is based on the required motor horsepower, voltage, amperage, voltage loss, and cable size. The surface voltage is the sum of the downhole motor no-load voltage plus the voltage losses resulting from cable size and other component losses. Voltage losses associated with transformers range from 2.5 to 6%, depending on the manufacturer. Additional impedance is associated with VSD transformer sizing. Transformers must also be selected on the basis of the primary voltage available and the required hookup method— $\Delta\Delta$, $Y\Delta$, or YY .

The protector selection variables are motor and pump series, motor horsepower, and well temperature. Normally the protector is the same series as the pump and motor. Large horsepower motors (150 hp and larger) may require a larger oil capacity. For large horsepower motors, a positive seal double-bag model or a tandem "labyrinth path" model is used. An ambient well temperature of 250°F or higher generally requires the use of the labyrinth path protector.

ESP equipment selection in high-water-cut, low-GOR wells is relatively straightforward. Equipment selection

Fig. 7.21--Shipping boxes positioned at the wellsite.

in high GOR or viscous crude wells, however, can be very complicated. One ESP manufacturer has developed a sophisticated computer program to provide comprehensive analysis of alternative equipment selections in such situations. It can be used to select equipment or to evaluate previously selected equipment. This capability means that, over time, the engineer can evaluate the pump fit as well as changes in conditions. If well inflow performance changes significantly, the sizing of the downhole equipment may need to be checked both to optimize production and to prevent premature failure.

The computer program contains analytic models for pump performance, reservoir response, and fluid characteristics. It uses the Chew and Connally⁵ correlations for live fluid viscosity based on the quantity of gas in solution. Another option uses Orkiszewski's⁶ two-phase vertical flow model to compute pump discharge pressure and horsepower required. Standing's⁷ correlations are used to provide surrogate PVT data when actual values are not available.

Handling, Installation, and Operation

This section provides recommended practice on the handling, installation, and operation of an ESP system. Because both safety and economic run life are dependent on correct procedures, the importance of following the recommended practice cannot be overemphasized.

Handling

The downhole components—motor, pump, protector, and intake—are shipped in a metal shipping box (Fig. 7.21). The shipping boxes are painted red on the end that should be placed toward the wellhead when the equipment is delivered to the wellsite. The shipping boxes should be lifted with a spreader chain or bridled with a sling at each end. Severe equipment damage can result from dropping, dragging, or bouncing the boxes. The shipping boxes should never be lifted by the middle of the box only.

The cable reel should be lifted by using an axle and a spreader bar (Fig. 7.22). If a fork lift is used, the forks should be long enough to support both reel rims when the reel is picked up from an end. The ends of the cable should be covered or sealed to protect them from the elements.

Transformers and switchboards are provided with lifting hooks. To avoid damage, the recommended practice is to lift with a spreader bar to maintain a vertical position. Variable-speed drives are normally skid-mounted with fork lift slots and lifting eyes. Some VSD models are manufactured with pull bars.

Additional information on ESP handling and installation procedures is available in "API Recommended Practice for Electric Submersible Pump Installations."⁸

Installation

There are three segments to every ESP installation. These are well preparation, site layout, and run-in and startup of equipment. The well-preparation procedure in-

Fig. 7.22--Cable reel lifting procedures.

volves determining the **downhole** clearance conditions. Site layout prescribes equipment and rig locations as well as size and capacity. Running equipment in the well and startup procedures define the steps in equipment handling, test procedure, and responsibility of the rig crew and servicemen.

Prior to beginning installation of the ESP equipment, the well must be cleared of any tubing, rods, packers, etc., that would prevent the **downhole** equipment from reaching target setting depth. The casing flange and well head should be examined for burrs or sharp edges. This is very important in small-diameter casing because cable damage can be caused by burrs or edges catching cable bands.

A gauge ring should be run in (particularly in 4.5-in. casing) to below the setting depth of the **downhole** equipment. If gauging indicates tight spots, a scraper or reamer should be used to remove the obstruction (scale, paraffin, burrs, or partially collapsed casing). This will ensure adequate clearance for the ESP **downhole** equipment as it is run into the well.

The blowout preventer (BOP), if used, should be checked for adequate clearance as well as burrs and sharp edges. Cut-out rams are available for most tubing and cable sizes. They should be installed in the BOP for well control in the event of a kick during equipment installation.

The pulling rig should be centered over the well as closely as possible. A guide wheel/cable sheave should be secured safely to the rig mast no higher than 30 to 45 ft above the wellhead. The guide wheel should be at least 54 in. in diameter.

The cable reel or spooling truck should be positioned about 100 ft from the wellhead in direct line of sight of the rig operator. One person should be responsible for the cable operation. The responsibilities of this person are to ensure that there is minimum tension on the cable (the cable should be run at the same speed as the tubing), that the cable is kept clear of power tongs during tubing makeup or break, and that no one stands in front of the cable reel/spooler.

The cable junction box must be located at least 15 ft from the wellhead (Fig. 7.16). The switchboard must be located a minimum of 50 ft from the wellhead and 35 ft minimum from the junction box. The junction box normally is located 2 to 4 ft above ground level to ensure adequate air circulation and easy access. The junction box must **never** be located inside a building.

The ESP manufacturer's field representative checks all equipment before installation. During installation his responsibility is to supervise the pulling and/or running of the **downhole** equipment. All equipment delivered to the wellsite is checked to determine that all components necessary to complete the installation have arrived and are not damaged. The ESP manufacturer's field representative will perform the following checks and procedures.

1. Remove shipping box covers and record all component serial numbers from nameplates (Fig. 7.23).
2. Check casing, wellhead, and packoff material.
3. Check the switchboard for proper fuses, potential transformer setup, and current transformer ratios.
4. Check all couplings for shaft diameter and spline match.

Fig. 7.23—Checking nameplates.

3. Check flat cable length, size, and pothead type.
 6. Check power transformers for correct primary and secondary voltage rating.
 7. Confirm that the pump design setting depth and capacity match the well conditions.
 8. Check the power cable and flat cable with instruments and high-voltage megger.
- Once the equipment, cable, and verification procedures are completed, the assembly and run-in of **downhole** equipment can begin. The manufacturer's field representative directs the assembly and checks equipment as it is being run in. The steps of assembly and checks of equipment can be summarized as follows.
1. Assemble motor, protector, intake, and pump.
 2. Fill the motor/protector assembly with motor oil.
 3. Mechanically check free rotation of **downhole** components.
 4. Check electrical connection and test the motor, power cable, and flat cable pothead.
 5. Correct torque of connecting bolts.
 6. Band cable to tubing string.
 7. Splice cable or repair damaged cable.
 8. Connect power cable to junction box and switchboard.
 9. Pack off wellhead.
 10. Complete flowline connections and valve position.

Once the run-in procedures are completed and final electrical tests completed, the manufacturer's representative will complete the electrical connections. The switchboard underload and overload adjustments are set according to the conditions expected for each well. The pump is then started. Fluid pump-up time, load and no-load voltage, and amperage on each phase are recorded. Phase rotation should be checked carefully to ensure that the pump is rotating in the correct direction.

The quantity of production of oil, gas, and water should be monitored on startup and regularly for the time required to achieve stability. A careful study should be made on a pump installation that does not produce as designed. As much information as possible should be gathered to aid in specific identification of the problem and appropriate remedial action. This will ensure that subsequent installations will provide satisfactory run life.

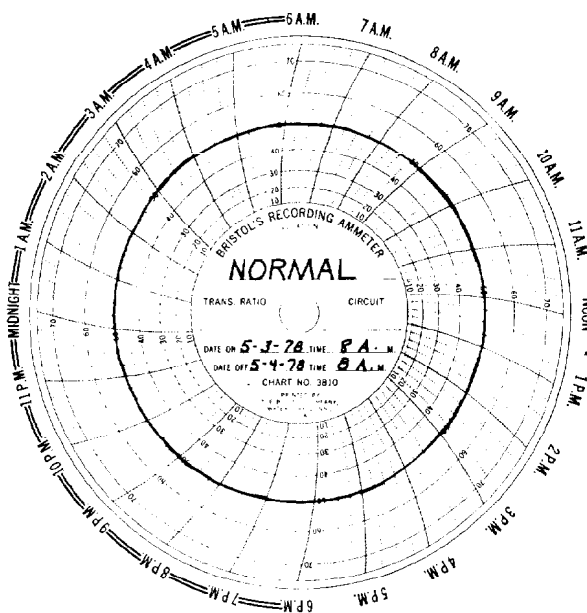

Fig. 7.24—Normal ammeter chart.

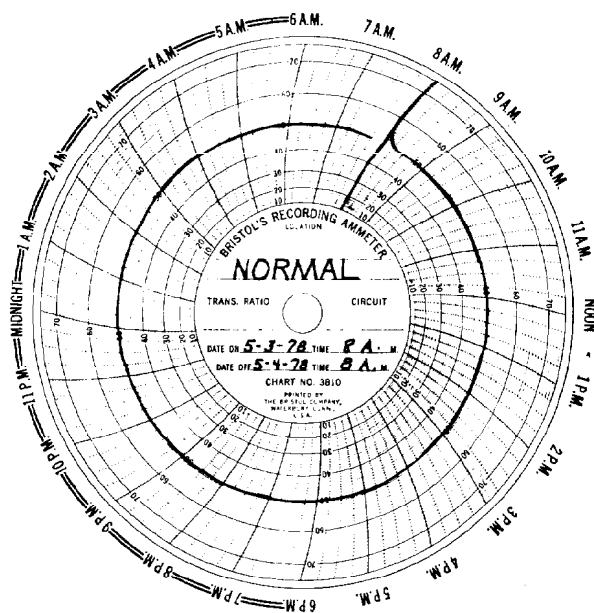

Fig. 7.25—Normal startup chart.

Pulling equipment out of a well involves essentially the reverse process of run-in. The equipment and cable should be handled with the same care as new because they are still valuable. Cable damage and missing bands should be recorded at the depth they occurred to aid in subsequent repair and evaluation. If the equipment failure is judged to be premature, the condition of cable, flat cable, pump rotation, and motor/protector fluid may be useful in determining the cause of the failure.

Troubleshooting

This section outlines a recommendation for identification and solution of typical ESP problems. The only way a failure can be analyzed and its cause determined is by data collection. When a problem occurs you simply cannot have too much information.

Information that should be routinely compiled on each ESP well includes production data (such as water, oil, and gas), run life, unit starts and stops, dynamic and static fluid level, and pump setting and perforation depth. Information also should be obtained on ammeter charts, well conditions (abrasives, corrosives, H_2S etc.), electric power quality (surges, sags, balance, negative sequence voltages, etc.), visual observations of equipment and cable condition on prior pulls, reasons for equipment pull (failure, workover, size change, etc.), and BHT.

When an ESP well is first put on production, data should be collected daily for the first week, weekly for the first month, and a minimum of monthly after the first month. Production data during the first month are very important because they will indicate whether the pump is performing as designed. If a downhole pressure instrument is installed, operating BHP is equally important.

The major source of information when troubleshooting an ESP installation is the recording ammeter. The recording ammeter is a circular strip-chart accessory

mounted in the switchboard that records the amperage drawn by the ESP motor (Fig. 7.13). A number of changes in operating conditions can be diagnosed by interpreting ammeter records. The following addresses ammeter chart "reading" and typical problem situations.

Normal Operation

A normal chart (Fig. 7.24) is smooth, with amperage at or near motor nameplate amperage draw. Actual operation may be either slightly above or below nameplate amperage. However, as long as the curve is symmetric and consistent over time, operation is considered normal.

Normal Startup

A normal startup will produce a chart similar to that shown in Fig. 7.25. The startup "spike" is caused by the inrush surge as the pump comes up to operating speed. The subsequent amperage draw is high but trending toward a normal level. This is principally a result of the fluid level being drawn down to the design TDH, resulting in a high but declining amperage draw.

Power Fluctuations

Operating ESP amperage will vary inversely with voltage. If system voltage fluctuates, the ESP amperage will fluctuate inversely to maintain a constant load (Fig. 7.26). The most common cause of this type of fluctuation is a periodic heavy load on the primary power system. This load usually occurs when starting up another ESP or other large electric motor. Simultaneous startup of several motors should be avoided to minimize the impact on the primary power system. Ammeter spikes also can occur during a thunderstorm that is accompanied by lightning strikes.

Fig. 7.26—Startup spikes chart.

Fig. 7.28—Fluid pumpoff chart.

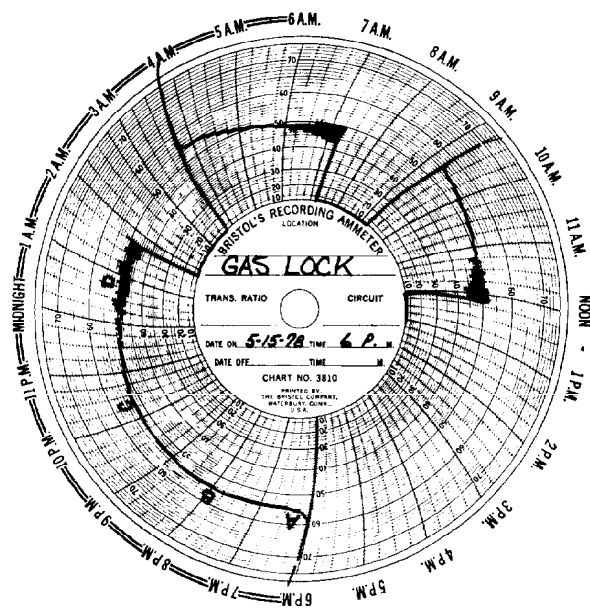

Fig. 7.27—Gas lock chart.

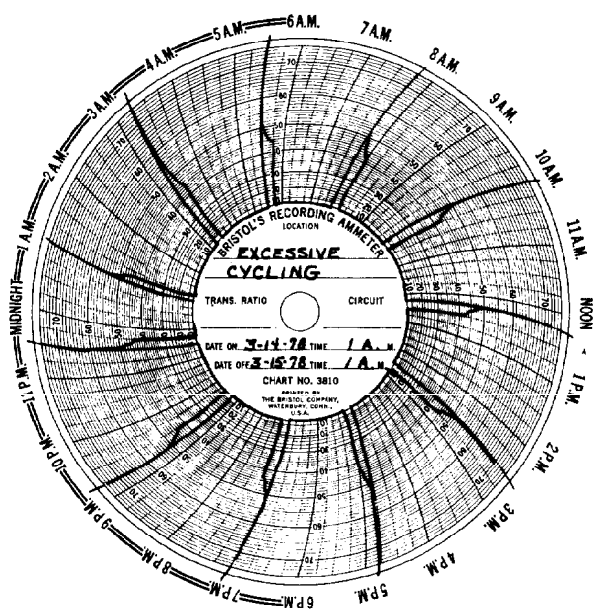

Fig. 7.29—Short duration cycling.

Gas Locking

Gas locking occurs as fluid level drawdown approaches the pump intake and intake pressure is lower than the bubblepoint. This situation is shown in Fig. 7.27. This ammeter chart shows a normal startup and amperage decline as the fluid level is drawn down. However, the chart shows erratic fluctuations as gas breaks out near the pump beginning at approximately 6:15 a.m. As the fluid level continues to draw down, cyclic loading of both free gas and fluid slugs leads to increasingly wider amperage fluctuations, ultimately resulting in shutdown at approximately 7:15 a.m. because of undercurrent loading.

There are three possible remedies for gas locking. The first is to install a gas separator intake and/or a motor shroud. The second is to lower the setting depth of the pump (but not lower than the perforations unless the motor is shrouded). The third remedy is to reduce the production rate of the pump by using a surface choke (but ensure that the production rate remains within the recommended range for that pump). It is entirely possible that none of these solutions is satisfactory. The pump should be replaced with a pump that does not draw down the fluid level or reduce intake pressure below the bubblepoint.

Fig. 7.30—Gassy or emulsion conditions.

Fig. 7.32—Overload shutdown condition.

Fig. 7.31—Debris or solids in a well.

Another possible solution is to add a VSD to the existing system. The VSD controls the speed of the pump, which in turn controls the pump capacity. Thus the pump output can be fine-tuned to protect against pumpoff and gas lock while contributing to improved pump life.

Fluid Pumpoff

Fluid pumpoff occurs typically when an ESP is too large in relation to the inflow capacity of the well. This condition is illustrated in Fig. 7.28. This chart shows a normal startup at 7:00 a.m. and normal operation until approximately 10:00 a.m. Then amperage draw begins to fall

slowly until the underload setting is reached and the pump is shut down about 2:15 p.m. Subsequent automatic restarts at 4:15 p.m. and 8:15 p.m. produce similar results.

The remedial actions are much the same as those listed for gas lock and, in addition, a well stimulation treatment may increase the well's productivity closer to a match with the pump.

In general, cycling an ESP is not conducive to optimal run life. As a temporary measure, the amount of time delay before automatic restart can be increased if the switchboard is equipped with a Redalert motor controller. This may allow the fluid volume to build up to prevent a high frequency of shutdown occurrence. Nevertheless, the pump and well are not compatible and the pump size should be checked on the next changeout or the well worked over to improve productivity.

A form of frequent, short-duration cycling is shown in Fig. 7.29. This shows an extreme pumpoff condition. While the initial reaction is to suspect a badly oversized pump, there may be another cause. If a fluid level sounding, taken immediately after pump shutdown, indicates fluid over the pump, the problem may be a tubing leak or a restricted valve or discharge line. A tubing leak typically is accompanied by a somewhat low discharge pressure and low surface production rate. If shutdown is caused by a plugged valve or discharge line, tubing pressure should be abnormally high.

Gassy Conditions—Emulsion

A gassy but normal producing well is shown in Fig. 7.30. The continuous amperage fluctuations result from alternating free gas and heavy fluid pumping. Generally this condition results in a reduction of stock-tank barrels in relation to pump design rate. This figure is also typical of an emulsion. The amperage fluctuations are caused by the frequent, temporary blockage of the pump intake. If

it is an emulsion block, spikes are normally lower or below the normal amperage line.

Solids and Debris

When debris or solids are found in a well, the amperage will display fluctuations immediately after startup. This condition is shown in Fig. 7.31. Typically when solids such as sand, scale, or weighted mud are found in a well, special care must be taken on startup to avoid pump damage. It may be necessary to put backpressure on the well to prevent excess amperage until the kill fluid is removed and/or sand production begins to decline to a safe volume.

Overload Shutdown

A pump will also automatically shut down in an overload condition. This condition is shown in Fig. 7.32. However, when an overload condition shutdown occurs the unit must not be restarted until the cause of the overload has been identified and corrected. Some motor controller overload-detection circuits contain a built-in time delay, ranging from 1 to 5 seconds at 500% of the set point to 2 to 30 seconds at 200% of the set point. However, they will not automatically restart the unit on an overload condition. A restart attempt in an overload condition can destroy the downhole equipment if the cause of the overload is not identified and corrected first.

The most common causes of an overload condition are increased fluid specific gravity, sand, emulsion, scale, electric power supply problems, worn equipment, and lightning damage.

Chapter 8

Subsurface Sucker-Rod Pumps

James R. Hendrix, OILWELL Div. of U.S. Steel Corp.*

Introduction

The general principles of sucker-rod pumps as used in oil wells are well known. Fundamentally, they consist of the usual simple combination of a cylinder and piston or plunger with a suitable intake valve and discharge valve for displacing the well fluid into the tubing and to the surface. However, the variety of problems encountered in pumping oil wells has resulted in a great number of modifications of this fundamentally simple unit to make it more effective for the various conditions encountered. In general, the pumping of oil wells often presents the widest variety of adverse conditions possible in a single installation of any pumping application. These may include high discharge pressures; low intake pressures; severe abrasive conditions resulting from sand or other solids in suspension; severe corrosive conditions resulting from corrosive gases or salt waters; deposits of lime, salts, or other solids from the water pumped; paraffin deposits from the oil pumped; and the requirement that the pump handle liquids, permanent gases, and condensable vapors under the pressure and temperature conditions existing at the pump. Strong magnetic forces that may interfere with valve action when the valves are made of magnetic material are encountered often, and electrolytic corrosion is likely to occur as a result of using dissimilar materials.

The bores of reciprocating oilwell pumps can range from 1 to 4 $\frac{3}{4}$ in. in diameter. The 4 $\frac{3}{4}$ -in. bore pump has a displacement about 22 $\frac{1}{2}$ times that of the 1-in. pump for a given speed and stroke length. This wide range of pump capacities is necessary to permit selection of the most efficient and economical pumping equipment for all conditions encountered. In many wells it is necessary to pump large volumes of water along with the oil, so the pump must have a capacity several times that indicated by the net oil production.

Subsurface pump bores now standardized by the API

are 1 $\frac{1}{4}$, 1 $\frac{1}{2}$, 1 $\frac{3}{4}$, 2, 2 $\frac{1}{4}$, 2 $\frac{1}{2}$, and 2 $\frac{3}{4}$ in. Stroke lengths range from a few inches to more than 30 ft, and production rates with this type of pump range from a fraction of a barrel per day—with part-time operation—to approximately 3,000 B/D.

There are two broad classifications of pumps operated by sucker rods. The older type is now known as a "tubing pump." This term indicates that the pump barrel is attached directly to the tubing of a pumping well and lowered to the bottom of the well, or to any desired location for pumping, as the tubing is run into the well. The plunger, or traveling valve, of a tubing pump is run in on the lower end of the sucker rods until it contacts the lower-valve (or "standing-valve") assembly. The rods are then raised sufficiently to prevent bumping bottom at the end of the downstroke and connected to a pumping unit, or jack, at the surface.

A more recent development is the "insert" or "rod" pump in which the entire assembly of barrel, traveling valve, plunger, and standing valve is installed with the sucker rods and seated in a special seating nipple, a tubing pump barrel, or other device designed for the purpose. The rod-type pump has the obvious advantage that the entire pump may be removed from the well for repair or replacement, with only a rod-pulling job, whereas with a tubing pump it is necessary to pull both rods and tubing to remove the pump barrel. The rod pump, however, is necessarily of smaller maximum capacity for a given tubing size.

Tubing-type pumps may have a standing valve seated in a coupling or seating shoe at the lower end of the barrel, or the standing valve may be seated in a coupling at the lower end of an "extension nipple" that extends below the lower end of the barrel. The ID of the extension nipple is somewhat larger than that of the barrel to permit the pump plunger to stroke out both top and bottom to produce uniform barrel wear and prevent accumulations of solids on the barrel wall.

*Original chapter in 1962 edition written by Roy L. Chenault.

TABLE 8.1—API PUMP DESIGNATION

Type of Pump	Metal Plunger Pumps		Soft-Packed Plunger Pumps	
	Heavy-Wall Barrel	Thin-Wall Barrel	Heavy-Wall Barrel	Thin-Wall Barrel
Rod				
Stationary barrel, top anchor	RHA	RWA	—	RSA
Stationary barrel, bottom anchor	RHB	RWB	—	RSB
Traveling barrel, bottom anchor	RHT	RWT	—	RST
Tubing	TH	—	TP	—

First letter:

R = Rod or "inserted" type; run on the rods; through tubing
 T = Tubing type; noninserted, run on tubing

Second letter:

H = Heavy-wall; for metal plunger pumps
 W = Thin-wall; for metal plunger pumps
 S = Thin-wall; for soft-packed plunger pumps
 P = Heavy-wall; for soft-packed plunger pumps

Third letter:

A = Top anchor
 B = Bottom anchor
 T = Bottom anchor; with traveling barrel

Rod-type pumps may also be equipped with extension nipples above and below the barrel for similar reasons. In addition, rod pumps may be "top-seating" (pump suspended from top of barrel), "bottom-seating" (pump seated at bottom of barrel), "stationary-barrel" (traveling plunger), or "traveling-barrel."

Both tubing- and rod-type pumps are equipped with one-piece "full barrels."

The API has adopted standard designations for the combinations listed above. The classification system given in Table 8.1 is from API Standard 11AX.¹

The following definitions are provided to clarify some of the more important terms used in connection with subsurface oilwell pumps since a majority of these terms are peculiar to deep-well pumping terminology.

Barrel. The barrel of an oilwell pump is the cylinder into which the well fluid is admitted and displaced by a closely fitted piston or plunger.

Plunger. The pump plunger is a closely fitted tubular piston fitted with a check valve for displacing well fluid from the pump barrel. This may be all metal or equipped with cups, rings, or other soft packing to form a seal with the barrel.

Standing Valve. This is the intake valve of the pump and generally consists of a ball-and-seat-type check valve. The valve assembly remains stationary during the pumping cycle.

Traveling Valve. This is the discharge valve and moves with the plunger of a stationary-barrel pump and with the barrel of a traveling-barrel pump. The entire assembly of a cup-type plunger, or plunger equipped with other type of soft packing, along with the check valve, is often called a "traveling valve."

Standing Valve Puller. This is a tool designed to attach to the standing-valve cage of a tubing-type pump when the sucker rods are lowered to the bottom. The standing-valve assembly is then unseated by raising the rod string and is removed along with the pump plunger

when the rods are pulled. This avoids having to pull tubing to remove the standing valve of the tubing-type pump.

Valve Rod. Valve rods are used in rod-type stationary-barrel pumps to connect the lower end of the sucker-rod string to the pump plunger. The valve rod runs through a guide at the top of the pump. API valve-rod sizes range from $1/16$ to $1 1/16$ in. in diameter. Modified line pipe threads are standard for API valve rods (see Table 1 of Ref. 1).

Pull Tube. Pull tubes are used in rod-type traveling barrel pumps to connect the plunger with the seating assembly or "holddown." (See Ref. 1 for thread dimensions for straight threads.) Tapered threads are used on some sizes of pull tubes by some manufacturers.

Seating Assembly. A seating assembly is an anchoring device for retaining a rod pump in its working position. The seating assembly is sometimes more commonly called a "holddown." The seating assembly may be located either at the top or bottom of a stationary-barrel rod pump but can be located only at the bottom of a traveling-barrel pump. A seating assembly may be equipped with composition cups or rings that form a tight fit in a seating nipple, or coupling, to hold the pump in its working position by friction, or it may be provided with spring clips that snap into position under a shoulder and require a definite pull upward on the rods to unlatch for removal. With the cup-type seating assembly, the cups or rings also serve as a seal to prevent leakage of fluid from the tubing back to the well after it has passed through the pump. With the mechanical seating assembly, an accurately ground seating ring fitted on a tapered mandrel seats on a mating taper to form a leakproof seal.

Pump Selection

The selection of a proper subsurface pump for the application is sometimes a point of conjecture. The following recommendations generally are accepted as suitable for most applications. Fig. 8.1 shows cross sections of

Fig. 8.1—API subsurface pump classification.

API pump classifications. There are many variations of the pumps shown, some within the specifications of API and some that are non-API that will still perform the desired function of pumping oil to the surface.

Fig. 8.1a shows a stationary-barrel rod pump with top-seating holddown. This is a pump that is run into the well with the sucker rods. In this pump the plunger is attached to, and moves up and down with, the sucker-rod string. The barrel is held stationary at its top end by the seating assembly. The barrel is on the left and the plunger assembly is on the right. This is the preferred seating for the rod pump when possible. The top seating holddown provides a seal just below the cage, where the well fluid is discharged into the tubing, so sand or other solid particles are prevented from settling between the barrel and the tubing, and the pump is not apt to become stuck in the tubing by packed sand. Since the body of the pump pivots from this top-seating arrangement, it aligns itself in crooked wells more readily than other types of pumps. Also, there is no tendency for the barrel to wear by rubbing against the tubing. This type of pump can handle low-gravity crude oil down to 400 cp quite well. In the stripper wells and in wells with low fluid levels, the top-seating design of the pump allows the standing valve to be submerged deep into the well fluid. This makes it

possible to pump the oil level lower than can be done with a bottom-seated pump. This is a particular advantage when the fluid flow from the oil reservoir is weak.

Fig. 8.1b shows a stationary-barrel rod pump with bottom-seating holddown. In this pump, the plunger is also attached to, and moves up and down with, the sucker-rod string. The barrel, on the left, is held stationary by a bottom-seating holddown, either mechanical lock or cup type, which is the type shown in the figure. This pump is more suitable for use in the deeper wells since the barrel does not elongate from the fluid column weight of the fluid in the tubing. Since the body of the pump pivots from its bottom-seating arrangement, it too can be used in crooked wells. However, there is a tendency for the valve rod to wear against the upper rod guide in this case. This pump also can handle low-gravity crude oil down to 400 cp quite well. Because of its bottom-seating arrangement, the pump can be seated easily in an old existing tubing pump barrel without pulling the tubing, where a top-seated rod pump might be too long to pass through an old tubing barrel.

The main disadvantage of this type of pump is that the pump barrel extends upward into the tubing. This makes it inadvisable to use a long pump, since it is not anchored at the top, and the action of the sucker-rod string will

Fig. 8.2—Plain (a) and grooved (b) metal-to-metal plungers.

tend to weave it back and forth, which may cause premature failure. Also, this pump is not recommended for extremely sandy conditions, because there is no circulation of the well fluid around the outside of the barrel. For this reason, the pump may become stuck in the tubing by packed sand.

Fig. 8.1c shows a traveling-barrel rod pump. Many operators prefer this type of pump because of its simplicity and because its construction also relieves the pump barrel of a tension load resulting from the weight of the fluid column. A theoretical advantage of this type of pump is that the pressure differential across the plunger is such that the high pressure is on the bottom of the plunger on the intake stroke and the direction of leakage, or slippage, past the plunger is opposite to the direction of the force of gravity, which tends to cause sand to settle on the plunger. For this reason there is less tendency for sand to be forced into the clearance space between the plunger and barrel and accelerate wear. Although the traveling-barrel rod pump is bottom seated, it is not so likely to become sanded in the tubing as is a bottom-seated stationary-barrel rod pump since there is a continual surging of the well fluid in and out of the lower end of the barrel while in operation. Also, the construction of this pump is such that sand cannot settle into the barrel when the pump is shut down. A disadvantage of the traveling-barrel rod pump is the long and somewhat restricted inlet for oil to be admitted to the pump barrel. This may result in a relatively high pressure drop through the "pull tube" and plunger to liberate excessive quantities of free gas or to cause the formation of condensable vapors that will adversely affect the volumetric efficiency of the pump.

Some suppliers offer a combination top-seal and bottom-seating stationary-barrel rod pump. While this pump is considered "nonstandard," it combines the advantages of top-seating and bottom-seating pumps. It is particularly advantageous when a long pump is required in a deep well. This type of pump reduces the possibility of a collapsed barrel caused by external pressure and reduces sedimentation around the barrel tube. Because of additional sealing arrangements, this pump is more costly than standard API pumps.

Fig. 8.1d shows the tubing pump, so named because its barrel assembly, including barrel, extension nipples (if any), and seating nipple, is screwed onto, and becomes a part of, the tubing. Since the tubing and barrel assembly are lowered into the well together, it is easy to position a tubing pump at any desired depth for pumping. After the barrel assembly is in position, the standing-valve assembly is placed in the tubing, and it falls until it is stopped and held by the seating shoe. The plunger can be lowered into the well by attaching it to the sucker-rod string or by lowering it with the barrel assembly. In the latter case, an "off-and-on" attachment is used to connect the sucker rods to the plunger. Another device, called a "standing-valve-puller" (see Fig. 8.1d insert), can be attached to the plunger to hold the standing-valve assembly, so both can be lowered together. The standing-valve assembly is released from the standing-valve puller by turning the sucker-rod string; so the standing valve assembly remains in place, held by the seating nipple. If this action is reversed, the standing-valve assembly can be attached to the plunger and pulled out of the well with the sucker-rod string. This eliminates the necessity of pulling the complete tubing string to replace the standing-valve assembly. Another advantage of using a standing-valve puller is that the standing-valve assembly is not in danger of being damaged or becoming stuck, as is possible if it is dropped through the tubing.

Tubing pumps have larger bores and correspondingly greater displacements for a given stroke length than rod pumps that can be used with the same size tubing. Therefore, tubing pumps commonly are used where it is necessary to lift large volumes of fluid and a pump of high displacement is required. A tubing pump has fewer working parts and is often lower in cost than a rod pump of corresponding size. However, the greater volume and resulting heavier fluid load may cause a loss in this advantage by excessive sucker rod and tubing stretch. Also, the entire tubing string must be pulled to service the barrel of a tubing pump.

Plungers

Fig. 8.2 illustrates the two most common types of "metal-to-metal" plungers used for displacing well fluid in oilwell pumps. The left side shows a plain plunger with "box-end" threads. This type of plunger generally is finished somewhat undersize at each end opposite the threads. This provides for the slight expansion of the plunger when tightened, without causing binding of the plunger in the pump barrel. The right side shows a grooved "pin-end" plunger.

Most subsurface-pump manufacturers provide both plain and grooved plungers in various materials. It has never been demonstrated conclusively that either type of

*48 in. long with 2,000 psi differential pressure and various plunger fits. Also slippage in percent pump displacement with fifteen 48-in. strokes per minute.

construction has any particular advantage over the other. Many operators feel that grooves facilitate lubrication of closely fitted plungers by providing spaces for the well fluid to accumulate in considerable quantities. However, there is considerable slippage past any plunger operating under usual conditions where the differential pressure across the plunger is several hundred or even thousands of pounds per square inch. This slippage will provide adequate lubrication with either type of plunger if the fluid has any lubricating value. One possible advantage of a grooved plunger is that any solid particle, such as a sand grain or a steel chip that gets between the plunger and the barrel, may become lodged in a groove and minimize scoring of the barrel and plunger. With a plain plunger, particles cannot escape from the finished surfaces until they have traveled the full length of the plunger. On the other hand, a grooved plunger stroking out of a barrel increases the probability of picking up and carrying solid material into the barrel.

The high differential pressures encountered in pumping deep wells require an effective sealing or packing means on the plunger. For wells of extreme depth, a closely fitted metallic plunger is almost always used to form a satisfactory seal with the barrel. Such plungers are commonly supplied with nominal clearances of 0.001, 0.002, 0.003, or 0.005 in. in the barrel. Such plunger fits are commonly referred to as -1, -2, -3, or -5 fits. For metal-to-metal pumps the API tolerance for barrels is +0.002 in., -0.000 in., and the tolerance for plungers is +0.0000 in., -0.0005 in., making it possible for the fit of a -1 plunger, for example, to vary from 0.0010 to 0.0035 in. diametral clearance.

Slippage Past Plungers

In slippage past a closely fitted plunger, the flow between the plunger and the barrel is in the viscous range, so leakage or slippage is inversely proportional to the absolute viscosity and to the plunger length. It is directly proportional to the plunger diameter, the differential pressure between the two ends of the plunger, and the cube of the diametral clearance.

The absolute viscosity of well fluids commonly pumped will range from approximately 1 to 100 cp at temperatures existing at the pump setting. In some cases the viscosity may be as high as 1,000 cp. As a result of viscosity variations, the slippage past the plunger of a particular plunger-pump assembly with a given plunger fit, length, and diameter may vary by as much as 100 to 1 under fairly common conditions, and as much as 1,000 to 1 under extreme conditions with the same differential

pressure across the plunger. Thus it is seen that a plunger pump may operate with acceptable efficiency in a well producing a highly viscous oil, whereas the same pump operated at the same speed and stroke may fail to deliver any oil to the surface when installed at the same depth in a well producing oil of low viscosity.

The following equation can be used to determine slippage losses past a pump plunger with sufficient accuracy for most purposes.

$$q = \frac{\pi d \Delta p \Delta d_c^3}{\mu L \times 2.32 \times 10^{-7}}, \dots \dots \dots (1)$$

where

q = slippage loss, cu in./min (or 0.2371 cm³/s),

d = plunger diameter, in.,

Δp = differential pressure across plunger, psi,

Δd_c = diametral clearance, in.,

L = length of plunger, in., and

μ = absolute viscosity, cp.

A specific application of this equation will illustrate the importance of plunger fits for a pump of a particular bore and stroke, operating with various plunger fits in fluids of various viscosities.

If we assume a 2¼-in.-bore pump having a 0.003-in. diametral clearance and operating with a pressure differential of 2,000 psi between the two ends of a 48-in. plunger at a rate of fifteen 48-in. strokes per minute in oil having a viscosity of 3 cp, then Eq. 1 becomes

$$q = \frac{\pi \times 2.25 \times 2,000 \times 2.7 \times 10^{-8}}{3 \times 48 \times 2.32 \times 10^{-7}} = 11.43 \text{ cu in./min.}$$

If we assume that the volume of the barrel below the plunger is completely filled during the upstroke, this rate of leakage can occur only during the upstroke, or approximately one-half of the total time. The net slippage past the plunger is 5.72 cu in./min, or 0.85 B/D. The displacement of a 2¼-in. pump operating at fifteen 48-in. strokes per minute is 426 B/D, and the slippage in this case is only about 0.2%, which is insignificant. The results of this and other plunger clearances with 3-cp oil are shown in Table 8.2.

In the case of 0.020-in. plunger clearance, the slippage loss when water or oil with a viscosity of 1 cp is pumped would be 755 B/D, which is more than the pump displacement, and it would be impossible to pump water

to the surface, or to a level requiring 2,000-psi pressure differential across the plunger. When pumping oil with a viscosity of 100 cp, however, the slippage would be only about 7.5 B/D, or less than 1.8% of the pump displacement, and a clearance of 0.020 in. is reasonably satisfactory for these conditions.

Slippage losses result directly in power losses, since the same power is required to lift the plunger, with 90% of the fluid slipping past the plunger during the upstroke as is required with 1% or less slippage. The energy dissipated in slippage losses results in an increase in temperature of the oil within the pump and a decrease in viscosity that further increases slippage losses. Also, when water is produced with oil, excessive slippage losses increase the chances of forming emulsions.

Close plunger clearances are relatively more important with small-bore pumps than with larger bores, inasmuch as the displacement for a given stroke length and speed varies as the square of the diameter, whereas slippage varies as the first power of the diameter. Close plunger clearances are especially important in small pumps

operated at extremely low speeds, as used in stripper wells in some areas. The method outlined here should be satisfactory for evaluating maximum slippage in most cases.

Soft-Packed Plungers

Fig. 8.3 shows the cup- and ring-type plungers. The left side shows composition-formed cups used to seal the plunger against the barrel. The right side shows composition rings (generally square or rectangular in shape) used for sealing. Some operators prefer a combination of both cups and rings on a single plunger. The applications of such soft-packing arrangements generally are limited to shallow wells and to those where abrasive conditions are not excessively severe. Where this type of plunger is satisfactory, it has the advantage of being easily and less expensively reconditioned with new cups or rings, and the flexible packing will compensate for considerable wear of the barrel as long as the barrel surface remains smooth.

Fig. 8.3—Soft-packed plungers: (a) cup type; (b) ring type.

Balls and Seats

Fig. 8.4 illustrates the type of ball-and-seat combination commonly used for check valves in subsurface pumps. Balls and seats are made in a variety of materials to resist extremely abrasive and corrosive conditions. API Standard 11AX¹ lists the important dimensions of standard sizes along with the pump sizes with which they are commonly used.

Double Valves

Fig. 8.5 shows common arrangements of two valves in series used both as traveling valves and as standing valves. Experience has shown that two valves in series will give much longer service than a single valve if the valve life is determined by wear or fluid cutting, rather than by corrosive action. This result appears entirely logical where sand or other solid material is lifted with the oil. In such cases failure is likely to occur as a result of fluid cutting when a solid particle is caught between the ball and seat and prevents perfect seating. A pressure differential of 2,000 psi will produce a jet of fluid having a velocity of over 500 ft/sec, which can easily damage

Fig. 8.4—Pump valve ball and seat.

Fig. 8.5—Double-valve arrangements.

Fig. 8.6—Bottom-discharge valve for use with bottom-seating stationary-barrel rod pumps. This valve is attached to the bottom of a pump and through it part of the well fluid is diverted up the side of the pump to help dislodge sand that may have settled between the pump and the tubing.

the lapped valve-seating surface on balls and seats in a short time. The rate of damage is accelerated if the fluid jet carries solid material in suspension.

The life of a ball and seat will depend largely on the number of times it is subjected to damage by fluid jets. By use of double valves this can be greatly decreased, since a jet cannot occur until both balls are held off their seats during the same stroke. For example, if conditions are such that a single ball and seat is prevented from seating properly once out of each 100 strokes, the chances of both valves in series failing to seat properly will be reduced to 1 in 10,000 strokes. Furthermore, if the two valves fail to seat, the pressure drop will be distributed between the two valves and the cutting action will be less severe than with a single valve.

Bottom-Discharge Valve

The bottom-discharge valve shown in Fig. 8.6 is used in connection with bottom-seating stationary-barrel rod pumps and is designed to cause part of the fluid discharged from the pump to circulate up around the outside

Fig. 8.7—Top seal and bottom seating for stationary-barrel rod pumps.

of the pump barrel. This is done to prevent sand from settling around the pump, which may make it impossible to pull the pump on the sucker rods. The bottom-seating arrangement for a rod-type pump is desirable in wells of extreme depth since the pump barrel is relieved of the fluid load, which places the barrel in tension. When top seating is used, the barrel is subjected to a high pressure which tends to expand the barrel.

Fig. 8.7 illustrates another means for utilizing the advantages of bottom seating with a stationary-barrel rod pump and preventing sand from settling around the outside of the pump barrel. This assembly utilizes a mechanical bottom-seating assembly, with seating cups or rings that fit into a slightly restricted seating nipple, properly spaced in the tubing to form a seal at the top of the pump barrel.

Three-Tube Pump

This type of pump is illustrated in Fig. 8.8 and gets its name from the three tubes used in its construction. The complete pump assembly is lowered into the well on the

sucker-rod string and is positioned in the well by contacting either a cup-seating assembly or a mechanical lock holddown. The middle tube of the pump is stationary, attached to the holddown. The other two tubes attached to the sucker-rod string move over the middle stationary tube, one on the outside and one on the inside. The tubes used in this pump are relatively long and have a relatively large operating clearance in comparison with the usual pump plunger. The resistance to flow between the tubes is adequate to create the seal necessary to displace the fluid past the standing valve and through the traveling valve against the tubing pressure. This pump is designed primarily to clean out wells after workover operations or formation-fracturing operations, which may make the well produce large quantities of sand for a considerable time. It is also used in wells producing from loose-sand formations that consistently produce quantities of fine floating sand.

Gas Anchors

Where conditions are such that there is considerable free gas in the well fluid at the pump intake, it is desirable to prevent as much gas as possible from entering the pump and permit the gas to rise to the surface through the casing annulus rather than through the tubing. Numerous so-called gas anchors are in use that are designed to separate the free gas and deflect it up the casing annulus. Fig. 8.9 illustrates a common type of gas-anchor arrangement in which the well fluid must enter the perforated nipple and circulate downward at a low velocity before entering the gas-anchor tube, which is attached to the pump intake. This gives the free gas an opportunity to separate and rise to the uppermost ports in the perforated nipple where it may return to the casing. A large portion of the gas will rise through the casing before passing through the perforated nipple.

Special Pumps

There are many other special types of subsurface pumps for use in special problem situations. Most of these are considered "non-API" pumps, although they may use some parts that meet API specifications in their construction. One special pump is the casing pump, which is designed to be inserted directly into the casing without a string of tubing. Such pumps are set in the casing on a packer or casing anchor that grips the casing and holds the pump in position. Such pumps are limited in size only by the casing size and can be made to have a very large capacity in relatively shallow wells. However, with this arrangement, all the gas produced with the well fluid must pass through the pump, and this may seriously limit the effective capacity in wells producing large quantities of gas.

Another special type of pump that is used to some extent is an arrangement where two displacing plungers are designed to act in series. This increases the displacement of a pump that will run in a given size of tubing and at a given stroke length. Another variation of this concept uses two valves and seats in the lower plunger and none in the upper plunger. This allows a fluid load on the lower plunger at all times and assists the sucker rods in falling on the downstroke, which is desirable for the more viscous fluids.

Fig. 8.8—Three-tube pump. Fig. 8.9—Gas-anchor arrangement.

Fluids with large amounts of gas can cause gas locking or at least reduced flow because of expansion of gas in the chamber between the plunger and the standing valve on the upstroke. This situation can sometimes be relieved by a special pump having two so-called compression chambers that serve to increase the compression ratio in those chambers above that normally obtainable in a standard pump.

Corrosion

In some areas resistance to corrosion of the materials used in subsurface pumps is of major importance. A wide variety of alloy irons, steels, nonferrous alloys, and elements have been used to combat corrosive conditions

in various locations. Some of the corrosive agents commonly found in various locations are hydrogen sulfide, carbon dioxide, salt waters containing sodium chloride, calcium chloride, magnesium chloride, and other salts. Chemical corrosion inhibitors are now widely used by many operators. Such inhibitors are fed either continuously or intermittently down the casing into the well. Protective films are formed on the tubing and rods, as well as on pump parts. However, since protective films cannot form on wearing surfaces, the closely fitted pump parts in rubbing contact are not protected as well as the rods and tubing by corrosion inhibitors. For this reason it is more important to use corrosion-resistant materials in the construction of subsurface pumps.

Effect of Gases and Vapors

In selecting pumping equipment for oil wells remember that in a majority of cases some of the constituents of the fluid being pumped are above or near their boiling points at the pressure and temperature conditions existing within the pump. These conditions may cause release of large volumes of dissolved gases and vapors with a slight drop in pressure of the well fluid, in addition to the free gas initially in the fluid. For this reason it is very difficult to pump some wells down. Many wells apparently will pump off with several hundred feet of fluid standing in the hole because the condensable vapors and gases occupy the entire displacement volume of the pump. Under these conditions, without a relatively high intake pressure, which decreases compression ratio, the pressure below the plunger cannot be raised to the tubing pressure. (This is necessary before the traveling valve can open and deliver oil to the tubing.) On the downstroke the vapors may condense and occupy a very small volume without an appreciable increase in pressure, and only the permanent gases are effective in increasing the pressure in accordance with the gas laws.

There are two precautions to take to minimize the adverse effects of vapors and gases.

1. The compression ratio should be made as high as possible. This is accomplished by using a closed-cage-type valve below the plunger with a stationary-barrel pump, or a valve above the plunger with a traveling-barrel-type pump. It is also important to space the pump so the traveling valve and standing valve come as near to each other as possible at the lowest position of the rods without making contact, and to use as long a stroke as possible with the equipment available.

2. Flow velocities and turbulence at the pump inlet should be kept at a minimum. This is accomplished by using the largest standing valve possible and a suitable gas anchor with the largest possible flow passages.

Conclusions

Most items covered in this section are discussed in Ref. 2, which was first issued in 1968 and is updated regularly. It is recommended that this source be referred to for state-of-the-art information about subsurface pumps.

It is well known that because of the dynamics involved in the sucker-rod string, the fluid, and the tubing during pumping cycles, the plunger stroke of the subsurface pump is seldom equal to the stroke of the pumping unit and its accompanying polished rod at the top of the well. During pump operation the fluid load, which is alternately transferred from the tubing to the sucker rods, causes the tubing to increase in length on the downstroke when the tubing is supporting the fluid load. When the rods are carrying the load on the upstroke, there is a shortening of the tubing with an increase in the length of the sucker rods. Both effects tend to shorten the plunger stroke in the well in comparison with the polished-rod stroke at the surface.

Because of the dynamic effects and the inertia and elasticity of a string of sucker rods, there will be some additional stretch in the rods during the pumping stroke. This effect is known as overtravel and results in an increase in the stroke length at the subsurface pump.

In years past, the calculation of sucker-rod and tubing stretch, as well as overtravel, was accomplished with a rather simple set of equations using tables and curves developed for this purpose. Later it was recognized that there are many factors in a pumping well that make the calculations a complex problem. In 1954 a group of users and manufacturers of sucker-rod pumping equipment formed Sucker Rod Pumping Research Inc., a non-profit organization, to study the problems of pumping wells. They in turn retained Midwest Research Inst. of Kansas City to achieve their objectives. Their study covered several hundred pumping wells and resulted in design calculation methods that more nearly match actual pumping conditions than previous methods. The results of the study were turned over to the API Production Dept. The API in turn adopted these methods.³ These design calculations are too involved and lengthy to be included in this section. It is suggested that Ref. 3 be used to determine the design values of a pumping system.

Chapter 9

Sucker Rods

Dean E. Hermanson, LTV Energy Products Co.*

Introduction

A sucker rod is the connecting link between the surface pumping unit and the subsurface pump, which is located at or near the bottom of the oil well. The vertical motion of the surface pumping unit is transferred to the subsurface pump by the sucker rods.

Two types of sucker rods are in use today—steel rods and fiberglass-reinforced plastic sucker rods. It is estimated that slightly less than 90% of the rods sold in 1985 were steel rods, while slightly more than 10% were fiberglass rods.

Steel rods are manufactured in lengths of 25 or 30 ft. Fiberglass rods are supplied in 37½- or 30-ft lengths. Both types of rods are connected by a 4-in.-long coupling. The pin ends of the sucker rod are threaded into the internal threads of the coupling, as illustrated in Fig. 9.1. Individual rods are connected to form rod strings that can vary in length from a few hundred feet for shallow wells to more than 10,000 ft for deeper wells.

Sucker rods were originally made from long wooden poles with steel ends bolted to the wooden rod. An improvement was to use steel instead of wood and to forge the upset end on the steel rod. Forging the end generates a heat transfer zone by the upset, which is susceptible to corrosion attack. Full-length heat treating of the steel rod eliminated this problem. While the general geometry of the steel rod has remained relatively unchanged, improvements in surface finish, surface condition, end straightness, metallurgy, and quality control have been responsible for increased performance.

API Spec. 11B details information—such as workmanship and finish, material grades, dimensions, and gauging practice—on sucker rods (pony and polished rods and couplings and subcouplings).

The general dimensions for a sucker rod published by API¹ are listed in Table 9.1 and Fig. 9.2.

The general dimensions for sucker rod couplings are listed in Tables 9.2 and 9.3 and Fig. 9.3. At the present time, there is one grade of couplings, API Grade T. This coupling has a hardness designation of 16 minimum and 23 maximum on the Rockwell C scale. The hardness is controlled to provide resistance to embrittlement by H₂S and to provide a minimum strength level.

API has specified three grades of rods; their chemical and mechanical properties are listed in Table 9.4. The industry typically supplies sucker rods to the various categories, as listed in Tables 9.5 and 9.6. Other chemistries and types of rods are also available for special application.

Steel Sucker Rods

Manufacture of Sucker Rods

One-Piece Steel Sucker Rods. One-piece steel sucker rods are manufactured from hot-rolled steel finished with a special quality surface. The surface finish of the rod is very important, because rods fail prematurely as a result of discontinuities on the surface. These discontinuities can cause stress concentration that results in fatigue cracks.

The first operation in manufacturing a sucker rod is straightening the rod. In the second operation, the end of the rod is heated to about 2,250°F, and the lower bead, wrench square, pin shoulder, and pin are upset forged. The next operation is full-length heat treating. Heat treating develops the desired physical properties in the rod and provides a uniform surface structure to minimize corrosion. The type of heat treatment depends on the chemistry of the rod and the desired physical properties. Normalizing, normalizing and tempering, quenching and tempering, and surface hardening are heat treatments in use today.

*Author of the original chapter on this topic in the 1962 edition was Walter H. Ritterbusch Jr.

Fig. 9.1—Steel sucker rod and coupling connection.

After heat treatment, the rods are shot cleaned to remove scale. Any scale left on the rod provides the opportunity for a corrosion cell to begin. The pin ends of the rod are then machined and roll threaded. Roll threading puts the root of the pin thread in compression and hence increases the fatigue life.

The final operations are inspection, painting, and packaging. Most manufacturers protect steel sucker rods with an oil-soluble paint combined with a corrosion inhibitor.

Three-Piece Steel Sucker Rods. The three-piece sucker rod differs from a solid one-piece sucker rod in that the upset configuration is machined from a separate piece rather than integrally upset with the rod body as in a one-piece rod. The rod body of a three-piece rod is generally manufactured from cold drawn steel. The rod is threaded and screwed into the machined metal end connectors. The threads are usually joined by an adhesive. Their primary use has been in shallow wells.

Application

The selection of the size and grade of sucker rods depends on the rod stress and well conditions. The rod stress, in turn, depends on several variables—the amount of production required; the size of the tubing, which can influence the diameter of the pump, couplings, and rods; and the pumping unit, which will determine the surface stroke length. Generally, to determine rod stresses for a given well, the following information must be either known or approximated: fluid level, the net lift (in feet), pump depth (in feet), surface stroke length (in inches), pump plunger diameter (in inches), specific gravity of the fluid, nominal tubing diameter (in inches) and whether the tubing is anchored, pumping speed (in strokes per minute), sucker rod size(s) and design, and pumping-unit geometry.

With this information, the following can be calculated: plunger stroke (in inches), pump displacement (in barrels per day), peak polished rod load (in pounds force), minimum polished rod load (in pounds force), peak crank torque (in pounds force-inches), polished rod horsepower, and counterweight required (in pounds force).

Predictive Calculations

The method to perform these calculations is detailed in API RP11L.² This method was developed by simulating the sucker rod pumping system with an analog computer to resolve the many complex variables associated with a rod pumping system. API RP11L is a more reliable performance-predictive method than the previously available simplified equations. Remember that the API method, along with other methods, yields predictive performance results for typical wells.

†The length of box-and-pin rods shall be measured from contact face of pin shoulder to contact face of box.

‡Dimensions d_b , r_a , and r_c became mandatory dimensions on June 20, 1986. Before this, d_b was not to exceed d_{pb} .

Well conditions—such as slanted or crooked holes, which result in excessive well friction, and viscous fluid, which results in abnormal loads, excessive sand production, large amounts of gas production through the pump, and wells that flow off—will result in actual performance that differs from predictive performance. API RP11L was developed to predict the performance of API-designated steel-only sucker rod strings with conventional-geometry surface pumping units and medium-slip motors. Enhancements available from various manufacturers include high-slip motors, advanced pumping unit geometry, and non-API sucker rod string design.

A FORTRAN source code listing for the API design calculations can be obtained from the Dallas API office.

In addition to the API program for predicting performance, proprietary mathematical solutions using partial-differential equations are solved by numerical methods with the aid of computers. These mathematical model solutions using the wave equation are flexible and can also be used for solving fiberglass rod calculations by changing the modulus of elasticity of the input file. These programs are available for installation and use on personal computers.

API also publishes API Bull. 11L3³ for those who (1) do not have access to a computer with either the API program or a proprietary wave equation predictive program and (2) wish to avoid the tedious manual calculation of API RP11L. This design book lists a grid of conditions that have been calculated on a computer with the API RP11L method, and the results are tabulated. Pump depth varies from 2,000 to 12,000 ft in 500-ft increments. Various production rates are tabulated with different rod strings. An application can then be selected from the various pump diameters, stroke lengths, strokes per minute, peak and minimum polished rod loads, stresses, peak torques, and peak polished rod horsepower that are listed. In general, the smallest pump diameter—consistent with a reasonable cycle rate—that will achieve the desired production is the proper choice. This should result in the lightest fluid load and rod string, which, in turn, will require smaller surface equipment.

Another general rule of thumb is to use the longest stroke length and slowest cycle rate to achieve the production. The longer stroke length minimizes the effect of rod stretch, and the slower cycle rate generally minimizes the dynamic effects. A comparison of several trial calcu-

lations or a review of the tabulated answers in API Bull. 11L3³ will give a basis for final selection of pumping parameters. The analog computer study, which resulted in the API design calculations, did not denote any significant effects, such as increased loads, in pumping at so-called synchronous pumping speeds. The damping effects of the well system apparently nullify any theoretical loading increase.

The maximum practical pumping speed is limited by the fall of the sucker rods. It is advisable to maintain a minimum load of several hundred pounds so that the polished rod clamp does not separate from the carrier bar on the downstroke. Extraneous loads can work against free fall of the rod string. Crooked holes and viscous fluid both retard the fall of rods, thus making the minimum load less than anticipated. Fig. 9.4 can be used to approximate the maximum practical pumping speed for a given stroke length with a conventional pumping unit. The actual maximum pumping speed will depend on the well conditions and the geometry of the pumping unit. A pumping unit with a faster downstroke than upstroke will have a lower maximum permissible speed than a conventional unit.

TABLE 9.4—CHEMICAL AND MECHANICAL PROPERTIES

Grade	Chemical Composition	Tensile Strength, psi	
		Minimum	Maximum
K	AISI 46XX	85,000	115,000
C	AISI 1536*	90,000	115,000
D	Carbon or alloy**	115,000	140,000

*Generally manufactured from, but not restricted to, American Iron and Steel Inst. 1536.

**Any composition that can be effectively heat-treated to the minimum ultimate tensile strength.

The various rod string designs for given plunger diameters are listed in Table 9.7. Use of these percentages results in the stress in the top rod of each rod size being approximately equal.

Allowable Loading

The selection of a sucker rod's size and grade depends on the allowable stress and the well conditions. After the minimum and maximum stresses for the application are determined, the permissible stress is determined from the API modified Goodman diagram (see Fig. 9.5). For a given minimum stress, the maximum allowable stress can be determined from a graph of the API modified Goodman diagram for the particular rod in question or from the equivalent mathematical equation.

Example Problem 1. Assume that the minimum stress of an application is 15,000 psi [103 N/mm²]. Determine the maximum allowable stress for a Grade C rod that has a minimum tensile stress of 90,000 psi [620 N/mm²] and a service factor, F_s , of 1:

$$\begin{aligned}
 \sigma_a &= (0.25\sigma_T + 0.5625\sigma_{\min})F_s \\
 &= [0.25(90,000) + 0.5625(15,000)]1.0 \\
 &= 30,938 \text{ psi.}
 \end{aligned}$$

The application stress should be below 30,938 psi to be within the guidelines recommended by API. The diagram is not a failure diagram but is an operating diagram. The API Goodman diagram has been modified by a safety factor of 2 for the left side of the diagram and a safety factor of 1.75 for the higher portion of the diagram.

TABLE 9.5—TYPICAL SUCKER ROD CHEMISTRIES

Steel Type	C	Mn	P	S	Si	Ni	Cr	Mo	Other
API Grade K (Nickel/molybdenum)	4621	0.18 to 0.23	0.79 to 0.90	0.04	0.05	0.20 to 0.35	1.65 to 2.00	0.20 to 0.30	
API Grade C (Carbon steel)	1536	0.30 to 0.37	1.20 to 1.50	0.04	0.05	0.15 to 0.30			
API Grade D (Chrome/molybdenum)	4142	0.39 to 0.46	0.65 to 1.10	0.04	0.04	0.20 to 0.30	0.75 to 1.20	0.20 to 0.30	
API Grade D (Special alloy)	Special	0.17 to 0.22	0.80 to 1.00	0.035	0.04	0.15 to 0.30	0.90 to 1.20	0.80 to 1.05	0.20 to 0.30 0.02 to 0.03 V 0.40 to 0.60 Cu

*Maximum values.

Service Factor

The effects of corrosion and corrosion pits serve as stress raisers on the body of the rod. The effect can vary widely, and if well history does not indicate the service factor to be used, the following downward adjustments are recommended: reduce H_2S from 0.85 to 0.60, CO_2 from 0.90 to 0.70, and salt water from 0.90 to 0.80.

Some trial and error may be necessary for final selection. An effective corrosion-inhibition program should be implemented, if possible.

The limiting factor in rod string design is considered to be the rod body. The slim-hole coupling can be a limiting factor because of the reduced coupling cross-sectional area combined with the stress concentration factor of the thread. Slim-hole-coupling derating factors have been developed for use with the API modified Goodman diagram and are listed in Table 9.8. This F_d factor can be used in the same manner as the service factor—i.e., if Grade D $\frac{7}{8}$ -in. rods are used with $\frac{7}{8}$ -in. slim-hole couplings in $2\frac{3}{8}$ -in. tubing, multiply the allowable rod-body stress from the API modified Goodman diagram by the slim-hole coupling derating factor, F_d , of 0.690.

Rod Grades

The selection of which grade of rod to use should be made according to these guidelines. The lowest-cost rod is a Grade C rod, and its applicability should be checked first. The API Grade D rod (chrome moly) should be analyzed next. Other grades of rods contain various alloying elements. These alloying elements are not added in the quantity necessary to make a rod truly corrosion resistant, as the 18% chromium/8% nickel corrosion-resistant trim does on a valve. Experience has shown, however, that these relatively small alloy additions can have a positive

Fig. 9.4—Maximum practical pumping speed (conventional unit).

TABLE 9.6—TYPICAL SUCKER ROD MECHANICAL PROPERTIES

	Yield Strength (1,000 psi)	Tensile Strength (1,000 psi)	Elongation 8 in. (%)	Reduction of Area (%)	Brinell Hardness
API Grade K (nickel/molybdenum)	68 to 80	85 to 100	18 to 25	60 to 70	175 to 207
API Grade C (carbon steel)	60 to 75	90 to 105	18 to 25	55 to 66	187 to 217
API Grade D (chrome/molybdenum)	95 to 110	115 to 135	10 to 13	50 to 60	235 to 270
API Grade D (special alloy)	90,000	115,000	12 to 16	50 to 60	227 to 247

*Rod number shown in the first column refers to the largest and smallest rod size in eighths of an inch. For example, Rod 76 is a two-way taper of 7/8 and 5/8 rods. Rod 85 is a four-way taper of 3/4, 7/8, 5/8, and 1/2 rods. Rod 109 is a two-way taper of 1 1/4 and 1 1/8 rods. Rod 77 is a straight string of 7/8 rods, etc.

Fig. 9.5—OS-Modified Goodman diagram for allowable stress and range of stress for sucker rods in noncorrosive service.

effect on reducing the pitting of a rod. For many applications, it is the pitting of the rod that causes an increased stress concentration, which can then lead to failure.

The API Class K rod is one alloy rod specifically recognized by the API. The rod selection chart also lists special-alloy rods that meet the API Class D requirements. Because of the addition of the alloys, the initial cost of these rods is more than a Grade D chrome moly rod. This cost must be judged against possible increased life and reduced pulling costs and well expenses.

Miscellaneous and special-service rods are also available that are generally used in special situations.

Failures

The control and minimization of sucker rod failures is one of the key elements in controlling lifting costs. Proper classification of failures and the determination of the cause is the first step in corrective action. A formal failure reporting system can help provide the discipline necessary to identify the problems and causes of failures and to provide the impetus for equipment and/or operation review to remedy the situation.

Fig. 9.6—H₂S rod part (note cracks caused by corrosion pits).

Steel sucker rod string failures can be segregated into four categories: body failures, upset failures, pin failures, and coupling failures. The most common failure is a body break. The most common cause of body breaks is corrosion caused by H₂S, CO₂, salt water, O₂, or a combination of these corrosive materials.

H₂S (sour corrosion) occurs in almost half of U.S. wells and has its own distinctive corrosion pattern. A black iron sulfide scale is deposited on the rod, and a rotten-egg odor is associated with H₂S. The corrosion pits formed are generally small and sharp and have the effect of a notch on the surface. This corrosion pit or notch creates a stress concentration effect on the surface of the rod. The stress concentration effect, along with the effect of the hydrogen in the metal, can cause rapid failure of a rod. The failure looks as though the rod were brittle. In many cases, the actual corrosion pit that initiated the failure can be seen only with the aid of magnification. Close examination of the rod may also locate adjacent corrosion pits that are the focal point for additional fatigue cracks. Fig. 9.6 illustrates this condition.

CO₂ corrosion (sweet corrosion) is caused by carbonic acid, which is formed when CO₂ combines with water. Carbonic acid combines with the iron to form iron carbonate, which is a hard, dark scale. The corrosion forms pits that appear rather smooth in nature and are usually larger than the H₂S-type pits. In addition, the pits can be connected, and the metal loss is usually much larger before breakage than the metal loss of the H₂S breaks. The stress concentration effect of CO₂ corrosion pits is generally not as severe as the H₂S pits. CO₂ corrosion is illustrated in Fig. 9.7.

The vast majority of wells contain salt water to some degree. Water is necessary for both H₂S and CO₂ corrosion. However, salt water by itself is also corrosive and causes a generalized pitting attack, but it is not as severe as other types of corrosion.

Oxygen sometimes enters the pumping system through the tubing casing annulus. In the presence of water, the corrosion, while general in nature, can occur in a comparatively short time.

An effective corrosion inhibition program abates these corrosive attacks. Such a program is required for the entire production system, including the rods. The rods are

Fig. 9.7-CO₂ corrosion

Fig. 9.8-Rod failure (cause of failure is in dark area 180° from ductile projection).

probably the most sensitive to pits because they operate in fatigue and therefore are susceptible to the effects of stress concentration.

One of the problems encountered in maintaining this effective inhibition film is wear. When the rods rub the tubing, the protective film can be destroyed. The inhibitor acts to reduce the frictional force and has deterred problems encountered with light wear. Wear on rods can be identified by a flat spot on one side of the rod.

When a rod fails, the last area to part generally fails in a ductile mode and leaves a small tip on one face. The cause for the failure usually can be found 180° opposite this tip. This condition is found in Fig. 9.8. Corrosion pits can be difficult to identify, but handling marks or marks caused by hatchets when the bundle is broken can be more easily identified.

Many body breaks occur within 2 ft or so of the upset. This can be attributed to a bend of the body in relation to the upset, which imposes a bending moment on the rod. All rods have straightness tolerances, and the maximum of the tolerance, as specified by API, will produce an added stress of about 20%. For example, if the axial stress (determined by dividing the load by the area) is 20,000 psi and the rod end has the maximum bend allowed by API, the true stress will be the summation of the axial stress and the 20% extra stress caused by the bend, or 24,000 psi.

The API modified Goodman diagram has a safety factor of about 2. The bending moment infringes on this safety factor. Because of the greater cross-sectional area of the upset, failures in this part of the rod are rare.

Sucker rod pin failures can be caused by overtightening the joint. This type of failure can be identified by the reduction in area of the undercut portion of the pin. In addition, the shoulder of the pin will generally have an indentation caused by the force exerted by the coupling face.

The load on a sucker rod pin consists of two components: the load that results from tightening the joint, or preload, and the external load resulting from the pumping cycle. As long as the face of the coupling and the face

of the pin remain in contact during the pumping cycle, the pin will see only a part of the upstroke load and a part of the downstroke load. The amount of each upstroke and downstroke load is determined by the metal cross-sectional area relationship of the pin and coupling. Because the pin experiences a varying load, it also is subject to fatigue. This fatigue failure will occur at the root of the first thread adjacent to the relief. If the joint loosens and the pin and the coupling faces separate, the failure will occur in the same place in the first engaged thread. It is extremely important that the joint be clean and the faces free from nicks so that the joint will have the best chance of retaining the preload.

API recommends the use of circumferential displacement values rather than torque to achieve the desired pin preload stress. When power tongs are used, they should be calibrated for initial use and checked each 1,000 ft.

The method of marking the joint for circumferential displacement is indicated in Fig. 9.9. The circumferential displacement values are listed in Table 9.9.

Thread galling is another joint problem that sometimes occurs. Galling is generally caused by cross threading or making up threads that were not cleaned properly.

Coupling failures typically break at the plane of the last engaged thread of the pin. This is the plane where the load is transferred totally to the coupling. If failures occur at any other location, an examination should be made to determine the origin of the failure. A likely cause is cracks created by hammer marks.

As the clearance between the coupling and tubing is minimal, the coupling can be subjected to wear. The metal spray coupling has a hard, corrosion-resistant coating with a very low friction coefficient. This coupling is popular in wells where failure as a result of corrosion or coupling wear is a problem. This coupling should not be used indiscriminately, however, because it may, in some circumstances, transfer the wear to the tubing. As with all couplings, hammer blows should not be used to loosen couplings. The metal spray coupling is especially susceptible to the formation of cracks from hammer blows because of the hard, brittle coating.

Fig. 9.9—Marking for circumferential displacement.

Care and Handling

Sucker rods are handled in the factory with equipment and facilities specially designed for protecting sucker rods from damage. The rods are shipped from the factory in packages also designed to protect the rod from damage. Care must be exercised in handling and storing the rods in the field so that the rods are run in the well in the same condition as they left the factory.

A successful sucker rod operation includes attention to detail while the rods are out of the well and a sound in-the-well program. It is particularly important to protect the surface of the rod from any handling damage, such as nicks or gouges. These discontinuities concentrate the stress in the same manner as a corrosion pit. Rods should always be properly supported so that no bends or kinks are induced. All rods with nicks, gouges, bends, or kinks should be discarded. Rods are shipped with end caps that protect not only the threads but also the pin shoulder. If any rods are without end caps, inspect the pin end, and if it is undamaged, clean and grease the end and replace the cap. Do not remove end caps until the rods are ready to be run. If it is necessary to walk across rods, provide a wooden walkway to protect the rod surface.

Unloading and Loading

Rod packages should always be lifted and laid down with handling equipment that supports the package without damaging the rods. When packages are stacked, the bottom supports should be placed directly on the top supports of the next lower package. Tie-down chains, straps,

or cables should be placed over the crosswise supports and should not be in contact with the rods.

Individual rods should be picked up and supported near each end. Locate the pickup points to minimize sag in the rod. Do not drag the rod across surfaces. Rods should never be flipped from one position to the next.

When unpackaged rods are transported, the rods should be supported with wooden or nonabrasive material so that the rod body and ends do not rest on the bed. A minimum of at least four supports is required. The rod layers should be separated by spacers positioned directly above the bottom supports. The spacers should be long enough to extend beyond the stack on each side. If the spacers are not notched, the spacers should be chocked on each side to prevent the rods from rolling off. The tie-down chains, cables, or straps should be placed over the crosswise supports and should not be in contact with the rods.

Rod Storage

Rods should be stored off the ground to minimize corrosion and grouped separately by grade and size to minimize misidentification. Inspect the rods at scheduled intervals. Replace any missing end caps and brush rusty surfaces with a wire brush until they are clean. Recoat the affected area with a suitable protective coating. Rod coatings are generally oil-soluble and contain an inhibitor. Rod manufacturers can identify a proper, compatible coating.

Good storage practices will protect the surface of the rod. The same general common-sense rules for unloading and loading also apply for storage.

Running and Pulling

At the wellsite, rods should be placed off the ground on supports. Single rods should be tailed into the mast with care, so that no contact is made with the ground or other equipment. The rods should not be raised with elevator latches during tailing. When the pin is stabbed into the coupling, the rod should be positioned directly over the well and hung straight without slack to minimize the possibility of cross threading. The couplings and pin should be brushed with a mixture of oil-soluble, film-forming corrosion inhibitor and refined oil for lubrication and corrosion protection. Use power tongs, calibrated to circumferential makeup values, for the most consistent makeup results.

The joint should never be hammered when the well is pulled or when connections are broken out. Use cheater bars, if necessary, to loosen the joint. Any overtorqued connection should be checked and thrown away if damaged. Rods should be inspected for damage—e.g., kinks, bends, and nicks—and discarded if any are found. The faces of the pins and couplings should be smooth and free of irregularities, such as scratches or nicks, that prevent proper makeup.

Fiberglass Sucker Rods

The first fiberglass rods were introduced in the 1970's. A fiberglass rod consists of long parallel strands of fiberglass embedded in a plastic matrix. Steel end fittings are then placed on the ends of the rods and held in place by wedges formed by an adhesive. The steel end fittings terminate in a standard API sucker rod pin. The rods can

*Minimum length exclusive of fillet.

**The extension is that portion of the rod body or that portion of the end fitting that is immediately adjacent to the smaller end of the elevator taper. If this section of the end fitting is longer than 0.25 in., the maximum OD shall not be more than 0.200 in. larger than the diameter of the rod body. If this section of the end fitting is 0.25 in. or less in length, the OD shall not be more than 0.25 in. larger than the diameter of the rod body.

[†]The length of pin-and-pin rods shall be measured from contact face of pin shoulder to contact face on the field end of the coupling.

be joined together with standard couplings to form rod strings. The fiberglass rods are lighter in weight than steel rods, about 0.84 lbm/ft for a 1-in. fiberglass rod compared to 2.9 lbm/ft for a 1-in. steel rod, and have a lower modulus of elasticity, about 7.0×10^6 compared to 29.5×10^6 for steel.

A typical fiberglass-reinforced plastic rod string contains about 50 to 70% fiberglass rods at the top of the rod string and 50 to 30% steel rods at the bottom. Sometimes heavy sinker bars replace the steel rods. The steel mass on the bottom of the string helps the fiberglass rods achieve overtravel and keeps the fiberglass rods in tension. Fiberglass rods are generally used in wells with relatively high fluid levels so that excessive rod stretch (also the result of high elasticity) does not destroy the efficiency of the installation.

Physical Dimensions

API has published a specification for reinforced plastic sucker rods.⁴ This document covers materials, performance, quality control, general dimensions, packaging, inspection, and recommended practice for care and handling of rods.

The general dimensions for a plastic rod published by API⁴ are listed in Table 9.10 and Fig. 9.10.

Plastic Sucker Rod Chemical and Mechanical Properties

Unlike steel, which has an infinite fatigue life when applied at stresses in a noncorrosive environment below the endurance limit, fiberglass has a finite life. If a given maximum and minimum load is cyclically applied to a plastic rod, the rod will eventually fail in fatigue. If a higher load combination is applied, the rod will fail in fewer cycles. In addition, the plastic rod is subject to loss of strength caused by increasing temperature. A stress-range diagram for plastic rods should always state the number of cycles to first expected failure and the corresponding temperature. API specifies that a basic stress-range diagram be constructed for 7.5 million cycles (1.8 years at 8 cycles/min) and 160°F. Modifiers for 5, 10, 15, and 30 million cycles to first expected failure and modifiers for other temperatures should be listed.

The end fittings for the rods are designated Grades A and B. The classifications are similar to designations for steel rods. Table 9.11 lists the end-fitting chemical and mechanical properties.

Fig. 9.10—General dimensions for reinforced plastic sucker rods (see Table 9.10).

Fig. 9.11—Schematic of pultrusion process.

Manufacture of Fiberglass Sucker Rods

Fiberglass sucker rods are manufactured in three separate steps. The fiberglass rod body is produced by the pultrusion process. The metal end fittings are then assembled on the rod and locked in place with an adhesive.

The fiberglass rod body consists of high-strength fibrous glass reinforcement held in place by a resin system. A single strand of fiberglass may contain thousands of individual glass filaments. A fiberglass rod body is produced with many single-strand or multistrand glass rovings. Consequently, when a load is applied to the rod body, the load is distributed over many thousands of individual glass filaments.

The resin system protects the glass fibers and generally is the component that determines the chemical resistance and temperature performance. The resins used in fiberglass rods are thermoset resins that react during processing to form a cured material that cannot be remelted or reprocessed. Thermoset resins used in fiberglass rods, such as vinyl ester, isothalic, or epoxy, have different physical and chemical properties. This is similar to the different grades of steel, which have different physical properties and chemical resistance. The resin system also contains additives and fillers for either enhancement of properties or aids in processing.

The fiberglass rod body is manufactured by a process called pultruding. The schematic of the pultrusion process, Fig. 9.11, illustrates the manufacturing operations. Fiberglass roving spools are held on a creel and fed through a carding plate. The glass is then impregnated with the resin system paste and then preheated by a radio-frequency preheater. The final forming of the shape and curing of the rod occurs in the metal die. The power for

the system is provided by the friction pullers. The rod is cut to length by a flying saw after it leaves the friction pullers.

The metal end connectors are machined with an API pin thread on one end and an internal bore with a series of wedges on the other end. Mold release is sprayed into the ID of the steel end connector. Adhesive is then placed in the box and the rod is inserted into the cavity. The adhesive fills the machined wedges. After the adhesive has cured, the rod is then pulled on each end. Because of the mold release that was applied to the steel, the adhesive breaks loose from the steel and adheres to the fiberglass rod; thus the internal wedges are set. Fig. 9.12 shows the geometry of this unique connection.

Application

There can be several advantages to the use of fiberglass sucker rods. Because these rods cost more than steel rods, their use has to be justified. The most common and generally sought-after advantage is to increase production. The lower modulus of elasticity, about one-fourth that of steel, allows greater overtravel of the plastic rods compared to steel rods. If the fiberglass/steel rod string is operated as close to the natural frequency of the system as possible, subsurface pump stroke lengths can be achieved that are significantly longer than the surface stroke.⁵ Because the reduced modulus of elasticity is responsible for increased overtravel, it also is responsible for increased rod stretch caused by the fluid load of the pump. To decrease the effects of rod stretch, applications with fluid levels above the pump, with smaller-bore pumps, and well depths in excess of 3,000 ft are more favorable toward greater net downhole-pump-stroke length.

** Any composition that can be heat treated to give the specified tensile strength.

Fig. 9.12—Typical fiberglass-reinforced plastic rod-body-to-steel connector-joint design.

Fig. 9.13—Typical fiberglass stress-range diagram.

The lighter weight of fiberglass, about 30% that of steel, can also translate into cost savings. The total effect of the dynamics is reduced, which in turn requires less horsepower and lower power costs. In addition, the lighter weight of the total rod string means reduced pumping unit requirements, which allow smaller pumping units to be used.

Another advantage is the inherent corrosion resistance of the fiberglass. Corrosion inhibition should be used to protect the well system, casing, tubing, flowlines, and sucker rods. In many cases, however, inhibition of the rod string is ineffective. This can be a result of the physical breakdown of the film on the rod caused by rubbing against the tubing. In some instances, maintaining a film is not cost-effective. The corrosion resistance of the fiberglass rod can reduce pulling costs and well downtime. The end connectors are made from steel, and corrosion can occur on these fittings. The stresses in the connectors are relatively low, and corrosion generally has not been a factor in their performance.

Predictive well-performance calculations are made with a computer program using the wave equation discussed in the section on steel rod application. The selection of rod size is a function of stress on the rod. In practice, the most popular rod diameters by far are 1 and 1 1/4 in.

After the maximum and minimum stresses are determined, the allowable stresses are specified from a stress-range diagram. As an example, Fig. 9.13 is a stress-range diagram for 7.5 million cycles and 110°F for 7/8- and 1-in. rods. Fig. 9.14 illustrates the general relationship between stress, stress range, and expected life. A small lowering of the maximum stress can result in a significant increase in rod life. Each manufacturer publishes data and modifiers for cycles, temperature, and rod size.

Some operating and well conditions should be avoided with plastic rods. High temperatures cause a loss of

Fig. 9.14—Expected life of fiberglass rods.

strength. While bottomhole temperatures of slightly more than 200°F have been pumped with fiberglass rods, the limiting factor is the temperature that the lowest fiberglass end connector reaches. In these hot wells, more steel rods are used on the bottom of the string to reduce the operating temperature of the fiberglass rod connections. Hot oiling of wells should be done down the tubing/casing annulus.

Compression loading and wear of the rods must be avoided. These conditions can result in early failure. To prevent overstressing the fiberglass rod string when an attempt is made to pull a stuck pump, shear pin tools are usually run above the subsurface pumps.

Failures

Because fiberglass sucker rods do not have a finite endurance limit, the rods can be expected to fail eventually. The actual life of the rod can be many years and depends on the maximum and minimum stresses. The point of expected eventual failure is a breakdown of the end-connector joint, which results in the metal end connector separating from the rod. This type of failure can be fished with an overshot.

Body breaks do sometimes occur and are generally the result of mishandling, which causes nicks or damage to the surface. Occasionally, body breaks are caused by misalignment of the fiberglass rovings. Body breaks can be fished with special overshots.

Care, Handling, and Storage

The surface of the fiberglass rod is much more easily damaged than a steel rod. Therefore, it is even more important to keep the rod from contacting the ground or any object that could scratch or injure the surface.

The rods need to be protected from ultraviolet light if they are going to be exposed to the sun longer than a few months. This can be achieved by covering the rods with a dark plastic blanket.

Nomenclature

- d_b = diameter of sucker rod bead, in.
- d_{ef} = maximum diameter of end fitting, in.
- d_{oc} = outside diameter of coupling, in.
- d_p = plunger diameter, in.
- d_{pb} = outside diameter of sucker rod pin shoulder and box, in.
- d_x = maximum diameter of extension, in.
- F_d = derating factor, dimensionless
- F_s = service factor, dimensionless
- l_{wf} = distance between coupling wrench flats, in.
- L_{max} = maximum length of end fitting, ft
- L_{min} = minimum length of coupling, in.
- L_{rb} = total length of sucker rod box, in.
- L_{wf} = length of coupling wrench flat, in.
- L_{ws} = length of sucker rod wrench square, in.
- m = slope of curve
- r_a = outer radius of sucker rod bead, in.
- r_c = inner radius of sucker rod bead, in.

- w_{ws} = width of sucker rod wrench square, in.
- W_r = sucker rod weight, lbm/ft
- σ_a = maximum allowable stress, psi
- $\Delta\sigma_a$ = maximum allowable range of stress, psi
- σ_{min} = minimum stress, psi
- σ_T = minimum tensile strength, psi

Chapter 10

Pumping Units and Prime Movers for Pumping Units: Part 1—Pumping Units

Fred D. Griffin, Lufkin Industries Inc.*

Introduction

When oil wells cease flowing, some means of artificial lift is required to produce the well. About 85% of all the artificial production of oil is accomplished by the use of sucker rods lifting the fluid. A relatively simple, reciprocating, plunger-type pump is attached to the lower end of the sucker rod string. Oil is lifted by means of a plunger and a traveling valve being moved up and down inside a polished cylinder with a valve at the bottom. The cylinder is called a "working barrel." The plunger is attached to the string of sucker rods that extends to the surface. The upper end of the rod string is attached to a polished rod, which is moved up and down by a pumping unit. Pumping units are discussed here and prime movers for pumping units in Part 2 of this chapter.

Pumping Units

A pumping unit is a mechanism which imparts reciprocating motion to a polished rod, which in turn is attached to the sucker rod string below the wellhead stuffing box. Several types of pumping units are available today. The component parts of most of the units are basically the same but the arrangement of the parts differs. Selection of the proper size and type of pumping unit for a particular application is important. Like most other machinery, pumping units must be properly installed, lubricated, and maintained. Built into the majority of pumping units is some method of counterbalance, which in most cases consists of adjustable weights on the rotating cranks or air pressure pushing up on the walking beam. The counterbalance system, whichever type is used, opposes the weight of the sucker rod string and a portion of the fluid to be lifted. The actual well load on a pumping unit should be measured and analyzed often to ensure that the counterbalance is correct and that the load and torque capacity of the unit has not been exceeded.

Types

Pumping units generally are typed according to the method of counterbalance. This is true for beam balanced units, air balanced units, conventional crank balanced units, and special geometry (or Mark II) crank balanced units.

In addition to the method of counterbalancing, the geometric arrangements of the principal components are distinguishing features. The beam balanced, the conventional crank balanced, and some special geometry units are classified as Class I lever systems because the samson post bearing (pivot point for the walking beam) is located between the well load and the actuating force of the pitman side members.

The air balanced and the Mark II crank counterbalanced units are classified as class III lever systems because the walking beam hinge point is located at the rear of the unit and the actuating force of the pitman side members is located between this pivot point and the well.

The type of pumping unit best suited for a particular pumping problem very often is a matter of personal preference. The conventional crank balanced pumping unit is the choice of many operators mainly because it has been readily accepted by field personnel for many years. Many other operators' choice is the Mark II special geometry unit with its capability of a more uniform torque pattern on the gear reducer. Usually these special geometry units will require one size smaller gear box size than other type units for a particular application. The American Petroleum Inst. (API) lists standard gear box sizes in their specification API Spec 11E.¹ Other operators specify the air balanced pumping unit, which is readily adaptable to platform or pier installations and other unstable substructures. This is because the inertia and shaking forces of air balanced units are very low. Air-balance units also are compact and light in weight compared with other types of pumping units of the same structural and gear box rat-

*Authors of the chapter on this topic in the 1962 edition were this author and L. A. Little, F. Ben Elliott Jr., J. Taylor Hood, and John H. Day Jr.

Fig. 10.1—Conventional pumping unit.

ing. The beam balanced pumping unit is manufactured only in the smaller sizes and economics is the prime factor for selecting this unit type.

Pumping Unit Geometry

Pumping units are manufactured in various geometric configurations in addition to methods of counterbalance. As mentioned before, beam balanced and conventional crank balanced units are Class I lever systems, and air balanced and Mark II units are Class III lever systems. Within these two lever systems are variations effected by moving the gear reducer on the structural base with respect to the equalizer or cross yoke.

In the case of the Mark II, the cross yoke is not located directly above the slow speed shaft of the gear reducer but shifted forward toward the horsehead. This shifting, accompanied by a specified direction of rotation of the cranks, results in a longer time interval for the upstroke and a shorter time interval for the downstroke.

Conventional Crank Balanced Units

The conventional crank balanced pumping unit is the type most commonly used today, especially in the short and medium stroke lengths. It adequately serves a wide variety of field applications. Fig. 10.1 shows a conventional crank balanced unit with the various parts labeled. The rotation of the cranks connected to the pitman side members causes the walking beam to pivot about the center bearing, thereby causing the polished rod to move up and down through its connection to the wireline and horsehead. The adjustable counterweights located on the cranks are heavy metal castings. Fig. 10.2 illustrates the mechanics of the

counterbalance system. Adjustment of the counterweights and their effect at the polished rod are discussed later in this section.

Fig. 10.2—Crank-counterbalanced diagram.

Fig. 10.3—Air-balanced pumping unit.

Air Balanced Units

The air balanced pumping unit is basically the same as the crank balanced unit in that the rotation of the cranks causes the walking beam to pivot and move the polished rod up and down. Fig. 10.3 shows a typical field installation of an air-balanced unit with the various parts labeled. The unit is compact and relatively light. The long cylindrical tank at the front of the unit houses a piston and air cylinder. Force exerted by compressing air in the cylinder is used to partially counterbalance the well load. A special sealing device is used to prevent air leaks between the piston and cylinder. One of the features of the sealing device is a pool of oil on top of the piston acting as an air seal. Fig. 10.4 shows how the counterbalance force works to partially offset the well load. An auxiliary air compressor is used to maintain the system air pressure at an optimal working level. The operation of the compressor normally is controlled automatically by a pressure switch to maintain air pressure within a manually preset range.

Beam Balanced Units

Fig. 10.5 shows a beam counterbalanced unit. This unit is very similar to the crank balanced unit except that the counterweights are mounted on an extension of the walking beam. In general, use of this type of unit has been limited to the smaller sizes. The primary reason for this is that the pumping speed is limited. High pumping speeds can result in shaking forces, which can wreck the unit unless the pumping speed is reduced.

Mark II Units

Fig. 10.6 shows the Mark II unit with the various parts labeled. This type unit has two unique features.

Fig. 10.4—Air-counterbalance diagram.

1. The cross yoke bearing which is actuated by the pitman side members is moved forward and is located very close to the horsehead rather than directly above the gear reducer crankshaft.

2. The cranks have a dogleg (angular offset) in them to produce an out-of-phase condition between the torque on the gear reducer exerted by the well load and the torque exerted by the counterbalance weights.

With these two unique features and with the cranks allowed to rotate in one direction only, a more uniform torque is applied to the crankshaft. The torque peaks, normally more prominent in conventional crank balanced units, are reduced in magnitude.

Fig. 10.5—Beam-balanced pumping unit.

Fig. 10.6—Mark II pumping unit.

In most cases, this reduction in the torque peaks is sufficient to permit the use of one API size smaller gear reducer than would be used otherwise for a comparable conventional crank balanced unit. Fig. 10.7 illustrates how the torque on the gear reducer follows a more uniform pattern under ideal field conditions.

Crank Balanced Units (With Special Geometry)

Some crank balanced units are manufactured with the gear reducer shifted from a position directly underneath the equalizer to a position on the structural base farther away from the centerline of the well. This change from the conventional geometry causes a change in the torque factors on the upstrokes and downstrokes. This geometric change also causes a change in the time interval between the up- and downstrokes.

These type units usually have the out-of-phase system of counterbalance described previously and usually require a specific direction of rotation.

Fig. 10.7—Unitorque geometry.

Component Parts

The main parts of a pumping unit consist of structural members, bearings, speed reducer, and drive. Since the crank balanced pumping unit consists of parts typical for most units, the discussion is limited to this type.

Structure

The main structural parts of a crank balanced pumping unit are the base, samson post, walking beam, horsehead, equalizer, and pitman side members.

The structural base serves as a rigid member to which the samson post, gear reducer, and prime mover are attached for the proper alignment to effect satisfactory operation.

The samson post normally is constructed from three or four legs of rolled steel shapes. The samson post must be sufficiently rigid and strong to support at least twice the maximum polished rod load.

Centered on top of the samson post is the center bearing, which supports the large structural beam called the walking beam. The walking beam must be strong enough to resist bending caused by the well load at one end and the actuating force from the pitman side members at the other. API specifies the maximum allowable stresses and other design criteria for walking beams in API Spec 11E.¹

The horsehead is attached to the well end of the walking beam and supports the polished rod through a wireline and carrier bar assembly. The center of curvature of the horsehead is the center bearing. Thus, the polished rod moves in a straight line tangent to the arc of the horsehead.

On the other end of the walking beam are the equalizer and pitman side members. The rotary motion of the cranks attached to the speed reducer slow speed shaft is transferred to the walking beam by the equalizer and the pitman side members. The equalizer usually is mounted on the beam in such a manner that it can move and compensate for some misalignment in manufacturing and erection tolerances.

Loading on the pitman side members is tension on conventional crank balanced units, compression on Mark II units, and alternating tension and compression on air balanced units.

Structural Bearings

Trouble-free operation of a pumping unit depends on the proper functioning and design of the various structural bearings. Some characteristics to consider for proper selection of bearing design are the type and speed of the bearing as well as the direction and magnitude of load. On a conventional crank balanced pumping unit, the center bearing and equalizer bearing support an oscillating load while the crank pin shafts (and bearing inner races) rotate with respect to the load.

Various types of bearings and bearing materials have been used in these applications. High-lead bronze bearings were used for many years in all three of these bearing points. Bronze bearings operate with little damage even under marginal conditions of lubrication. In recent years, bronze structural bearings generally have been replaced by straight roller, tapered roller, or spherical roller antifriction bearings. These bearings can be grease lubricated and require less maintenance in general than do bronze bearings, which require oil lubrication.

Pumping unit bearings should be designed or selected very conservatively because they are often subjected to severe shock loads. Provision must be made for adequate lubrication and for protection from dirt and moisture.

Gear teeth proportions, hardness, and many other variables that affect the API torque rating are outlined in API Specification for Pumping Units, API Spec 11E.¹

Reducer

A speed reducer is used to convert high-speed, low-torque energy into low-speed, high-torque energy. A reduction ratio of about 30:1 commonly is used. This means that if the input speed is from 300 to 600 rev/min, the output speed or pumping speed of the pumping unit will be 10 to 20 strokes/min.

The speed reduction is accomplished by means of her-ringbone or double helical gearing in most cases. Helical gearing has been used in some instances; however, care must be taken that thrust bearings inherently required with helical gears must be adjusted properly to take the thrust from the frequently reversing loads of the pumping unit. Spur gearing and chain drives have also been used but to a much lesser extent. Pumping unit speed reducers must be sturdy and dependable. Reducer design should include provisions for adequate and proper distribution of oil.

Gear teeth proportions, hardnesses, and many other variables that affect the API torque rating are outlined in API Spec 11E.¹ This publication also outlines design parameters for chain reducers.

Drive

V-belts are the most universal driving means between the prime mover and the pumping unit gear reducer. They are dependable means of transmitting power and providing a certain amount of cushioning effect between the prime mover and gear reducer. This cushioning effect is highly desirable with slow-speed, single-cylinder engines. Sheave sizes can be changed easily to adjust pumping speeds. Provisions must be made to adjust belt tension periodically. A belt cover or guard usually is provided to protect the belts from the elements and for personnel safety (see Guarding of Pumping Units).

Pumping Unit Loading

There are many variables that affect the loading on the sucker rod string and pumping unit. Some of these variables are listed in Table 10.1.

Unfortunately, many of these variables are unknown when design calculations for sizing a pumping unit are made. See Fig. 10.8 for a visual representation of some of these loads.

Dynamometer Card Analysis

A dynamometer card is a continuous plot of polished rod load vs. polished rod displacement, or it may be a continuous plot of polished rod load vs. time. A polished rod load plot can in some instances be useful in analyzing downhole problems as well as identifying the resulting loads on the surface equipment.

A typical dynamometer card is shown in Fig. 10.8. When pumping speed is elevated above zero, the card takes on a different shape. Some of the load values are

TABLE 10.1—VARIABLES THAT AFFECT SUCKER ROD STRING AND PUMPING UNIT LOADING

Polished rod load
Pumping speed
Pump setting or depth
Physical characteristics of the rod string
Dynamic characteristics of the rod string
Plunger diameter of the pump
Specific gravity
Pump intake pressure
Polished rod acceleration pattern
Mechanical friction
Fluid friction
Pump submergence
Compressibility or gas interference
Pumping unit inertia
Pumping unit geometry
Counterbalance
Torque characteristics of prime mover
Flowline pressure

increased over the zero-pumping-speed card shown by the dotted lines and some values are decreased.

While this section is not intended as a treatise on polished rod dynamometer card interpretation, certain conclusions can be drawn from the card and knowledge of subsurface conditions.

As noted under Pumping Unit Loading (Table 10.1), there are many variables that affect loading on the polished rod. Sometimes some of these variables nullify each other, sometimes they are additive, and sometimes they are shifted time-wise because of rod string dynamics, making it virtually impossible to make a meaningful interpretation of the dynamometer card shape. This is particularly true in deep wells with a relatively elastic sucker rod string. At other times, certain type cards have a very distinctive pattern and downhole problems can be identified quite easily.

Fig. 10.9 shows a dynamometer card that is particularly detrimental to all surface and subsurface equipment. This card depicts a severe fluid pound. The condition generally is caused by attempting to produce fluid at a greater rate than the reservoir will give it up. The result is incomplete pump fillage and a fluid pound when the plunger hits the fluid on the downstroke. If the pound occurs very near the top of the pumping unit stroke, or at a low plunger speed, the effect is not so damaging; however, if the pound occurs at high plunger speeds in the pumping cycle, a progressively detrimental effect and equipment damage is

Fig. 10.8—Basic loads on polished rod.

Fig. 10.9—Example of fluid pound.

generally the result. If a fluid pound does exist, the operator should make every effort to correct this costly practice by decreasing the displacement of the bottomhole pump. This can be accomplished by either reducing the pumping speed, shortening the stroke length, or installing a smaller-bore bottomhole pump. Sometimes it is necessary to try a combination of these remedies to prevent a decrease in production.

Fig. 10.10 shows a group of representative dynamometer cards illustrating the effect of pumping speed, rod stretch, and polished rod load. The abscissa, F_o/Sk_r , is a dimensionless factor representing sucker rod stretch and load. F_o is the differential fluid load on the full plunger area in pounds and Sk_r is the load in pounds necessary to stretch the sucker rod string in an amount equal to the polished rod stroke.

The ordinate, N/N_o , is a dimensionless pumping speed factor, where N is the pumping speed in cycles/min and N_o is the natural frequency of the tapered sucker rod string in cycles/min.

This family of dynamometer cards show the various effects of nondimensional pumping speeds and nondimensional sucker rod stretch on the shape of dynamometer cards. The dynamometer card on the upper left corner is a rather extreme example of an overtravel card. Overtravel cards have the distinct shape of sloping up from right to left. Undertravel cards, illustrated by the dynamometer card in the lower right-hand corners, slope up from left to right. While these two examples may be on the extreme ends of the spectrum, there are many other examples in between that reflect various combinations of pumping speeds and rod stretch.

As a general rule, most operators limit the pumping speed factor to 0.3 or 0.35 and the stretch factor to 0.5.

Very often certain card shapes favor certain types of geometry pumping units. This means that a pumping unit with a particular geometry, owing to its unique set of torque factors and perhaps phasing of counterbalance, may be able to lift the rod string with less average net torque on the gear reducer than will a pumping unit with a different geometry. In general, crank balanced units, properly balanced, will usually produce less torque on wells with undertravel cards, whereas Class III lever system units with phased counterbalance usually will show an advantage on wells with overtravel cards.

Fig. 10.10—Representative dynamometer cards.

Counterbalance

One of the most important aspects of torque loading on a gear reducer is the level of counterbalance. Improper counterbalance, either too much or too little, is probably the biggest single factor involved in overloading a pumping unit gear reducer.

In general, the counterweights are positioned on the cranks so that their effect approximately balances out the weight of the sucker rod string and a portion of the fluid to be lifted.

In some special geometry units such as the Mark II, the counterbalance torque on the gear reducer is out of phase with the torque on the gear reducer exerted by the well load. This means that when the pitman side members go over top and bottom dead center with respect to the reducer slow speed shaft, the reducer torque exerted by the counterweights is either leading or lagging the well load torque. This is accomplished by putting a dogleg in the crank so that the counterweights do not go over top and bottom dead center of the reducer slow speed shaft at the same time as do the pitman side members. The net effect of this combination of torque loading is illustrated in Fig. 10.7.

Torque Factors

For any position of the cranks there is a number, when multiplied by the polished rod load, that equals the torque on the gear reducer caused by the well load. This number is called a "torque factor." As the cranks are rotated through one complete stroke of the pumping unit, the torque factor changes for every crank position.

The pattern of torque factors around the pumping cycle is altered by the particular type geometry unit in question. This changing pattern of torque factors, in conjunction with phased counterbalance (see Counterbalance section), is used to an advantage in reducing the net torque on the gear reducer in some cases. Torque factors usually are expressed in inches.

Torque factors usually are available from the manufacturer of the pumping unit or can be calculated as illustrated in API Spec 11E¹ if the geometry dimensions of the pumping unit are known.

Polished Rod Velocities and Acceleration

Torque factors also provide a useful tool for calculating polished rod velocities and accelerations.

It can be shown that for any particular pumping speed of the pumping unit, the polished rod velocity at any Crank Position 1 is

$$v_{pr_1} = 0.00873 F_{t_1} \times N, \dots \dots \dots (1)$$

where

v_{pr_1} = polished rod velocity at Crank Position 1, ft/sec,

F_{t_1} = torque factor at Crank Position 1, in., and

N = pumping speed, strokes/min.

In Eq. 1, if v_{pr_1} is expressed in m/s, F_{t_1} in millimeters, and N in strokes/s, then the constant 0.00873 becomes 0.0121.

If the pumping speed is not constant around the pumping cycle, the equation is still true if the instantaneous pumping speed at Crank Position 1 is used in the equation.

Similarly, the average polished rod acceleration between any two Crank Positions 1 and 2 can be expressed as

$$\bar{A}_{pr_{1,2}} = 0.0524 N^2 \left(\frac{F_{t_1} - F_{t_2}}{\theta_1 - \theta_2} \right) \dots \dots \dots (2)$$

where

$\bar{A}_{pr_{1,2}}$ = average polished rod acceleration between Crank Positions 1 and 2, ft/sec²,

F_{t_1}, F_{t_2} = torque factors at Crank Positions 1 and 2, in.,

θ_1 and θ_2 = angle cranks rotate between Positions 1 and 2, degrees, and

N = pumping speed, strokes/min.

In Eq. 2, if $\bar{A}_{pr_{1,2}}$ is expressed in m/s², F_{t_1} and F_{t_2} in millimeters, θ_1 and θ_2 in rads, and N in strokes/sec, then the constant 0.0524 becomes 0.0695.

Sizing

Over the years there have been several methods of calculating the structural rating and the gear reducer rating of a pumping unit; however, it should be emphasized that the sizing of pumping unit is not an exact science. This is true because in virtually every case many of the variables previously outlined are unknown at the time the pumping unit is selected.

The most commonly used method for sizing pumping units today is outlined in API RP 11L² that was developed from test results conducted by Midwest Research Inst.

In those instances where the majority of the listed variables are known, there are more exotic computer programs available that may result in a more accurate sizing of the unit in some instances.

API RP 11L² covers the conventional pumping unit only; however, the manufacturer has modified this recommended practice to include air balanced and Mark II units.

The API, Midwest Research Inst., and the author make no guarantee as to the degree of accuracy of this sizing method when compared with measured field results and do hereby expressly disclaim any liability or responsibility for loss or damage resulting from its use.

The method of sizing conventional pumping units that is recommended by API RP 11L² and this same method as modified by the manufacturer for air balanced and Mark II units are listed on the following pages. Sample calculations for a given set of typical well conditions are filled in and circled for each type unit in Figs. 10.11 through 10.13.

Installation

An improperly installed pumping unit can result in early structural and bearing failures and overall unsatisfactory operation. An adequate foundation must be provided, and the unit must be properly erected.

Foundation

A reinforced concrete block is always the best type of foundation for a pumping unit. Concrete blocks may be cast in place although very often they are precast and moved to location for the installation of the unit. Hold-downs are provided in the concrete foundation in the form of anchor nuts or slotted pipes embedded in the concrete to receive hold-down clamp bolts.

The top of the concrete foundation should be level and smooth to support the pumping unit structural base. If the structural base members do not bear properly on the concrete, they may deflect with each stroke of the unit. This repeated deflection can result in ultimate failure of the structural steel base or the concrete foundation or both.

Other types of foundations are acceptable under certain circumstances. Foundations of heavy timbers set on alternate layers of sand and gravel have been used successfully in some areas. This board mat type of foundation must be supervised closely during its preparation to provide correct setting of the timbers. Usually, wide (portable) bases are required when board mat foundations are used.

Details for the design of the concrete foundation as well as the design of the board mat foundation is outlined in the API Recommended Practice for Lubrication of Pumping Unit Reducers, API RP 11G.³

Always use a current certified foundation print provided by the manufacturer.

Erection of the Unit

Before placing the structural base on the foundation, draw a chalk line from the center of the well along the center of the foundation. Place the base on the foundation lining

Company: _____ Well Name: _____ Date: _____
 Field: _____ County: _____ State: _____

ALL TYPES OF UNITS

1. $F_o = \text{Depth} \times G \times \text{Fluid Load (Fig. 10.12)} = 8,650 \times 1.0 \times 1.041 = 9,005$
2. $\text{SKR} = 1000 \times \text{Stroke} + [\text{Er (Fig. 10.12)} \times \text{Depth}] = 1000 \times 168 + (.0007 \times 8,650) = 27,746$
3. $F_o/\text{SKR} = 9,005 \div 27,746 = .325$
4. $N/\text{No} = \text{SPM} \times \text{Depth} \div 245,000 = 7.6 \times 8,650 \div 245,000 = .268$
5. $N/\text{No}' = (N/\text{No}) \div F_e(\text{Fig. 10.12}) = .268 \div 1.164 = .230$
6. $\text{BPD (100\% eff.)} = \text{Pump Const. (Fig. 10.12)} \times \text{SPM} \times \text{Stroke} \times \text{SP (Fig. 10.13)} = .357 \times 7.6 \times 168 \times .771 = 351$
7. $\text{WRF} = \text{Rod Weight (Fig. 10.12)} \times \text{Depth} \times [1 - (.128 \times G)] = 2.185 \times 8,650 \times [1 - (.128 \times 1)] = 16,481$
8. $\text{WRF}/\text{SKR} = 16,481 \div 27,746 = .594$
9. $\text{TA} = 1 + [\%(\text{Fig. 10.13}) \times (\frac{\text{WRF}}{\text{SKR}} - .3) \times 10] = 1 + [(-.0075 \times (.594 - .3) \times 10)] = .978$

CONVENTIONAL UNITS

10. $\text{PPRL} = \text{WRF} + [F_1(\text{Fig. 10.13}) \times \text{SKR}] = 16,481 + (.497 \times 27,746) = 30,270$
11. $\text{MPRL} = \text{WRF} - [F_2(\text{Fig. 10.13}) \times \text{SKR}] = 16,481 - (.177 \times 27,746) = 11,570$
12. $\text{CBL} = 1.06 \times (\text{WRF} + F_o/2) = 1.06 \times (16,481 + \frac{9,005}{2}) = 22,243$
13. $\text{PT} = T(\text{Fig. 10.13}) \times \text{SKR} \times \text{Stroke}/2 \times \text{TA} = .348 \times 27,746 \times 84 \times .978 = 793,200$
14. $\text{Rod Stress} = \text{PPRL} \div \text{Area (Fig. 10.13)} = 30,270 \div .785 = 38,561$

AIR BALANCED UNITS

15. $\text{PPRL} = \text{WRF} + F_o + .85 \times [F_1(\text{Fig. 10.13}) \times \text{SKR} - F_o] = 16,481 + 9,005 + .85 \times (.497 \times 27,746 - 9,005) = 29,553$
16. $\text{MPRL} = \text{PPRL} - [F_1(\text{Fig. 10.13}) + F_2(\text{Fig. 10.13})] \times \text{SKR} = 29,553 - (.497 + .177) \times 27,746 = 10,852$
17. $\text{CBL} = 1.06 \times (\text{PPRL} + \text{MPRL}) \div 2 = 1.06 \times (29,553 + 10,852) \div 2 = 21,415$
18. $\text{PT} = T(\text{Fig. 10.13}) \times \text{SKR} \times \text{Stroke}/2 \times \text{TA} \times .96 = .348 \times 27,746 \times 84 \times .978 \times .96 = 761,500$
19. $\text{Rod Stress} = \text{PPRL} \div \text{Area (Fig. 10.13)} = 29,553 \div .785 = 37,647$

MARK II UNITS

20. $\text{PPRL} = \text{WRF} + F_o + .75 \times [F_1(\text{Fig. 10.13}) \times \text{SKR} - F_o] = 16,481 + 9,005 + .75 \times (.497 \times 27,746 - 9,005) = 29,075$
21. $\text{MPRL} = \text{PPRL} - [F_1(\text{Fig. 10.13}) + F_2(\text{Fig. 10.13})] \times \text{SKR} = 29,075 - (.497 + .177) \times 27,746 = 10,374$
22. $\text{CBL} = 1.04 \times (\text{PPRL} + 1.25 \times \text{MPRL}) \div 2 = 1.04 \times (29,075 + 1.25 \times 10,374) \div 2 = 21,862$
23. $\text{PT} = (\text{PPRL} \times .93 - \text{MPRL} \times 1.2) \times \text{Stroke} \div 4 = (29,075 \times .93 - 10,374 \times 1.2) \times 168 \div 4 = 612,800$
24. $\text{Rod Stress} = \text{PPRL} \div \text{Area (Fig. 10.13)} = 29,075 \div .785 = 37,038$
25. NOTE: Do Not Use Less Than One Size Smaller Reducer Than Required For Conventional Unit

Figure numbers in parentheses indicate where values were obtained. Abbreviations and nomenclature used here are indigenous to this form.

BRAKE HORSEPOWER REQUIRED BASED ON 100% VOLUMETRIC EFFICIENCY:

Conventional and Air Balanced Units:

For slow speed engines & high slip electric motors

$$\text{Depth } 8,650 \text{ Ft.} \times \text{BPD } 351 = 54 \text{ BHP}$$

56,000

For multi-cylinder engines & normal slip electric motors

$$\text{Depth } 8,650 \text{ Ft.} \times \text{BPD } 351 = 68 \text{ BHP}$$

45,000

Mark II Units:

For slow speed engines & high slip electric motors

$$\text{Depth } 8,650 \text{ Ft.} \times \text{BPD } 351 \times .8 = 44 \text{ BHP}$$

56,000

For multi-cylinder engines & normal slip electric motors

$$\text{Depth } 8,650 \text{ Ft.} \times \text{BPD } 351 \times .8 = 54 \text{ BHP}$$

45,000

EXPLANATION OF SYMBOLS

Fo = Fluid Load on Full Plunger Area

SKR = Load required to stretch the rod string to an amount equal to the stroke length

Fo/SKR = Percent of the stroke length which the fluid load will stretch the rod string

N/No = Ratio of SPM to natural frequency of straight rod string

N/No' = Ratio of SPM to natural frequency of tapered rod string

BPD = Barrels per day production at 100% volumetric efficiency

WRF = Weight of rod string in fluid

TA = Torque adjustment for peak torque for values of WRF/SKR other than .3

PPRL = Peak polished rod load, pounds

MPRL = Minimum polished rod load, pounds

CBL = Counterbalance required, pounds

PT = Peak reducer torque, inch pounds

Wr = Average Weight of rods in air, pounds per foot

G = Specific Gravity of produced fluid

Plunger Dia.	Fluid Load lb. per ft.	Pump Constant
1-1/16	0.384	0.132
1-1/4	0.531	0.182
1-1/2	0.765	0.262

Fig. 10.13—Pumping unit design calculations.

up the center of the base with the chalk line. The distance from the well to the front of the structural base should be given on the certified print provided by the manufacturer.

Follow the manufacturer's instructions and assemble the rest of the unit. Proper alignment of all working parts of the mechanism is essential. This may be checked by use of a level, plumb bob, or a transit. Make necessary adjustment to align the wireline hanger with the well. Tighten all bolts and nuts. Some pumping unit manufacturers specify that all structural bolts be hammer-tight.

After all other adjustments and inspection have been made and the unit is in operation, visually check alignment of moving parts. This may be done by observing the distance between the cranks and pitman side members on each side of the unit. The distances should be approximately equal. Check the wireline to see if it is tracking the horsehead properly. Objectionable noises or knocks usually indicate that some part of the unit is loose or out of alignment. All necessary adjustments should be made at this time. Misalignment may result in excessive axial motion of bearings which are designed primarily for radial load.

Guarding of Pumping Units

Guarding should be provided for all pumping units to prevent bodily injury or death from contacting moving parts of the unit by anyone inadvertently walking into the unit, falling, slipping, tripping, or any similar action. Guards should be provided around the V-belt drive as well as around the entire pumping unit.

The type of guarding around the unit depends on the location. For remote locations, usually a rail type guarding is considered satisfactory. For more populous areas, wire mesh guards several feet high are provided to ensure a greater degree of safety to personnel. Details for guarding can be found in API RP 11ER.⁴

Lubrication

Pumping units should be given periodic lubrication and maintenance checks. When they are subjected to heavy variable loads, extreme temperature conditions, or adverse moisture or dust conditions, it might be necessary to increase the frequency of the checks.

Structural Bearings

All the structural bearings (i.e., center bearings, equalizer bearings, crank pin bearings, etc.) require an adequate amount of the proper type of lubricant. A fluid lubricant

is more efficient in moving to the areas where the lubricant is most needed within the bearing housing; however, good quality grades of greases are recommended by most manufacturers for their particular bearings. In general, sleeve type bearings require oil as a lubricant and antifriction type bearings operate satisfactorily with grease lubrication.

Gear Reducers

Lubrication procedures for gear reducer drives and chain drives are recommended in accordance with API standards. Temperature and viscosity ranges for gear reducers and chain reducers are tabulated in API RP 11G³ (also see Tables 10.2 and 10.3).

It is not possible to describe adequately suitable lubricants by brief specifications or by Soc. of Automotive Engineers (SAE) or Intl. Standards Organization (ISO) viscosity numbers alone. Adequate lubrication instructions cannot be condensed sufficiently to be placed on the nameplate because of the many variables in operating conditions to which pumping units are subjected.

The proper oil for pumping unit gear reducers is best chosen with the advice of a representative of a reputable supplier of lubricants and should be based on the service conditions that are established by the design of the reducer and the service conditions of the particular installation.

The areas in contact on gear teeth and on chains and sprockets are relatively small, and, therefore, the unit pressures produced in transmitting high torque loads are correspondingly high. These gears, chains, and sprockets are designed to operate under these high unit pressures provided the lubricant used is also capable of withstanding these unit pressures during the periods of peak loads.

The temperature of the air in the vicinity of the reducer is of considerable importance in selecting oil of the proper viscosity. For high-temperature operations, an oil with a higher SAE or ISO viscosity number should be selected. For low-temperature operations, the oil should have sufficient fluidity to insure a free flow of oil through the lubricating channels.

The operating temperature of oil in pumping unit gear reducers normally would be at least 25°F above ambient temperature. The temperature increase in the oil will be

TABLE 10.2—VISCOSITY RECOMMENDATIONS FOR GEAR REDUCERS

*Operating temperature of oil in a chain case on a pumping unit normally will be from air temperature to 25°F above air temperature. The temperatures shown in the table are the limiting values between which satisfactory lubrication can be expected.

**SAE gear oils are not recommended for use in chain reducers for this range of temperatures.

†SAE 75 gear oil is not usually available.

negligible in slow operating, lightly loaded reducers but will reach the upper limit in heavily loaded reducers operating at the higher speeds. Because most pumping units will be stopped at times, the lowest temperature of oil in the reducer usually will be the lowest temperature reached in the locality where the pumping unit is operating. This is an important consideration when selecting the viscosity number of oil for winter operation. Most manufacturers recommend an American Gear Manufacturer's Assoc. premium grade oil with a mild extreme pressure additive and with a viscosity number suitable for the prevailing operating conditions.

The permissible range of operating oil temperature for each viscosity number of automotive-engine oil may be used provided the viscosity number of the oil is suitable for the prevailing operating conditions. In each case, the minimum temperature is based on the ability of cold oil to flow properly through the lubricating channels and the maximum temperature is based on the ability of the hot oil to maintain adequate lubrication. The temperature ranges are wide for the purpose of permitting year-long operation with one viscosity grade of oil in localities where seasonal air temperature range will allow. The operator should select the grade best meeting his temperature range. If the summer-to-winter range is too great for a single viscosity grade, the oil must be changed accordingly.

It is suggested that nameplates on pumping unit reducers carry at least a reference to API RP 11G.³

Changing the Oil

The life of a pumping unit reducer may be increased by using oil of a suitable viscosity and by keeping the oil free from foreign material, sludge, and water. Oil should be changed in the spring and fall to maintain proper viscosity if the seasonal temperature range exceeds the temperature range of the oil used in Table 10.2 or 10.3.

The method used to determine how often oil should be changed to maintain the desired condition is a matter of

policy with the individual company. Some operators periodically inspect reducers and take samples of oil for laboratory analysis to determine the percentages of water and solid material in the oil. Checks may also be made on viscosity and properties such as acidity. Oil is changed whenever the analysis shows that the limit set for any one of the various factors has been exceeded.

Other operators depend upon periodic visual inspection to determine when to change oil. An inspection includes a look inside the reducer case and an examination of a sample of oil that has been drawn off the bottom of the reducer case and allowed to settle. Oil is changed when an inspection shows (1) deposits on the surfaces inside the reducer, (2) emulsification of oil, (3) sludging of oil, or (4) contamination of oil with foreign material such as dirt, sand, or metal particles. Sludging and emulsification of the oil are usually found if there has been an excessive accumulation of water in the reducer.

A small amount of water can accumulate in the bottom of the reducer. Such water should be drawn off to prevent accumulation to the point where it will be carried with the oil and cause emulsification or sludging.

The time interval between inspections to determine the condition of the oil depends upon operating conditions. Adverse conditions that may require inspection and change of oil as often as every 3 or 4 months include (1) intermittent operation, (2) excessive dust, (3) hydrogen sulfide fumes, or (4) a combination of high humidity with high variation in daily air temperature. Under the most favorable conditions of minimum daily and seasonal temperature changes, low humidity, and freedom of atmospheric dust, a reducer may operate through one or more years before the oil becomes contaminated or deteriorates to the point that an oil change is required.

If petroleum solvent is used for flushing, all the flushing agent should be removed and the reducer immediately refilled with a suitable oil. If the reducer is not immediately returned to operation, the unit should be operated for at least 10 minutes, or longer if necessary, to ensure that all surfaces are covered with a protective film of oil.

Chapter 10

Pumping Units and Prime Movers for Pumping Units: Part 2—Prime Movers for Pumping Units

Sam Curtis, SPE, Sargent Oil Well Equipment

Ernest Showalter, SPE, Sargent Oil Well Equipment

Introduction

Pumping units are driven by either electric motors or internal-combustion engines. Each type of prime mover has characteristics that make it more appropriate, depending on field conditions and energy availability. These prime mover characteristics are covered in detail in their respective sections.

In this section, wellsite is considered the area around the well where the pumping unit and prime mover are located.

Internal-Combustion Engines

The availability and economics of the power source frequently dictate that internal-combustion engines be selected to drive pumping units. For the sake of brevity, internal-combustion engines are simply called “engines” throughout this chapter. Basically, engines used on pumping units are divided into two speed classifications: slow-speed engines and high-speed engines.

Slow-speed engines are those with one or two cylinders, which generally have a maximum crankshaft speed of 750 rev/min or less. High-speed engines are multicylinder (usually four or six cylinders) and have an average speed of more than 750 but not more than 2,000 rev/min.

Generally, high-speed engines have less torque than comparable horsepower, slow-speed engines. Therefore, high-speed engines will experience greater speed variation on the cyclic load of a pumping unit. Considerable speed variation at the prime mover has many benefits on various components of a sucker-rod-beam-type pumping unit system.^{5,6} While governors tend to limit speed var-

iation, it will not be eliminated. Speed variations of up to 35%, with resulting reductions in cyclic loads, have been measured on high-speed engine-driven pumping units.

Two-Stroke Cycle

Two-stroke cycle engines or two-cycle engines complete their work in only two strokes of the piston, which is accomplished with one revolution of the crankshaft. The two strokes are compression and power. The process of filling the cylinder with a fresh charge and exhausting the burned gases occurs almost simultaneously near the end of the power stroke. The horizontal sliding piston first uncovers exhaust ports and then uncovers intake ports, which charges the cylinder and thereby flushes out the exhaust gases. Because some of the fuel is lost at this point, two-cycle engines, above about 40 hp, are equipped with fuel injection systems that raise their fuel efficiency close to that of a four-cycle engine. Normally, a two-cycle engine, for a given displacement and speed, develops 1.6 times the power of an equivalent four-cycle engine.

The two-cycle engine normally is built as a crosshead type. This construction uses a bore in the engine base, where a crosshead is mounted to take the angular thrust of the connecting rod, and places a seal between the cylinder and crankcase. Contamination of lubricating oil is thereby reduced. Lubrication of the cylinders is accomplished by using an auxiliary oiler that injects a prescribed amount of oil into the cylinder/piston area.

Fig. 10.14—Slow-speed, four-stroke engine on a beam-type oilwell pumping unit.

Most two-cycle engines are the slow-speed variety. These are available with a single cylinder or multiple cylinders in sizes ranging from about 15 to 325 hp. These engines have twice the power strokes of four-cycle engines and, for that reason, a smaller flywheel is required and additional speed variation is possible.

To operate most efficiently, two-cycle engines should be fairly well loaded. The proper size and length of exhaust pipe is very critical on this engine. Actually, the exhaust system completes the scavenging system. The properly sized pipe then is fitted to the correct length, as recommended by the manufacturer. This tuning of the pressure waves allows the engine to develop maximum efficiency and power. Incorrect exhaust-pipe length has a detrimental effect on the life, power, and operation of the engine.

Ideally, this type of engine operates only on natural gas or liquid petroleum (LP) gas. Some sizes may be operated on diesel fuel, but these engines must be derated.

Four-Stroke Cycle

An engine designed for four-stroke cycle or Otto cycle is called a “four-cycle engine.” The four-stroke cycle includes intake, compression, power, and exhaust. Intake and exhaust valves are mounted in the cylinder head or the block and are actuated by cams and push rods. The crankcase is connected directly to the cylinder, and contamination of the lubricating oil occurs sooner than it does in crosshead-type two-cycle engines.

The four-cycle engine is built in slow- and high-speed versions. Slow-speed engines usually have their cylinders

mounted horizontally, whereas high-speed engine cylinders are mounted vertically.

These engines use trunk pistons fastened to the crankshaft by connecting rods. Intake and exhaust valves are mounted in the cylinder head and actuated by cams and push rods.

A slow-speed, four-cycle engine as shown in Fig. 10.14 usually is built with a single horizontal cylinder. A large unenclosed flywheel is provided to store energy and deliver at a fairly constant speed to the pumping unit.

High-speed, four-cycle engines are multicylinder and can operate at speeds up to approximately 2,000 rev/min. Normally, four- and six-cylinder engines are not operated at more than 1,400 rev/min to maximize engine life.

A typical four-cycle, high-speed engine used as a prime mover on a beam-type pumping unit is shown in Fig. 10.15. This type of engine can operate on natural gas, LP gases, or gasoline.

Diesel and Oil Engines

Some slow-speed, single-cylinder engines burn diesel or fuel oil by high-pressure injections into the cylinder. The compression is much greater than gas engines. Heat, developed by compressing the air in the cylinder, ignites the fuel sprayed into the cylinder. These engines are divided into two types: full diesels, which are cold-starting, and semidiesels, which require heating to start.

The cold-starting diesel has a compression ratio of 14:1, resulting in a pressure of approximately 500 psi. The semidiesel has approximately 250 psi compression, which requires a hot tube heated by a torch or electric glow plug

Fig. 10.15-Typical four-cycle, high-speed engine used as prime mover on a beam-type pumping unit.

to produce enough heat to ignite the charge. Once these engines are started, enough heat is produced in the cylinder to cause ignition of the fuel as it is injected into the cylinder.

High-speed, multicylinder diesel engines have been improved until they are now adaptable for oilwell pumping. These are not used commonly where gas is readily available. Diesel engines fill a need where other fuels are not readily available.

Selection of Engine

Five factors should be considered when determining which engine to purchase: fuel availability, equipment life and cost, engine safety controls, horsepower, and installation.

Fuel Availability. Natural gas is the logical choice. Taken from the wellhead casing annulus, it is called "wet gas" and is used most frequently. Where there is insufficient gas available at the wellhead, gas may be piped to the engine from the field separator. In either case, the gas must be scrubbed to remove oil and water. This is done in a double compartment volume tank where gas pressure also is reduced by a regulator. Gas from the separator will have most of the moisture and oil removed and is considered a better fuel.

Sour gas is a natural gas that contains excessive sulfur or CO_2 and is not considered a good fuel. Two percent sulfur is considered excessive. Where sour gas must be used, suitable treaters are required to improve the quality of the fuel. Sour gas causes severe etching and wear of engine parts as well as quick contamination of the lubricating oil in the four-cycle engines. Two-cycle engines fare slightly better because of their construction.

Residue gas is natural gas that has had impurities removed at a refinery and then is piped back to the field. This is sometimes called "dry gas."

LP gases, butane, and propane are excellent gases for internal-combustion engines, if economically available. Such gases must be stored under pressure in suitable pressure tanks to keep them liquefied for transportation. Vaporizers must be provided to turn the liquid into gas form for use in engines. On small engines, the vapor usually can be drawn off through a reducing regulator to provide sufficient gas; however, on larger engines, the fuel must be vaporized before entering the engine. Butane freezes to liquid at 0°C , while propane does not reach this state until -42°C . A blend of butane/propane is often used in mild climates.

Dual-fuel engines can use natural gas as long as it is available, but as soon as the pressure drops, the standby fuel is fed automatically to the engine in sufficient quantity to keep the prime mover going continuously. Such systems are designed primarily for gaseous fuels, but similar systems can switch from dry gases to gasoline or vice versa. Dual-fuel installations should not be overlooked if there is a shortage of natural gas.

Diesel fuel specifications are supplied by manufacturers of diesel engines. These fuels must be free of moisture and in clean dirt-free containers. Filters must be used to ensure that only clean fuel gets to the engine.

Some engines that are really semidiesel can burn crude oil of light gravity, but this must be cleaned satisfactorily. The type of crude must meet the standard set by the engine's manufacturer.

Equipment Life and Cost. The fact that the slow-speed engine may run at 400 rev/min and the high-speed engine may operate at 1,200 rev/min lends logic to the the-

ory that slow-speed engines generally outlast high-speed engines. Compared with high-speed engines, slow-speed engines have a longer life, are heavier, and cost more initially. A slow-speed engine requires fewer parts and is easier to repair; thus maintenance will cost more for the high-speed engine. A slow-speed engine's average life between major overhauls is somewhere between 5 and 10 years, whereas a high-speed engine's life is 2 to 5 years; albeit, there are exceptions to these averages.

Pumping unit and sucker rod life should be longer if a high-speed (lower-torque) engine is used because of greater speed variation.

Longer-interval maintenance features are available on all engines to reduce costs and extend equipment life.

1. Low-tension ignition provides better ignition with longer life to magnetos and spark plugs.

2. Extended service clutch requires lubrication only once each 6 months.

3. Automatically filling the crankcase on the engines from drums of oil ensures correct oil-level at all times.

4. Water makeup condensers provide water for the radiator automatically as required.

Engine Safety Controls. Every oilfield engine should be provided with reliable safety controls since the engines in this type of service usually are unattended. Some engine manufacturers provide safety controls as standard equipment. If not originally equipped, safety controls are available from supply companies.

Safety controls usually ground the magneto, and will shut off the fuel to stop the engine. Most desirable safety controls for engines are: (1) high water temperature, (2) low oil pressure, (3) overspeed, and (4) pumping unit vibration (to shut down the unit in case of sucker rod break).

Horsepower. API 7B-11C covers the procedure for testing and rating of engines.⁷

Maximum standard brake horsepower for engine and power unit (including accessories) is measured at various rev/min for intermittent and continuous operation. Torque and fuel consumption measuring procedures also are outlined in the API specification.

At any rotational speed, maximum brake horsepower will be the greatest horsepower corrected to standard conditions [29.4°C and 29.38 in. of mercury] as outlined under Test Procedures.

The manufacturer usually shows rating curves below the API curve, which is based on the power that the engine can produce for various conditions of service. Experience has shown that, for the cyclic load of oilwell pumping, high-speed engines must be derated more than slow-speed engines to provide a margin of safety to stand up in continuous service. Normal oilfield horsepower ratings for continuous duty, at the speed the engine will be operated, are (1) slow-speed engine (API)=maximum standard bhp×0.80, and (2) high-speed engine (API)=maximum standard bhp×0.65.

Altitude and temperature corrections (approximate) for altitude and temperature for naturally aspirated engines may be made as follows.

1. Deduct 3% of the standard brake horsepower for each 1,000-ft rise in altitude above sea level.

2. Deduct 1% of the standard brake horsepower for each 6°C rise in temperature above 29°C, or add 1% for each 6°C fall in temperature below 29°C.

Information concerning these corrections for turbo-charged engines should be secured from the manufacturer.

Calculations. Sizing prime movers to drive pumping units was discussed as part of the pumping unit load calculations in Part 1. The equation used to calculate brake horsepower, P_b , for slow-speed engines and high-slip NEMA (Nat'l. Electrical Manufacturers Assoc.) D motors* is⁸:

$$P_b = \frac{q \times D}{56,000}, \dots \dots \dots (3)$$

where

P_b = brake power, hp,

q = fluid flow rate, B/D, and

D = depth (lift), ft.

The bhp equation given for high-speed engines and normal-slip NEMA C motors** is⁷

$$P_b = \frac{q \times D}{45,000}, \dots \dots \dots (4)$$

These equations are empirical and result from modifications of the basic horsepower equations.

Hydraulic horsepower needed for actual lifting of the fluid is only a small portion of the total power required by the pumping system.

$$P_h = \frac{q \times D \times W}{33,000 \times 24 \times 60}, \dots \dots \dots (5)$$

where

P_h = hydraulic power, hp,

q = fluid flow rate, B/D,

W = weight of barrel of fluid, lbm,

D = depth (lift), ft, and

33,000 = conversion factor, ft-lbf/min.

For a fluid with 1.0 specific gravity

$$\begin{aligned} P_h &= \frac{q \times D \times 42 \times 8.3356}{33,000 \times 24 \times 60} \\ &= \frac{q \times D \times 350}{47,520,000} \\ &= \frac{q \times D}{135,735}, \dots \dots \dots (6) \end{aligned}$$

*High-slip motors are defined here as NEMA D, 5 to 8% slip. The sizing of ultrahigh-slip motors with over 13% slip is presented in the electric motor portion of this section.

**Normal-slip motors are defined as NEMA C, 3 to 5% slip.

where

42 = conversion factor, gal/bbl, and
8.3356 = conversion factor, lbm/gal.

Additional power is required to offset the frictional losses in the subsurface system.

Frictional horsepower has been defined empirically by Slonneger.⁹ (This may be low for extremely viscous crudes, such as those of 10°API gravity encountered in the Boscan field in Venezuela.)

$$P_f = \frac{\frac{1}{8}W_r \times 2S \times N}{33,000}, \dots\dots\dots (7)$$

where

P_f = power to overcome subsurface friction, hp
 W_r = weight of rods, lbm,
 S = polished-rod stroke, ft, and
 N = strokes per minute.

Frictional horsepower added to hydraulic horsepower equals polished-rod horsepower. The power required at the prime mover can be calculated by assuming a surface efficiency of 75 to 93%, depending on geometry and type of bearings in the pumping unit.

Example Problem 1. A well of 6,000-ft depth, producing 200 B/D of 1.0 specific gravity fluid using a 64-in. stroke unit, a pump with a 1½-in. bore, ¾-in. rods (1.64 lbm/ft, 14.4 strokes/min, and anchored tubing being assumed), can have its hydraulic and frictional horsepower calculated as follows:

$$\begin{aligned} P_h &= \frac{q \times D}{135,735} \\ &= \frac{200 \times 6,000}{135,735} \\ &= 8.84 \end{aligned}$$

and

$$\begin{aligned} P_f &= \frac{\frac{1}{8}W_r \times 2S \times N}{33,000} \\ &= \frac{\frac{1}{8}(1.64 \times 6,000)2(64/12) \times 14.4}{33,000} \\ &= \frac{(1,230)(10,666) \times 14.4}{33,000} \\ &= 5.72. \end{aligned}$$

The horsepower required at the polished rod, P_{pr} , is

$$\begin{aligned} P_{pr} &= P_h + P_f \dots\dots\dots (8) \\ &= 8.84 + 5.72 \\ &= 14.56. \end{aligned}$$

The horsepower required at the prime mover, P_{pm} , assuming a pumping unit with an efficiency of 85% is

$$\begin{aligned} P_{pm} &= \frac{P_{pr}}{85\%} \dots\dots\dots (9) \\ &= \frac{14.56}{0.85} \\ &= 17.13. \end{aligned}$$

Because of the cyclic nature of pumping unit loads and the fact that the preceding calculations reflect average horsepower, a factor must be applied in sizing to ensure that there is adequate horsepower available to handle peak loads.

Both high-speed engines and 3- to 5%-slip electric motors have limited torque available and should be derated 35% to handle peak loading. Generally, slow-speed engines, with higher torque capabilities, and NEMA D electric motors do not require more than 20% derating.

When using the cyclic load derating factor, F_{cl} , of 0.8 in the equation, the following prime mover horsepower will be required.

Slow-speed engine or NEMA D motor horsepower:

$$\begin{aligned} P_{pm} &= \frac{P_h + P_f}{E_{pu} \times F_{cl}} \dots\dots\dots (10) \\ &= \frac{8.84 + 5.72}{0.85 \times 0.80} \\ &= 21.41, \end{aligned}$$

where E_{pu} = pumping unit efficiency and F_{cl} = cyclic load derating factor.

High-speed engine and NEMA C horsepower:

$$\begin{aligned} P_{pm} &= \frac{8.84 + 5.72}{0.85 \times 0.65} \\ &= 26.35. \end{aligned}$$

The results of this method of horsepower calculations compare favorably with the results of the abbreviated method of Eqs. 3 and 4 as follows.

Slow-speed engine horsepower:

$$\begin{aligned} P_h &= \frac{q \times D}{56,000} \\ &= \frac{200 \times 6,000}{56,000} \\ &= 21.43. \end{aligned}$$

High-speed engine horsepower:

$$P_b = \frac{q \times D}{45,000}$$

$$= \frac{200 \times 6,000}{45,000}$$

$$= 26.66.$$

Under most conditions, the use of the illustrated method should provide adequately sized prime movers. Sizing prime movers for viscous crude may require additional frictional horsepower. In this case, experience is the best guide.

A rule commonly used in sizing high-speed engines for long life on pumping units is: 10% of engine's cubic-inch displacement as available brake horsepower. Hence, an engine with 817 cu in. of displacement can be relied on to handle an 81.7-hp pumping load.

A prime mover's minimum operating speed always should be greater than its speed at maximum torque output. This will ensure that, as the torque requirement of the pumping unit increases and the prime mover speed decreases, adequate torque capacity will be available. This is extremely important on high-speed engine drives.

Installation

The prime mover must be installed correctly to ensure good results. Most pump installations use a V-belt drive from prime mover to pumping unit. Slide rail motor mounts or some means of adjustment is necessary to provide for installation and proper tension that allows for power to be transmitted with minimal loss through belt slippage. When the prime mover is installed, the belts should be aligned and tightened properly but not over-tightened. Overtightening will overload the prime mover's shaft and bearings.

Slow-speed engines require sturdy foundations such as a steel base set on concrete or set directly on rails embedded in concrete. The slide rails should be set in line with the cylinder because of the horizontal moving forces. Cross rails, sometimes called universal rails, should be used only on small engines. Most manufacturers provide prime movers with properly designed slide rail assemblies.

Multicylinder or vertical engines, in which the forces are in a vertical plane, can be set on much lighter foundations. Cross rails on such installations are the preferred method.

Provisions must be made for exhaust and fuel lines to the engine. The manufacturer furnishes specifications for their installation. Usually, four-cycle engines come equipped with both a small silencer and a short exhaust pipe. Two-cycle engines are not equipped with such equipment unless specifically ordered by the customer.

The gas line is brought to a scrubber, then through a regulator to reduce the gas pressure to a few ounces before entering the volume tank. Normally, 1-in. pipe is the smallest size recommended from the volume tank to the engine. Larger engines may require larger lines. The purpose of the volume tank is to prevent fluctuations of gas pressure. It should have a volume of at least five times the cylinder displacement of the engine.

The gas regulator must be fitted with a properly sized orifice to maintain the proper gas flow. A regulator with too large an orifice will cause surges, whereas too small an orifice will not supply enough fuel to produce the power required.

Suitable cutoffs are required between the source line and volume tank, and the volume tank and engine. These cutoffs assist with draining the scrubber and volume tank, and also servicing of the reducing regulator.

For engine starting, many types of starters are used. Electric starters were put in automobiles, and soon were adapted to multicylinder oilfield engines. Formerly, slow-speed engines were started by manually turning the large flywheel. Some manufacturers provide electric or other built-in starters as optional equipment. Examples of starters include the following.

1. For electric starter motors requiring from 6- to 24-V direct current, power is furnished by batteries.
2. 110- to 440-V AC power and lighting circuits also are used for starter motors.
3. Air or gas motor starters in which a small vane-type air motor turns the engine through reduction gears and a Bendix-type engaging mechanism. This type of starter requires from 20 to 50 psi of gas or air pressure to operate.
4. Friction wheel starters for slow-speed engines use a small gasoline motor or an electric motor to turn a friction wheel, which engages the engine flywheel and turns the engine.
5. High-pressure air starting is sometimes applied to slow-speed engines, in which a valve admits air compressed from 125 to 200 psi into one or more cylinders to cause the engine to rotate. Usually a small engine-driven compressor is connected to a tank, which is used as a compressed air storage tank.
6. Diaphragm gas starters in which a rather large rubber diaphragm is expanded by 20- to 50-psi gas pressure cause a rack to turn a pinion attached to the engine crankshaft.
7. Gasoline-driven engine starters mounted on the engine can be used to provide power through reduction gears to start an engine.

The electric motor starter of 6 to 24 V is probably the most widely used of all starters on small engines. The battery can be located near the engine and charged by an engine-mounted generator. Portable cables from the engine can be attached easily to the batteries in trucks or automobiles. In this case, only one set of batteries would be required for starting several engines.

Large slow-speed engines are best started by using high-pressure air supplied by a small compressor and storage tank assembly. This system is simple and foolproof. The air compressor also can be used for cleaning or spray painting around the installation. Compressor units mounted on pickup trucks will accommodate starting a large number of engines and reduce the installation expense.

API RP 7C-11F is a good guide for engine operators.¹⁰ This publication should supplement the manufacturer's recommendations for installation, maintenance, and operation of internal-combustion engines.

Electric Motors for Oilwell Pumping Design Standards

Three-phase induction motors generally are classified by NEMA as being either B, C, or D. Ultrahigh-slip motors are classified by NEMA as a special purpose motor. The

Fig. 10.16—Typical ratings for horsepower rated motors and ultrahigh-slip motors.

following is a portion of the NEMA specifications for these classified motors (Fig. 10.16).

NEMA B. Normal slip no greater than 3%, and normal starting breakaway torque 100 to 175% of full-load torque.

NEMA C. Normal slip no greater than 5%, and starting torque 200 to 250% of full-load torque.

NEMA D. High slip 5 to 8%, and starting torque 275% of full-load torque.

NEMA D Special. High slip 8 to 13%, and starting torque 275% of full-load torque.

Ultrahigh-slip motors, which have greater than 13% slip in high-torque mode, fall into an area not standardized

by NEMA. This motor, classified as a special purpose motor, is manufactured exclusively for the beam-type oil-well pumping unit. Designed with ultrahigh slip, the resulting wide speed variations produce benefits for the mechanical loading on the pumping unit. Fig. 10.16 illustrates typical ratings for one size of a multiple-rated ultrahigh-slip pumping motor.

High-Torque Mode. Maximum slip 17%, and high starting torque 410% of full-load torque.

Medium-Torque Mode. Maximum slip 21%, and starting torque 320% of full-load torque.

Medium-Low-Torque Mode. Maximum slip 27%, and starting torque 260% of full-load torque.

Low-Torque Mode. Maximum slip 32%, and starting torque 225% of full-load torque.

Horsepower Ratings of Motors

Three-phase induction motors are available in a wide range of horsepower ratings: 1, 1½, 2, 3, 4, 5, 7½, 10, 15, 20, 25, 30, 40, 50, 60, 75, 100, 125, 150, and 200. Most motors found on pumping units range from 10 to 75 hp. These motors are available in synchronous speeds of 600, 720, 900, 1,200, 1,800, and 3,600 rev/min. The majority of the three phase 460-V induction motors used on pumping units are 1,200 rev/min.

Multiple Horsepower Rated Motors

When a new well is completed, sizing is based on basic information provided by the depth of the pump and fluid, size of pump, stroke length, speed of pumping unit, and specific gravity of the fluid. There are many variables in calculations that are not always considered and may affect the required motor size. Sometimes, overlooked variables influencing loading on the motor are: actual fluid level, viscosity of fluid, deviation of hole, friction in the pump, friction in the stuffing box, excessive friction coming from the pumping unit, and quality of electric power available. Because of the many variables involved, it is sometimes difficult to size a motor accurately for new installation on the first attempt. Sometimes multiple-rated motors are considered as pumping unit drivers.

Multiple horsepower rated motors usually have three different modes available. Table 10.4 lists typical sizes available.

TABLE 10.4—TYPICAL SIZES (hp) OF MULTIPLE-HORSEPOWER-RATED MOTORS

HP	HP	HP
5	3.5	2
10	7	4
15	9	6
20	14	8
25	14	10
30	21	12
40	28	16
50	35	29
75	52	30

Multiple Size Rated Motors

An ultrahigh-slip motor is also a multiple-rated motor, usually being quadruple rated. The stator winding of this motor has been designed for multiple connections. The ultrahigh-slip capability is a result of special design characteristics incorporated in its rotor. Fig. 10.16 is two graphs that show a comparison of ultrahigh-slip motors to the horsepower rated motors. The first illustration shows the horsepower rated motors with only one torque mode available. The second shows an ultrahigh-slip motor with four-mode capability. For maximum benefits, the ultrahigh-slip motor should be used in the lowest-torque mode possible without exceeding its thermal limit.

Single-Phase Motors

Single-phase (AC) motors are also found in the oilfield in sizes up to 10 hp, although their use is limited. These single-phase motors are confined to shallow stripper wells producing in fields where three-phase power is not available.

Single-phase motors initially cost more than their three-phase counterpart with like rating. These operate less efficiently. To ensure high starting torque and low operating current, single-phase motors of the capacitor-start capacitor-run varieties should be used.

DC Motors

Direct-current (DC) motors have a very limited use on the beam-type pumping unit. DC voltage cannot be changed by transformers, which make transmission and distribution difficult without high line losses. Initial costs and maintenance for DC motors and controls are higher than for induction motors. Power available from utilities is normally 60 Hz AC, and cannot be used for DC motors.

Electric Generating Systems

Where utility-furnished power is not available, generators may be used to provide electrical power required for operation of the pumping units. This system allows the operator the benefits of electrification. When selecting equipment for the generating system, consider which type of motor will most efficiently use generator power. The ultrahigh-slip motors, which use fewer kilovoltamps (kVA) than conventional horsepower rated motors, are very popular. Distribution equipment for the generator system would be the same as for utility power if it were furnished. Generated voltage depends on the size of the electrified field. The following considerations determine the most desirable generated voltage.

1. Where the system consists of a small number of wells (one to five) with short distances from generator to well-site, the generator voltage may be the same as the motor rated voltage.

2. Where the field consists of many (5 to 50) wells, the distribution voltage should be higher than the motor rated voltage to minimize voltage drop. At each motor, a step-down transformer would be used. This system would be considered a moderately sized system with a generator having a distribution of 2,300 or 4,160 V.

3. In an exceptionally large field (50+ wells), the generator voltage would be stepped up to 7,200 or 13,800 V for distribution. At each wellsite, a transformer would be installed to drop the distribution voltage to motor rated

voltage. The generated voltage could be 2,300 or 4,160 V. The higher voltage allows smaller conductors to carry the loads and lessen line drop voltage within acceptable limits.

The procedure used in selecting primary and secondary equipment should be the same as that used by the utility companies. Protective devices and grounding procedures outlined in this chapter apply to either system.

Selecting Motor Size

Proper operation of the pumping unit depends mainly on properly sizing the components. Too often motors are oversized because the operator does not want to risk underpowering equipment. Choosing a large enough motor will ensure minimum motor failures and perhaps longevity of the motor. This does not take into consideration the effects a too-large motor has on the mechanical loading of the pumping system and the added cost in electrical power consumption.

For sizing of horsepower rated motors, refer to prime mover horsepower calculations shown in the engine section.

Proper use of the ultrahigh-slip motors requires that the motors not be oversized to obtain maximum speed variation and resulting benefits. Ultrahigh slip motor manufacturers have established methods of sizing their motors for pumping units. It is important that the sizing method used be approved by the motor manufacturer. Motors having different characteristics require different considerations for sizing. Table 10.5 shows a method used by one manufacturer.

Voltage Frequency

Induction motors may be operated from utilities or generators where frequency is other than the designed frequency. It is a common practice to operate 60-Hz motors at 50 Hz when certain conditions are met. If the V/Hz ratio is maintained as frequency is changed, the motors will operate satisfactorily but with new characteristics.

$$F_c = V/f \dots\dots\dots (11)$$

or

$$V = F_c f,$$

where

F_c = characteristics ratio, V/Hz,

V = electrical potential, V, and

f = frequency, Hz.

Example Problem 2. If a 460-V, 60-Hz motor is used where a 50-Hz frequency is available,

$$\begin{aligned} F_c &= \frac{460}{60} \\ &= 7.66 \end{aligned}$$

SIZING INSTRUCTIONS

$$\text{Load calculated} = C \times D \times S \times F_s \times \gamma,$$

where

C = a constant, the value of which is different for each size of plunger as shown above,

D = depth to fluid, ft,

S = polished rod stroke, in.,

F_s = a constant, the value of which is different for each number of strokes per minute (see above), and

γ = specific gravity of fluid being lifted.

The load capacity must be greater than load calculated.

Example: 1 $\frac{3}{4}$ -in. plunger, 120-in. polished-rod stroke, depth to fluid = 7,000 ft, 12 strokes/min., and specific gravity = 0.97.

$$\text{Load calculated} = 0.357 \times 7,000 \times 120 \times 0.193 \times 0.97 = 56,140.$$

A size 4, medium-torque mode, load capacity = 59,840.

Size 5*, medium-low-torque mode, load capacity = 59,590.

*The Size 5 MLT will have more maximum speed variation available as:

$$4 \text{ MT} = \frac{56,140}{59,840} \times 37\% = 35\% \text{ maximum SV.}$$

$$5 \text{ MLT} = \frac{56,140}{59,590} \times 45\% = 42\% \text{ maximum SV.}$$

Maximizing speed variation will maximize pumping load reductions.

Fig. 10.17--Ultrahigh-slip motor used as prime mover on a beam-type pumping unit.

and

$$V = 7.66 \times 50$$

$$= 383.1$$

If the voltage changes to 383 V, the motor will operate satisfactorily at the new ratings. The change in performance should be obtained from the manufacturer. Approximations of changes in characteristics when using 60-Hz rated motors on 50-Hz power are: synchronous speed is $\frac{5}{6}$ of 60-Hz rating, horsepower is $\frac{5}{6}$ of 60-Hz rating, torque is approximately the same, motor amps are the same as 60-Hz rating, and applied voltage is $\frac{5}{6}$ of 60-Hz rating. A standard voltage in some countries is 415 at 50 Hz, which is 10% over the design voltage for 50 Hz. The motor will operate satisfactorily but at different characteristics. Contact the motor manufacturer for the change in ratings and performance characteristics.

On either 50- or 60-Hz operation, control components so marked have dual rating. If the voltage is changed, as shown in the example for motors, the devices would operate equally well at 50 or 60 Hz. Where control devices are not marked for dual frequency, contact the manufacturer to obtain their rating at the new frequency.

Motor Performance Factors

Electric motors have a wide variety of operating characteristics. When buying equipment for oilwell pumping

units, factors that contribute to the performance of the electric motor must be understood. This section discusses terms that describe the operating characteristics of the electric motor (see Fig. 10.17).

Motor Slip. Motor slip applies only to induction motors. Induction motors have a synchronous speed that is a function of applied voltage frequency and the number of poles in the stator winding. Table 10.6 represents a relation between the number of poles and synchronous rev/min for 50 and 60 Hz.

The majority of oilwell units use the six-pole induction motor. Three-phase voltage, when applied to the stator winding of an induction motor, causes a rotating magnetic field at the synchronous speed shown in Table 10.6. As a result of this voltage in the stator, there will be current and a magnetic field in the rotor. The interaction in

TABLE 10.6--INDUCTION MOTOR
POLES VS. SYNCHRONOUS SPEEDS
FOR 50- AND 60-HZ FREQUENCY

Number of Poles	Rev/Min at 60 Hz	Rev/Min at 50 Hz
2	3,600	3,000
4	1,800	1,500
6	1,200	1,000
8	900	750
10	720	600

TABLE 10.7—FULL-LOAD SLIP FOR NEMA RATED AND ULTRAHIGH-SLIP MOTORS

NEMA RATED	
NEMA B:	no more than 3%
NEMA C:	no more than 5%
NEMA D:	5 to 8%
NEMA D:	(special) 8 to 13%

Medium mode	21
Medium-low mode	27
Low mode	32

the stator between the rotor magnetic field and the rotating magnetic field is responsible for the turning action or torque of the electric motor. The difference in percent between the speed of the rotating magnetic field and the rotor is the slip of the motor.

All motors have a design slip, which is the slip the motor has when running full load. Published slip values for motors are based on full load rating.

Table 10.7 illustrates the full-load slip for NEMA rated and ultrahigh-slip motors (see Fig. 10.22).

Slip is calculated by the following equation.

$$F_s = \frac{V_s - V_{fl}}{V_s} \times 100, \dots \dots \dots (12)$$

where

F_s = motor slip factor, %,
 V_s = synchronous speed, rev/min, and
 V_{fl} = full load speed, rev/min.

Example Problem 3. If a six-pole, 1,200-rev/min synchronous induction motor has a full-load speed of 850 rev/min, the motor slip is 29.16%.

$$F_s = \frac{1,200 - 850}{1,200} \times 100$$

$$= 29.16\%.$$

The design slip of the oilwell pumping motor is a very important feature. The speed of the induction motor is reduced as more torque is required. In the case of the pumping motor, when large amounts of torque are required there will be a slowing down of the motor's rotor. As the rotor slows down, less motor torque will be required to drive the pumping unit.

There are two different torque reductions to be considered. (1) Torque resulting from polished-rod loading is reduced as a result of lower acceleration at peak torque moments.⁵ (2) Torque reduction is achieved because of inertial effects of the changing speed of the pumping unit.⁶

Fig. 10.18 shows a comparison of speed/torque curves for motors of various slip ratings. All motors on this chart have essentially equal full-load capacity on a beam-type

Fig. 10.18—Comparison of speed/torque curves for motors of various slip ratings.

pumping system as a result of the derating factors necessary for cyclic load operation.

The broken-line curve in Fig. 10.18 represents the maximum torque and minimum speed under which each of these motors will operate on the same pumping load. One will see that the changing speed of the higher-slip motors will have beneficial effects on the pumping equipment.

Motor Speed Variation. Motor speed variation depends on a maximum and minimum rev/min of the motor. Motor slip and motor speed variation are two different but related factors. Each is represented by a value in percent and all are calculated by very similar equations.

Speed variation:

$$F_{sv} = \frac{V_{max} - V_{min}}{V_{max}} \times 100, \dots \dots \dots (13)$$

where

F_{sv} = speed variation factor, %,
 V_{max} = maximum motor speed, rev/min, and
 V_{min} = minimum motor speed, rev/min.

Example Problem 4. An oilwell pumping motor having a maximum speed of 1,180 rev/min and a minimum speed of 690 rev/min will have a speed variation of 41.52%:

$$F_{sv} = \frac{1,180 - 690}{1,180} \times 100$$

$$= 41.52\%.$$

Speed variation on the cyclic load of the sucker rod pumping is considered beneficial. As torque demand of the system increases, motor speed decreases, thereby reducing acceleration. The force required to accomplish

work equals mass times acceleration; hence, a reduction in acceleration causes a reduction in force ($F = m \times a$).

Another benefit of increased speed variation is increased plunger overtravel, which occurs frequently. The instantaneous speed of the pumping unit is significantly greater at the top and bottom of the stroke where there is little or no torque on the pumping unit and motor. At these points, the induction motor will speed up toward its synchronous (no-load) speed, frequently increasing plunger overtravel.

Motor Power Factor. Motor power factor, being a number between zero and one, is a measure of the phase relation between the volts applied to a motor and the amps of the motor. In an induction motor, the motor current will lag the voltage by a certain amount of electrical degrees. The cosine of this angle is the power factor. In cases where the current and voltage are in phase, the angle is zero; consequently the power factor is one. The other extreme would be where the current was 90° out of phase with the voltage, which would result in a phase angle of 90° with a power factor of zero. In the case of the induction motor, which involves magnetizing devices, the current will lag the voltage. In the case of a circuit containing a large amount of capacitance, the current may lead the voltage, which results in a leading power factor.

Motors and other magnetic devices used in the electrified oilfield develop lagging power factors. Operating conditions of the oilwell pumping motor influence the power factor. Motors operating at light load or multiple rating motors operating in too high a mode have a tendency to produce low power factors. Motors allowed to regenerate as a result of the pumping unit's being unbalanced will have a momentary power factor of near zero.

High power factors reduce line losses, lower voltage drops to the motor, and reduce billing where electric utilities have power factor penalty clauses in their contract. Power factor correcting capacitors, normally connected to the motor leads, may be used to improve the power factor of the motor. Capacitors connected in this way will be in operation only when the motor is running.

There are several variables associated with the electric motor that will influence the power factor. To improve the power factor of a pumping unit motor, these factors should be considered: (1) properly balancing the pumping unit, (2) operating properly sized motors, and (3) operating in lowest-torque mode possible.

Motor Torque. Torque is a force that produces a twisting or turning effect. Torque measured in foot-pounds or inch-pounds is calculated by multiplying the distance from the center of rotation to the point where the turning force is applied by the force in pounds causing rotation. The motor adjusts its speed range in accordance with its design to develop the required torque.

Different NEMA design motors have different torque characteristics. The illustration in Fig. 10.18 shows a comparison of torque characteristics in the different classes of motors.

Motor Efficiency. The efficiency of the induction motor is a number in percent, which is the ratio of the output vs. the input.

$$E_m = \frac{P_{out}}{P_{in}} \times 100, \dots\dots\dots (14)$$

where

E_m = motor efficiency,

P_{out} = power output, and

P_{in} = power input.

During the pumping cycle when the load is light, efficiency will be low; when motor is peak loaded, efficiency will be very good. Because of the changing loads on the pumping units, a motor will travel through a varying range of speeds and its efficiency will vary accordingly. Determining or calculating the true root mean square (RMS) efficiency of the motor is extremely difficult. A very effective method of monitoring the efficiency is evaluating overall efficiency of the pumping system. This is determined on a kilowatt-per-barrel per-foot-lift basis. One should measure, over a designated period of time, kilowatts input to the motor, total production, and accurate fluid levels. If these measurements are collected under optimized conditions, they can prove beneficial in evaluating a motor's contribution to total system efficiency. Pumping motors may have a point peak efficiency of 85 to 90%. On pumping motors where loading will range from no load to 80% overload twice in one cycle, it is important that one not be overly impressed by a single-point efficiency. RMS efficiency throughout the pumping cycle and how it affects all system components is important.

Motor Cyclic Load Factor. A motor applied to the cyclic load of the oilwell pumping unit will be thermally heated more than it would be if the same average load were applied on a steady load basis. For this reason, a motor used for beam-type oilwell pumping units must incorporate the cyclic load factor in its full-load nameplate rating for proper application. Table 10.8 shows typical derating factors for two types of motors.

Motor Service Factor. Motors having single-horsepower ratings normally will include on their nameplate a service factor. The rated horsepower multiplied by this service factor represents a load that can be carried by the motor, provided that rated voltage and frequency are maintained and the temperature does not exceed the thermal limit of the motor.

The load on the motor is temperature-limited by the temperature rise of the motor or temperature limit of the insulation. Because of the cyclic load of the oilwell pumping motor, the horsepower rating or the service factor becomes meaningless. The load limit of the motor depends on the thermal amps required by the cyclic motor load.

The service factor is a rating applied to motors that are used in industries where loads are steady state. In the oilfield, the thermal amp load of the motor is compared to

TABLE 10.8—DERATING FACTORS FOR
NEMA C AND D MOTORS

Motor Type	Motor Derating Factor	Cyclic Load Factor
Design C	0.6 to 0.7	1.43 to 1.67
Design D	0.7 to 0.8	1.25 to 1.43

TABLE 10.9—MAXIMUM MOTOR TEMPERATURE AT 40°C AMBIENT TEMPERATURE (°C)

Ambient	40
Motor rise	90
Total	130
Safety factor	25
Class F insulation rating	155

TABLE 10.10—TEMPERATURE RATING OF INSULATIONS

Class	Temperature Rating	
	°C	°F
A	105	221
B	130	266
F	155	311
H	180	356

the nameplate rating of the motor. If the thermal amp load exceeds the rating of the motor, the motor is overloaded. The service factor cannot be multiplied times the full load rating of the motor to obtain a new thermal amp rating for the motor.

Motor Temperature Rise. It is important to understand how motor temperature rise and ambient temperatures influence the operating temperature of the motor. Temperature rise is the temperature that a motor, when run at full load conditions, will rise above ambient until all parts of the motor are at maximum stabilized temperature. Motor temperature rise is a design feature that normally is listed on the nameplate in degrees Celsius. If a motor starting at ambient temperature is operated at nameplate values for current, volts, and frequency until it has reached maximum operating temperature, the increase in the motor temperature above the ambient is the temperature rise of the motor. For example, if the ambient temperature is 40°C and a motor rated 90°C temperature rise is operated under full load conditions until the temperature is stabilized, the stabilized temperature of the motor would be 40°C + 90°C = 130°C. All motors have their temperature rise based on an ambient of 40°C (Table 10.9).

This same reasoning can be used to determine maximum motor temperature at other ambient temperatures. A comparison can be made between the maximum motor temperature and its insulation temperature limit. This comparison may explain why a motor fails or will not carry the desired load if ambient temperatures exceed 40°C.

In the design of the motor, the temperature rise of the motor will be limited by the class of insulation used.

Insulation for Oilwell Pumping Motors

Users responsible for oilwell pumping motors need to be aware of the type of insulation used in electric motors and how its limitations affect operation of the oilwell pumping motor. There are several classes of insulation as well as different processes of application in manufacturing. All of these influence cost and durability of the motor.

Insulation Classification. Table 10.10 shows the temperature rating (maximum hot-spot temperature) of insulations by classes.¹¹

In Table 10.9, there is a safety factor of 25°C. On days when the ambient temperature exceeds 40°C or if adverse loading causes the temperature rise to increase above 90°C, the motor will approach the maximum temperature limit of the insulation, which is 155°C. By analyzing the performance of the motor and ambient operating conditions it may be possible to determine that a motor forced to operate beyond the temperature limit of its class of insulation reduces its life by heat damaging the insulation.

Winding Insulation Materials. The winding insulation of the pumping motor has two distinct functions: (1) to provide electrical insulation of the winding and (2) to maintain a tight package, which prevents movement of motor windings that could mechanically damage the insulation on the conductors. Recognize that the torque of the motor is applied through the rotor to the shaft of the pumping unit, and this same force is applied to the winding in the motor. If the windings are not rigid, there will be moving or shifting of the windings, which will cause insulation damage. The pumping cycle of the oilwell motor may have amps as high as 180% of rating during the peak periods. These peak amps cause a high peak torque value, which may cause shifting of the windings unless they are maintained rigidly by insulating materials. Motor manufacturers should have special materials and process of application to provide a winding that has the mechanical and electrical strength required by the cyclic loading of the pumping unit motor. When motors are repaired, the manufacturer's instructions must be followed to ensure that the reconditioned motor has all the original characteristics.

Motor and Control Enclosures

Motors and their controls used on oilwell pumping units are exposed to environmental conditions. It is important to recognize the different enclosure ratings of motor and control to allow proper selection of the equipment. The ratings assigned to motor and control enclosures follow.

Motor Enclosures. The following are Natl. Electric Code (NEC) classifications of enclosures for induction motors.¹²

Drip-Proof. A drip-proof motor is an open motor in which the ventilating openings are constructed so that successful operation is not interrupted when drops of water or solid particles strike or enter the enclosures at any angle through 0 to 15° downward from the vertical.

Splash-Proof. A splash-proof motor is an open machine in which ventilating openings are constructed so that the successful operation is not interrupted when drops of liquid or solid particles strike or enter the enclosure at any angle not greater than 100° downward from the vertical.

Totally Enclosed. A totally enclosed motor is one enclosed to prevent the free exchange of air between the inside and outside of the case but not enclosed sufficiently to be determined airtight. The totally enclosed motor may be a totally enclosed fan cooled (TEFC) motor or a totally enclosed nonventilated (TENV) motor. The TEFC motor is a totally enclosed motor equipped for external cooling by a fan or fans internal with the machine but ex-

ternal with the exposed parts. The TENV motor is not equipped for cooling by means external to the enclosing parts.

Explosion-Proof. An explosion-proof motor is enclosed in a case that is capable of withstanding an explosion of a specified gas or vapor that may occur within the case. It will prevent the ignition of a specified gas or vapor surrounding the enclosure by sparks, flashes, or explosion of the gas or vapor within the case. The external temperature of the motor case will operate such that a surrounding flammable atmosphere will not be ignited.

A majority of the motors used in the oilwell pumping field are drip-proof. The TEFC motors are used in some extremely corrosive climates such as offshore or hazardous atmospheres. They are more expensive than the drip-proof motor; however, they last longer in severe environments and sometimes are justified.

Control Enclosures. The following are NEMA classifications for control enclosures.¹³

Type 1—General Purpose Indoor. This type of enclosure is intended for use indoors, primarily to prevent accidental contact of personnel with enclosed equipment in areas where unusual service conditions do not exist. In addition, they provide protection against falling dirt. Ventilation openings may be provided.

Type 3. This enclosure is intended for use outdoors to protect the enclosed equipment against windblown dust and water. They are not sleet- (-ice) tight.

Type 3R. This enclosure is intended for use outdoors to protect the enclosed equipment against rain and meet the requirements of Underwriters' Laboratories Inc., Publication No. UL 508, applying to rainproof enclosures. They are not dust-, snow-, or sleet- (ice-) proof. Ventilation openings may be provided.

Type 4. This type of enclosure is intended for use indoors or outdoors to protect the enclosed equipment against splashing water, seepage of water, falling or hose-directed water, and severe external condensation. They are sleet-resistant but not sleet- (ice-) proof.

Type 4X. This type of enclosure has the same provisions as Type 4 enclosures, and in addition, is corrosion-resistant.

Type 12. This type of enclosure is for use indoors to protect the enclosed equipment against fibers, filings, lint, dust and dirt, light splashing, seepage, dripping, and external condensation of noncorrosive liquids. There are no holes through the enclosure and no conduit knockouts or conduit openings, except that oiltight or dust-tight mechanisms may be mounted through holes in the enclosure when provided with oil-resistant gaskets. Doors are provided with oil-resistant gaskets. In addition, enclosures for combination controllers have hinged doors that swing horizontally and require a tool to open.

Although not NEMA approved for outdoor use, the Type 12 enclosure has been used successfully for many years to house disconnect switches on well locations.

Control for Oilfield Motors

Every motor used for oilwell pumping units must include a control. The components in this control have two distinct purposes. A portion of the devices serve as a means of stopping, starting, or controlling the oilwell pumping

motors. Another group of components equally important to the system are protection devices. Depending on the manufacturers, this equipment may have different appearances but the purpose is the same. Voltage ratings, size, or unique characteristics of various components may differ from one manufacturer to another. Next the major equipment used in controls is briefly described.

Equipment for Control. Hand-Off-Auto Switch. This switch normally is located on the door of the motor control and gives the operator means of selecting shutting off the motor or either automatic or manual operation. Turning this switch to the off position will not remove all power from the control but will stop the motor or prevent it from starting.

In the hand position, the motor will operate continuously, bypassing automatic functions. In the hand position, none of the protective features incorporated in the control are bypassed.

In the automatic position, the programmer or time clock is included in the function of the control devices. If there are pumpoff controls or other computerized control functions wired into the control circuit, they generally would function only when the switch is in auto position.

Local Remote Switch. This switch is a device that allows the transfer of the hand-off-auto control feature from a remote location to a site near the pumping unit. This can be very useful when the control panel is not located at the pumping unit. In some areas, electrical codes require that the starting switch be in a direct line of sight with the pumping unit.

Line Disconnect Switch. This switch serves as a means of disconnecting all electrical power from the motor control. If it is necessary to do maintenance work on the pumping unit or the motor control, it is important that all electrical power be removed from the control for safety purposes. It is not uncommon for this disconnect switch to be housed in its own separate enclosure and located near the source of utility power. When any work is performed on the pumping unit, this switch should be open. This prevents accidentally starting the pumping unit and reduces the possibility of electrical shock.

Sequence-Restart Timer. Pumping motors should be equipped to restart themselves when the electrical power is restored after a power outage. If there are a group of motors obtaining power from the same source, restarting of all motors simultaneously would create a severe drop in voltage. This voltage drop may be sufficient to prevent starting or could cause operation of safety devices at the utility substation. To prevent starting all motors simultaneously, controls should be furnished with a sequence-restart timer. This consists of a device that has an adjustable time delay period before restart of each motor is permitted. Sequence-restart timers should be set randomly at different times to prevent simultaneous starting of several motors.

Programmer. It is common for the equipment installed on a well to have the capability of lifting more fluid than the well will produce. Under these conditions, if the pumping unit operates continuously, the pump does not fill completely on the upstroke. This is commonly referred to as a "pumped-off" well. During the downstroke, fluid pounding will occur, which causes severe shock loading

of the sucker rods and pumping unit. Proper selection of these time periods allows the pumping unit to produce all of the oil that the well will give up while reducing the shock load on the system. One type of programmer is sometimes called a percentage timer, based on a total cycle of 15 minutes. If the well is capable of producing only half of the pumping system capacity, the operator should set the programmer on 12 hours. On 60-cycle current this programmer would allow the pumping unit to run $7\frac{1}{2}$ minutes and then shut down $7\frac{1}{2}$ minutes. The cycle would be repeated 96 times daily. This type of programmer does not allow the well's fluid level to build up so high that the hydrostatic head would retard inflow into the wellbore. Also, the short operating cycle can reduce electrical demand. This frequent starting and stopping has no adverse effect on equipment or power consumption. In fact, power consumption is always reduced.

Another type of programmer is a minimum 15-minute time clock that has 96 tabs. The time-clock tabs allow operators to select 15-minute operation periods. It is favored if the operator wants to operate during specific hours of the day and be off during the other hours.

Automatic pumpoff controls are also available, which shut the equipment down when pumpoff occurs detected by change of load either at the polished rod or at the motor.

Motor Starter Contactor. A magnetic-operated device applies or removes electrical power from a motor. The contactor has certain requirements that are important to maintain for its satisfactory operation and longevity. If voltage is too high, excessive current in the contactor holding coil creates heat, which reduces the life of the coil. If the voltage is low, the contactor may not pick up or maintain proper contact pressure on the main contacts that carry the motor running current. Control wires to the contactor holding coil should be kept to a minimum to reduce the effects of voltage drop. Remote stop and start switches may require auxiliary relays to limit length of wires to contactor holding coils. The contacts of this device must be of sufficient rating to handle the full load amps without deteriorating from excessive heat. For short time ratings, the contact must be of sufficient rating to handle locked rotor amps to start the motor. For continuous ratings, the contact rating should be no less than the full-load current rating for the maximum rating of the motor.

Protection Equipment. Protection equipment for oilfield motors includes the following devices.

Motor Fuses. These protective devices mounted in the disconnect switch are located between the motor control and the utility power.

Sizing fuses and the choice of fuses are very important in maintaining the protection. Fuses are not intended to prevent failure of the pumping motor. The primary purpose of the fuse is to limit damage to the system providing power to the electric motor should the motor develop electrical or mechanical difficulty. Protection of the motor should be derived from protective devices installed in the control or located in the motor winding.

Dual- and single-element fuses have similar appearances, but performance is quite different. Single-element fuses have a very high response speed to currents beyond their rating. Single-element fuses provide excellent short

circuit protection. Temporary, harmless overload or normal starting currents may cause nuisance failure of single-element fuses. The dual-element fuse is designed to be used with normal varying motor loads. The dual-element fuse has two elements in series within its housing. One of these elements functions very much like the thermal element of a standard thermal overload relay. Moderate overloads for extended periods of time will cause this fuse to operate, removing the motor from the load. The short circuit element of the fuse is sensitive only to exceptionally high current. This portion of the fuse has a very short melt time, which protects the system under electrical faults. It is always advisable to use the dual-element fuse.

Air Circuit Breaker. This protective device is used sometimes instead of fuses for distribution system protection in case electrical difficulty develops in the motor. If this happens, the air circuit breaker will operate, removing the motor from the source of power. The circuit breaker has a distinct advantage over fuses because it can be reset when the thermal element in the breaker has cooled.

Circuit breakers may be obtained with two distinct protection capabilities: thermal and magnetic. Their thermal trip capability is based on current vs. time cycle. When the rating of the breaker is exceeded, the thermal element heats up, causing operation of the breaker. The length of time it takes to trip the breaker is inversely proportional to the amount of overload. The magnetic trip capability, which is adjustable, causes instantaneous action. When the overload current exceeds the rating of the magnetic trip there is instant operation. A typical adjustment range for the magnetic circuit breaker would be 5 to 10 times the rating of the circuit breaker. The thermal portion of the circuit breaker is intended to handle continuous overload. The magnetic part of the circuit breaker is responsible for the short circuit faults in the control or the motor.

Lightning Arresters. Fuses, circuit breakers, and other protective devices cannot protect against lightning strikes. The only protection against damage caused by lightning is a properly sized and grounded lightning arrester. It must be sized according to the voltage of the system. Grounding of the lightning arrester must be through a continuous copper conductor from the lightning arrester to the ground. The wellhead at the pumping unit serves as the best ground available and should be used if at all possible. (Refer to electrical system grounding covered in electrical distribution system.)

Undervoltage Relay. Common disturbances such as overloads in the utilities distribution system may result in lower-than-normal voltages at the pumping unit. Control devices normally will operate at voltages considerably below those acceptable for the motor. Loss of voltage to the motor causes a drop in torque, which reduces the motor's rev/min and increases the amp load. Undervoltage relays are used to sense abnormal voltage and stop the motor before any permanent damage is done.

Phase Loss Relay. Electric power available to oilfields is subject to loss of one of the three phases. A phase loss relay will stop the motor if any one of the three phases is lost. In a system where there are several motors operating from the same power system, there is a degree of regeneration occurring during the loss of one phase. It is possible for motors to continue to run as well as to restart, even though there is a loss of one phase. Phase

loss relays that work well on single large-motor installations or even single small-motor installations may not operate satisfactorily on a multiple-motor electrified oil-field system. Extreme care must be exercised in selecting phase loss relays to ensure that the expected protection is provided.

Thermal Overload Relay. The standard thermal motor overload relay can play an important part in protecting motors on the oilwell pumping unit. The thermal overload relay is sensitive to the thermal amps demanded by the motor. The heaters selected should be sized to correspond to full-load amp rating for which the motor is operating. It is extremely important for motors that have multiple ratings to use heaters or settings that correspond to the full-load rating of the particular mode used. If adequate motor winding temperature sensors and controlling devices are used, thermal overload relays may not be necessary.

Motor Winding Temperature Sensor. Some of the motors manufactured for the oilwell pumping units have temperature sensors embedded in the winding to shut the pumping unit down if the temperature of the winding exceeds its limit. There are several different types of sensors including thermostats, thermistors, remote temperature devices, and thermocouples. These devices are sensitive to changes in temperature. Controlling devices attached to each of these are used to shut down the motor if conditions generate excessive winding temperature. Sensors in each phase of the motor protect against single phasing, low voltages or other abnormal loading that would cause excessively high temperatures in the motor winding.

Overtemperature Lockout Circuit. When sensors are located in the motor windings to shut down the unit because of excessive temperature, control lockout circuits should be provided to prevent automatic restart. If thermal overload has caused shut-down of the unit, it must not be restarted until the situation has been corrected. Excessive loads from loss of phase, improper counterbalance, falling fluid level, parted rods, stuck pump, or other conditions may be responsible for temperature shut-down.

Pumping Unit Vibration Switch. Pumping units are subject to severe motor overload because of breaking or parting of the sucker rods. Parting of the sucker rod causes a varying degree of unbalanced loading, depending on the location of the parted rods. Rod parts may cause an extreme overload as the motor tries to lift the counterweights. Under this condition, the motor will run until thermal protection shuts down the unit. During this period there can be serious overloading of the gear box, which may contribute to mechanical failures. Properly adjusted vibration switches mounted on the pumping unit should signal rod string failures instantly and shut down the unit.

Control Fuses. These fuses, carefully sized, are installed to protect the system should there be a failure of a component in the control package.

Electrical Distribution System

There are a variety of options concerning the type of devices and how they are used in providing electric power to pumping units. The electrical distribution system is responsible for furnishing electrical power and partial pro-

tection of the electrified oil field. It is important to the economics and longevity of the system that distribution be designed adequately before installation. This section covers topics that must be considered to ensure the most desirable benefits from the electrical system.

Primary System and Voltages. Generally, to reduce losses, electricity distributed to an oil field is brought to the field at elevated voltages, ranging between 4,000 and 15,000 V. This elevated voltage distribution system is called a primary system. Higher voltages allow smaller conductors to be used; however, the transformers are more expensive. In general, where the primary system is responsible for delivering electrical power over a long distance, a higher voltage is favored. In this situation, the cost of the smaller cable over the longer distances will offset the higher costs of the transformers and protective equipment.

An electrified oil field has a high degree of exposure to electrical storms. Electrical storms cause high static voltages, and sometimes high transient voltages, the latter being lightning. Static lines and lightning arresters are used to reduce the damage to electrical equipment by the static voltages and lightning strikes.

During electrical storms, the formation of rain clouds creates a difference in potential between the cloud and the earth. Primary electrical systems that lie in a section between the cloud and the earth may inherit a high static voltage level. This static voltage level can result in motor winding insulation damage if not reduced by properly sized and grounded lightning arresters. When the potential difference between the cloud and the earth becomes large enough, there will be an electrical discharge or lightning strike. If this lightning strikes the primary system, it will create high, transient voltages that must be arrested by the lightning arresters or failure of the insulation of the motor will occur. Other electrical equipment in the system may include transformers or reclosures and is subject to failure by the same cause. In the construction of the primary electrical system of the electrified oil field, it is extremely important to the life of the electric equipment to take measures to reduce the effects of static and transient voltages caused by electric storms.

Secondary Electrical System. The secondary portion of the electrical system of the oil field includes the transformer at the end of the primary system and all of the cables, disconnect switches, controls, and other devices, which operate at the same voltage as the motor. In general, the voltage of all the devices within the secondary system should not be greater than 600 V. A special case of the secondary system is the installation of a 796-V system. This voltage is obtained by Y-connecting three transformers whose secondary voltage is each 460 V and results in a line-to-line voltage of 796 V at the motor. This is a special case in the application of the 460-V-rated transformers. The 796-V system is used to reduce line drop to the motor. Operating at 796 V requires less current than operating at 460 V. However, this benefit is more than offset by the 796 V overstressing the insulation of motors and control components. Many operators who installed 796 V years ago have since converted to 460-V operation.

The secondary system of the electrified oil field consists of a transformer, or group of transformers, that convert the primary system voltage to the motor operating voltage. Voltage from the transformer is provided to the motors through a fused disconnect switch or a circuit breaker. The control of the motor provides for its control and protection. Where the secondary system consists of overhead cables, there is exposure of the system to electrical storms. Therefore, it is desirable to install lightning arresters at the transformer to reduce the effects of static and lightning strikes, which may damage the insulation of the electrical equipment.

All the devices selected in the secondary part of the system should be sized properly to allow full loading of the motor without any thermal damage to the equipment. Sizing of this equipment also should take into consideration the protection of the electrical devices. Fuses, circuit breakers, transformers, and wire sizes should be selected on the basis of the full-load rating of the motor.

Distribution Transformers. Distribution transformers reduce the primary high voltage to a lower voltage used by the motors. The distribution transformers are rated in kVA. They must supply reactive power (kVAR) as well as the power used for work (kW).

To obtain full-load capability of the transformers and the motors, it is desirable to use three single-phase transformers or a single three-phase transformer. One advantage of using three single-phase transformers is the convenience of replacing one, should it fail.

Open-delta or T-connected transformers will not provide the balanced, three-phase voltage even if only moderately loaded.

Distribution transformers can be connected in several different configurations to deliver three-phase power. These consist of delta-delta, wye-delta, delta-wye, wye-wye, and open-delta connections. All of these connections are used in the oil field; however, some of these have distinct advantages.

Wye-Delta. The most desirable transformer connection is the wye-delta. Do not ground the windings of the transformer or the Y point at the wellsite. If the Y point is grounded at the wellsite, as is done in many cases, danger exists. If one of the primary wires should go to ground at some point in the primary system, the groundwire at the wellsite may be at primary voltage to ground potential. This would create a personnel safety hazard. The transformer "ground" should not be connected to the grounding system at the pumping unit because the latter includes the enclosures for the electrical equipment.

The wye-delta connection has the advantage of allowing harmonic voltages existing in the system to have a self-canceling effect in the delta-connected secondary. It is not necessary for units in a three-phase bank to have equal impedances. It is important for the primary to have balanced voltage because unbalanced primary voltages can cause circulating currents in the delta secondary.

Delta-Delta. The delta-delta connection is an acceptable transformer connection; however, it is not as desirable as the wye-delta. This connection requires all units in a three-phase bank to have impedances with less than a 10% differential. Where the delta-delta connection is used, none of the endpoints or midpoints of the primary or secondary winding should be tied to the ground sys-

tem at the wellsite. If either the primary or secondary winding of the transformer is tied to the ground, be aware that if the ground is not satisfactory, the groundwire could be at a potential anywhere from zero to the line-to-ground voltage available at the transformer.

Delta-Wye. The delta-wye is an undesirable connection. It is prone to allow harmonic voltages in the distribution system to be applied to the motor and control. Harmonic voltages can cause erratic behavior of control components as well as excess motor heat. If a delta-wye system is used, neither the primary nor secondary windings of the transformer should be connected to the ground system at the motor. If grounds are attached to any part of this winding, they may be subject to the same voltage discussed under delta-delta. It is not necessary for the impedance of each unit in the three-phase transformer bank to be the same.

Wye-Wye. The wye-wye is the least desirable connection because harmonic voltages in the system are not able to circulate in the transformer winding. If they exist, they will be transmitted to the motor and control. If the wye-wye is used, no part of the transformer winding should be connected to the ground system at the wellsite. If a primary circuit has a phase-to-ground, a grounded wye will carry ground-fault current. This connection does not require transformers to have equal impedance. The delta secondary will eliminate harmonic voltage in the motor and control circuit. It is not necessary for transformers to have equal impedances.

Open-Delta. The open-delta is an incomplete delta-delta. If one transformer on the delta-delta connection is removed, the connection is an open-delta circuit. This type of connection provides unsatisfactory performance of induction motors. The open-delta connection will have unbalanced voltages, which prevent utilization of full-load rating of the transformer and motor.

At no-load, and with balanced voltages supplied to this transformer, the output will be a balanced three-phase voltage. As this two-transformer system is loaded, the impedance changes, which provides an unbalanced voltage to the motor. The use of the two-transformer open-delta transformer connection does not allow full utilization of transformer kVA (kilovoltamps) or the full output rating of the motor.

Figs. 10.19 and 10.20 show a comparison of the three-transformer delta connection with an open-delta transformer connection.

In the open-delta connection (see Figs. 10.19 and 10.20), the total kVA is only 57% of the original 100 kVA. The two 33.3-kVA transformers remaining in the circuit would have a total kVA of 66.6 kVA. With one unit removed, the remaining units with 66.6 kVA provide only 57.7 kVA, or only 86.6% of the rating. This example shows that the transformers used in open-delta connections must be derated to obtain the desired kVA rating of an open-delta connection system.

As the open-delta connected transformers are loaded, the voltage shifts from a balanced voltage at low load to a seriously unbalanced voltage at rated load. Unbalanced voltages will contain a negative sequence component of voltage. When applied to a three-phase induction motor, this causes excessive heating in the rotor as well as some lost torque in the motor. Unbalanced voltages result in unbalanced currents.

Unbalanced voltage causes a three to five times greater current unbalance. This means that for a 3% voltage unbalance, a current unbalance of 9 to 15% can be expected. These unbalanced conditions require one to derate the motor used on the pumping unit. Use the curve shown in Fig. 10.21 to determine the derating factor for percent voltage unbalance at the motor terminals.¹⁴

$$V_{ub} = \frac{\Delta V_{max}}{\bar{V}} \times 100 = \frac{\bar{V} - (V_L)_{max}}{\bar{V}} \times 100, \dots (15)$$

where

V_{ub} = voltage unbalance, %,
 ΔV_{max} = maximum voltage deviation from \bar{V} ,
 \bar{V} = average voltage, and
 $(V_L)_{max}$ = line voltage, maximum difference from average voltage.

Example Problem 5. If line voltages are 465, 460, and 435, the average voltage is 453, and the maximum deviation is $453 - 435 = 18$:

$$V_{ub} = \frac{18}{453} \times 100$$

$$= 3.97$$

and

$$F_{dr} = 0.83 \text{ (read from Fig. 10.21),}$$

where F_{dr} is the derating factor. (This curve can be used any time three-phase voltage is not balanced.)

There are many installations in the electrified oil field that use the open-delta transformer connections. The only way the open-delta transformer will operate successfully on a pumping unit is to have transformers and the motor both oversized to handle the load of the pumping unit. Only during an emergency situation where one transformer has failed is the open-delta transformer connection recommended. For this emergency condition, derating of the transformer and the motor is required.

All distribution systems have a ground of some type associated with the installation. It is extremely important that the groundwire is terminated at an adequate ground. Reference should be made to the portion of this chapter on grounding of electrical systems.

Sizing of the distribution transformer is a very important part of satisfactory operation of the oilwell pumping motor. The industrial rule of thumb for sizing transformers is 1 kVA/connected hp. Because of the cyclic nature of oilwell pumping loads, some operators use 0.9 kVA/hp. Ultrahigh-slip motors do not have horsepower ratings; therefore, a factor of 0.75 times the full-load current of the motor in the high-torque mode should be used to determine the required kVA.

Electrical System Grounding

Grounding of electrical equipment at the wellsite is a very important part of the electrical system. Grounding of electrical equipment has two distinct purposes: (1) devices are grounded for personnel safety and (2) devices must be grounded to perform satisfactorily.

Fig. 10.19—Three transformers, delta-delta.

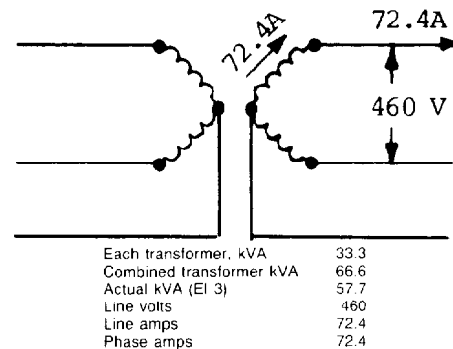

Fig. 10.20—Two transformers, open-delta.

For personnel protection at the wellsite, all enclosures that house electrical devices should be grounded. If wiring or other devices within an electrical enclosure should fail in some way and come into contact with the enclosure, it may have the same electrical potential as the broken wire. If the enclosure is grounded adequately, the stray voltage will be reduced to safe levels. If the enclosures are not grounded properly, unsafe voltages could exist, which could be fatal to the operating personnel.

The lightning arresters installed in electrical systems cannot operate satisfactorily unless they have good

Fig. 10.21—Effects of unbalanced voltages on the performance of three-phase induction motors.

grounds. Lightning arresters under elevated static voltage or lightning strikes will short-circuit the above-normal voltages to ground. If the lightning arresters are not grounded properly, elevated voltage will enter the windings of transformers, control, or motors, causing component failures.

Obtaining a satisfactory ground at the wellsite can present some difficulties. The wellhead normally can be considered an excellent grounding source through the well casing. The ground rods used at the wellsite can vary from acceptable in moderately wet soils to very inadequate in dry soils. The wellhead should be used whenever possible for grounding of the secondary electrical system. There are some conditions that should be considered when tying equipment to the wellhead for grounding. The following directions should satisfy most conditions existing at the wellsite.

1. All the secondary electrical system devices should have their enclosures tied to the wellhead for personnel safety. This includes the transformer tank, disconnect switch enclosure, motor control, and motor frame.

2. All secondary lightning arresters should be grounded to the wellhead. Different conductors should be used to ground the secondary enclosures and lightning arresters. The wire that grounds the lightning arresters should be a continuous unbroken cable no smaller than No. 6 wire from the lightning arresters to the wellhead ground.

3. Primary lightning arresters also should be grounded at a utility primary ground and not to the secondary ground or wellhead.

4. Utility static wires or grounding of transformer connections should not be attached to the wellhead. This equipment, if connected to the wellhead, can influence the malfunction of cathodic protection of well casing and production tubing. This part of the electrical system may include many miles of line exposure and many grounds that could influence the corrosion of the production equipment. Grounds for this part of the system should be grounding rods or ground pads located at the bottom of the utility poles. Other satisfactory grounds are wells drilled or ground mats constructed for this purpose at the electrical substation.

It is desirable to install ground rods at each location for each of the separate grounding wires run to the wellhead. During the servicing of the wells, the wellhead grounds may be removed. When service work is completed, these wellhead grounds should be reconnected.

5. It is recommended not to connect the grounds of telephone systems to the grounds of oilfield pumping motors. Induction motors can generate harmonic voltages that can cause noise on telephones when they share common grounds.

Voltage Drop in Electrical Systems

The electrical system of an oil field should be designed economically, but it must be capable of delivering the required current at adequate voltage to all motors for starting and running. To satisfy these conditions, all equipment must be considered. Each device in this system will have a voltage drop based on the full load of the motor or motors. All the voltage drops should be subtracted to obtain the voltage at the motors. In most field applications, the primary system is provided by a utility company. In these cases, it is necessary to evaluate the voltage from the utility drop point to the wellsite only. It is important to obtain from the utility company the voltage and kVA available at the drop point. The voltage obtained from the utility company is that voltage available at the drop point when all the required kVA delivered to the oil field is considered. This would be the source voltage level to use to calculate voltage drops. If the utility company furnishes the distribution transformer, only the size and type of wire to the well must be determined. For short runs (1 to 200 ft), voltage drop is minimal and the selection of a cable capable of carrying 125% full-load current normally is adequate. For extended secondary cable runs, voltage drop must be calculated. This is done by use of charts, tables, or formulas designated specifically for buried cable or overhead lines. Fig. 10.22 can be used for calculating voltage drops.

To use the graphs in Fig. 10.22 draw a vertical line from wire size in the graph with or without capacitors (whichever is appropriate) to intersect with horsepower. From horsepower, draw a horizontal line to cable length. At the intersection with cable length, draw a vertical line down to percent voltage drop. For example, a 20-hp, size-2 conductor, 666 ft long, has a starting voltage drop of 8%. The running voltage drop is 1.5%.

For ultrahigh-slip motors, multiply the high-torque mode amps by 0.75 to approximate the equivalent horsepower that should be used in calculating voltage drops.

The distribution transformer's voltage drop can also be obtained from the two charts in Fig. 10.23.

Fig. 10.23 shows that the starting voltage drop of a 20-hp motor with capacitors, using a 30-kVA transformer, is 11%. The running voltage drop is 1.7%. In the example, the total drop including the transformer and motor can be determined by using Eq. 16.

$$\Delta V_m = \Delta V_t + \Delta V_l, \dots \dots \dots (16)$$

where

ΔV_m = voltage drop at motor, %,
 ΔV_t = voltage drop at transformer, %, and
 ΔV_l = line voltage drop, %.

$$\begin{aligned} \Delta V_{ms} &= 11 + 8 \\ &= 19\% \end{aligned}$$

and

$$\begin{aligned} \Delta V_{mr} &= 1.7 + 1.5 \\ &= 3.2\%, \end{aligned}$$

where

ΔV_{ms} = starting voltage drop of motor, %, and
 ΔV_{mr} = running voltage drop of motor, %.

It is desirable to limit running voltage drop to 5% and starting voltage drop to 20%.

Complete tables and charts are available for calculating voltage drops from wire and cable manufacturers. Also it is recommended that electrical codes be considered when designing systems.

Fig. 10.22—Voltage drop for overhead and buried cable.

Power Factor and Use of Capacitors

Electric power required to drive a motor can be divided into three separate components. These are kilowatts (kW), kilovoltamp reactive (kVAR), and kilovoltamps (kVA). Kilowatts are the amount of work done by the motor and are the major quantity used for billing purposes. Kilovars are the electrical quantity needed by the motor and control for magnetizing purposes and lags kilowatts by 90°. Kilovoltamps are the amount of energy furnished by the utility company and are a resultant of kilowatts and kilovoltamps reactive (kilovars). These three components allow the creation of a motor power triangle (see Fig. 10.24).

Kilowatts are measured with a kilowatt-hour meter. Kilovoltamps can be calculated using Eq. 17.

$$EI = \frac{\sqrt{3} \times V \times I_{rms}}{1,000} \dots\dots\dots (17)$$

where

V = volts, and

I_{rms} = root mean square amps.

RMS amps are available from a thermal ammeter. The volts are the line-to-line volts to the motor. From kilovoltamps and kilowatts, the kilovoltamps reactive can be calculated as follows.

$$\text{kVAR} = \text{kVA} - \text{kW}.$$

The kilovoltamps reactive are the electrical quantity needed by the motor and control for magnetizing pur-

Fig. 10.23—Transformer voltage drop.

Fig. 10.24—Power triangle.

Fig. 10.25—Power triangle for heavily loaded motor.

Fig. 10.26—Power triangle for lightly loaded motor.

Fig. 10.27—Power triangle for motor at synchronous revolutions per minute.

poses. The kilovoltamps reactive quantity required for a pumping motor does not follow the cyclic loading like amps and kilowatts and is approximately the same from no load to full load.

Typical power triangles drawn for a motor with different load conditions are shown in Figs. 10.25, 10.26, and 10.27.

When a motor is loaded heavily (Fig. 10.25), the kilowatts are greatest. If the motor is loaded lightly, the kilowatts decrease (Fig. 10.26). If the motor is driven at synchronous speed by the pumping unit (regeneration), the kilowatts are zero and the triangle would shift to a vertical line as in (Fig. 10.27) and consists only of kilovars. For light loads, kilovoltamps are made up predominantly of kilovars. For heavy loads, kilovoltamps are made up predominantly of kilowatts. If a utility company is furnishing the supply for the motor, they would prefer the case of maximum kilowatts as they get a better return for the kilovoltamps they are providing.

The power factor is used to show the relationship between EI (kilovoltamps) and P (kilowatts):

$$F_p = \frac{P}{EI\sqrt{3}}, \dots\dots\dots (18)$$

where

F_p = power factor,

P = power, kW,

E = electromotive force, kV,

I = current, A, and

$EI\sqrt{3}$ = voltage-current product, kVA.

Because of the cyclic nature of pumping unit motor loads, the electrical conditions illustrated in Figs. 10.25, 10.26, and 10.27 frequently occur during each stroke of a pumping cycle. This range can go from near 1.0 to 0.

If motor rev/min is at synchronous rev/min, kW is essentially zero.

$$F_p = \frac{0}{EI} = 0. \dots\dots\dots (19)$$

At light loads where kilowatts are minimal, the power factor is near zero. At heavy loads, the kilovoltamps and kilowatts approach the same magnitude. If kilowatts could be made as large as kilovoltamps, the power factor would be one. The cyclic kW load on a pumping motor can cause the power factor to range from near 1.0 to near 0 if excessive adverse pumping conditions exist. Low power factors are the result of improper counter-balance, pumped-off wells, or oversized motors. Because power factor does vary greatly throughout the pumping cycle, even under optimum conditions, one should not be misled by single-point maximum power factor rating of a motor. Overall power factor, however, is important.

A utility company furnishing electrical power must furnish both kilovars and kilowatts. In some locations, the utility company will penalize the customer if a maximum power factor is not maintained.

The magnetizing kilovars required by a motor are inductive kilovars. Capacitive reactance supplied by capac-

itors has a cancelling effect on inductive kilovars reactance required by the motors. The utility company prefers the highest possible power factors because this means they get a greater return (kW billed) for their product supplied (kVA generated). Fig. 10.28 shows by the power triangle how capacitance can improve the power factor for a motor.

Fig. 10.28 shows how capacitance kilovars are related to inductive kilovars. It also shows how an improved power factor can influence the magnitude of line amps required to operate a motor at low and high power factors.

The improved power factor does not change the current required by the motor but does change the current required from the utility company. Selection of capacitance kilovars should not be made to correct poor power factors resulting from oversized motors or unbalanced pumping units. This may cause overcorrection, which can provide a leading power factor. Lead and lag power factors will decrease from 1.0 toward 0. Lag values are assigned negative values while lead is assigned positive values. Slightly leading power factors of 1.0 to 0.96 are not harmful; however, leading power factor less than 0.96 may be detrimental to the electrical system. Excessive power factor over-correction may cause over-voltages that would cause control component failure. If the contactor to a motor with connected capacitor is opened while the pumping unit is driving the motor, voltages high enough to cause motor winding failure can occur.

Use of Phase Converters

There are areas where only single-phase power is available to drive pumping unit motors. Single-phase motors are available only in small horsepower ranges, so, if an operator chooses to electrify his well, he must use a phase converter.

A phase converter is an electrical device that creates a form of three-phase power from single-phase power. A description of three types of phase converters follows.

Capacitor-Type Converter. This is the simplest type of phase converter because the additional phases are produced by a capacitor bank in series with a part of the motor winding. Fig. 10.29 shows the general concept of this type of phase converter.

This is not a desirable phase converter for a pumping unit motor because it does not provide the full torque required for the starting and running of the cyclic loaded pumping unit motor. This requires the motor to be derated up to 40% to compensate for this condition.

Autotransformer-Type Converter. This converter uses an autotransformer-capacitor. Fig. 10.30 shows how the autotransformer is connected in the converter circuit. The autotransformer has taps for selecting the best voltage for balancing current to the three-phase induction motor.

Of the three-phase converters discussed, the autotransformer converter is, because of its cost and effectiveness, the most desirable for a single pumping unit motor installation. While the motor must be derated approximately 15%, there are adjustments available with its transformers and capacitors to obtain fairly balanced amps for the motor.

Fig. 10.30—Autotransformer capacitor.

Fig. 10.31—Rotary converter.

Fig. 10.32—C114D-143-64 pumping showing the classified areas.

Fig. 10.33—Classified area of beam pumping well with cellar and typical wellhead equipment.

Rotary-Type Converter. The rotary converter consists of a rotating unit similar to a motor without an external shaft. Fig. 10.31 shows how the stator winding of the rotating converter is connected to the induction motor. Two of the three rotating converter terminals are connected directly to the single-phase power lines. The third rotating converting terminal is connected to one of the single-phase lines through the capacitor bank. The capacitors provide the rotating magnetic field to start and operate the converter. The generating action of the rotating converter, in combination with the phase shift of the capacitors, produces third-phase voltage to operate the motor.

The cost of rotary converters is best justified on multiple motor installations. It can provide satisfactory performance equal to the autotransformer converter. The rotary converter should be sized to be at least twice the size of the largest motor on the system and as large as the combined motor horsepower on the system, whichever is greater.

Hazardous Area Classification

NEC has classified areas surrounding production facilities both on- and offshore for safe installation of electrical equipment.¹⁵ Details of these classified areas (Figs. 10.32 and 10.33) are found later in this section. Fig. 10.33 shows classified area dimensions.

One should refer to the pumping unit dimensions to ensure that the electrical equipment is mounted in a non-classified area. All areas outside these dimensions are considered non-classified.

It is important to realize that pumping motors and controls located in non-classified areas are not required to be explosion-proof. However, other electrical equipment, such as pressure switches or other electrical devices, may require special enclosures.

Class 1 locations are those in which flammable gases or vapors are, or may be, present in the air in quantities sufficient to produce explosive or ignitable mixtures. Class 1 locations include the following.

Class 1, Div. 1.¹⁶ Locations (1) in which explosive or ignitable concentrations of flammable gases or vapors exist continuously, intermittently, or periodically under normal operating conditions; (2) in which explosive or ignitable concentrations of such gases or vapors may exist frequently because of repair or maintenance operations or because of leakages; or (3) in which breakdown or faulty operation of equipment or processes might release explosive or ignitable concentrations of flammable gases or vapors might also cause simultaneous failure of electrical equipment.

Class 1, Div. 2. Locations (1) in which volatile, flammable liquids or flammable gases are handled, processed or used, but in which the explosive or ignitable liquids, vapors, or gases will normally be confined with closed containers or closed systems from which they can escape only in case of accidental rupture or breakdown of such containers or systems, or in case of abnormal operation of equipment; (2) in which explosive or ignitable concentrations of gases or vapors are normally prevented by positive mechanical ventilation, and which might become

explosive or ignitable through failure or abnormal operation of the ventilating equipment; or (3) which are adjacent to Class 1, Division 1 locations, and to which explosive or ignitable concentrations of gases or vapors might occasionally be communicated unless such communication is prevented by adequate positive-pressure ventilation from a source of clean air, and effective safeguards against ventilation failure are provided.

Key Equations in SI Metric Units

$$v_{pr1} = 0.0121 F_{t1} \times N, \dots\dots\dots (1)$$

where

v_{pr1} = polished rod velocity at Crank Position 1, m/s,

F_{t1} = torque factor at Crank Position 1, mm, and

N = pumping speed, strokes/sec.

$$\bar{A}_{pr1,2} = 0.0695 N^2 \left(\frac{F_{t1} - F_{t2}}{\theta_1 - \theta_2} \right), \dots\dots\dots (2)$$

where

$\bar{A}_{pr1,2}$ = average polished rod acceleration between Crank Positions 1 and 2, m/s²,

F_{t1}, F_{t2} = torque factors at Crank Positions 1 and 2, mm, and

θ_1, θ_2 = angle crank rotates between Positions 1 and 2, rad.

$$P_b = \frac{q \times D}{3639}, \dots\dots\dots (3)$$

where

P_b = brake power for NEMA D motors, kW,

q = fluid flow rate, m³/d, and

D = depth (lift), m.

$$P_b = \frac{q \times D}{2924}, \dots\dots\dots (4)$$

where

P_b = brake power for NEMA C motors, kW.

$$P_h = \frac{q \times D \times W}{972.7 \times 24 \times 60}, \dots\dots\dots (5)$$

where

P_h = hydraulic power to lift the fluid, kW,

W = weight of fluid, kg,

24 = hours per day, and

60 = seconds per minute.

$$P_h = \frac{q \times D}{8821}, \dots\dots\dots (6)$$

where

P_h = hydraulic power for fluid with 1.0 specific gravity.

$$P_f = \frac{\frac{1}{8} W_r \times 2S \times N}{6118}, \dots\dots\dots (7)$$

where

P_f = power to overcome subsurface friction, kW,

W_r = weight of rods, kg,

S = polished-rod stroke, m, and

N = strokes per minute.

$$P_{pr} = P_h + P_f, \dots\dots\dots (8)$$

where

P_{pr} = polished rod power, kW.

$$P_{pm} = P_{pr} / 0.85, \dots\dots\dots (9)$$

where

P_{pm} = prime mover power, kW.

$$P_m = \frac{P_h + P_f}{E_{pu} \times F_{cl}}, \dots\dots\dots (10)$$

where

P_m = slow speed engine power or NEMA motor D, kW,

E_{pu} = pumping unit efficiency, fraction, and

F_{cl} = cyclic load derating factor, fraction.

Chapter 11

Oil Storage

William E. Roof, C-E Natco *

Types of Storage Tanks

Every facility involved in the production of petroleum and related products requires some type of storage. This chapter discusses the types of storage commonly used and also provides general guidelines to aid selection of the proper type of storage for a particular application.

References to various codes, standards, and recommended practices supplement the material provided in this chapter. Manufacturers also should be consulted for specific design information on a particular type of storage.

During the early days of oil production, the method of storing was almost exclusively white-pine wooden tanks, which were followed by cypress tanks, and then redwood tanks. However, because of the constant and steep rise in the cost of redwood lumber and the diminution of skilled erectors required, the installation of new wooden tanks is nearly nonexistent. The bolted-steel tank was developed next and virtually replaced the wooden tank.

Bolted-Steel Tanks

Bolted tanks are designed and furnished as segmental elements assembled on location to provide complete vertical, cylindrical, aboveground, closed- and open-top steel storage tanks. Standard API bolted tanks are available in nominal capacities of 100 to 10,000 bbl, and are designed for approximately atmospheric internal pressures. Bolted tanks offer the advantage of being easily transported to desired locations and erected by hand. To meet changing requirements for capacity of storage, bolted tanks can be easily dismantled and re-erected at new locations. If a tank develops a hole from corrosion or becomes damaged, a single sheet or more may be replaced. A complete tank bottom may be replaced in the field without dismantling the tank. Also, a section may be removed from the tank, a new connection installed in the sheet, and the section replaced without danger. This is not true

of any other type of steel construction. No special equipment (cranes, etc.) is required for the erection of bolted tanks. These tanks are erected by nonspecialized crews using hand tools and usually an impact wrench.

Bolted tanks are available with painted, galvanized, and special coatings, including factory-baked coatings. Painting on both sides of the sheets during fabrication gives the inside of the tank some corrosion protection. Galvanizing the sheets and all tank parts by the "hot-dip" process or applying a factory-baked coating affords high corrosion protection. The component parts of a typical bolted tank are shown in Fig. 11.1 and partial API specifications in Table 11.1.¹

Generally, bolted tanks are fabricated from 12- or 10-gauge steel and, if not galvanized or furnished with a protective coating for corrosion protection, they do not have the expected life of the welded-steel tanks, which are usually constructed of heavier steel.

Welded-Steel Tanks

Shop-fabricated welded, cylindrical-shape tanks are available in a large variety of sizes as shop-fabricated items. The API-12F specifications² for vertical shop-welded tanks (Fig. 11.2 and Table 11.2) list standard sizes for nominal capacities of 90 to 500 bbl. Shop-welded tanks fabricated to API specifications provide the oil production industry with tanks of adequate safety and reasonable economy for use in the storage of crude petroleum and other liquids commonly handled and stored by the production segment of the industry. Shop-welded tanks are usually fabricated from $\frac{3}{16}$ -in. or heavier steel and, therefore, will permit internal pressures up to 16 oz. The heavier steel also affords a corrosion allowance. Shop fabrication permits testing in the shop for leaks and also provides immediate storage. Tanks are merely up-ended from a truck on the location.

*The chapter on this topic in the 1962 edition was written by Don R. Boling

Fig. 11.1—Typical bolted tank.

Flat-Sided Tanks (Non-API)

Although cylindrical-shape tanks may be structurally best for tank construction, rectangular tanks frequently are preferred. When space is limited, such as offshore, requirements favor flat-sided tank construction because several cells of flat-sided tanks can be fabricated easily and arranged in less space than other types of tanks. Flat-sided or rectangular tanks normally are used as atmospheric-type storage.

Field-Welded Tanks

Field-welded tanks provide large storage capacities in a single unit. API Spec. 12D lists standard sizes ranging from 500- through 10,000-bbl nominal capacity. Although the sizes set forth in this specification are closely paralleled by bolted tanks, these field-welded tanks are of heavier-gauge steel with a minimum thickness of $\frac{1}{4}$ in. for the tank bottom and $\frac{3}{16}$ in. for the shell and deck.

Larger field-welded tanks providing storage capacities of 150,000 bbl or more have become quite prevalent for use in the storage of oil and petroleum products. Field-welded tanks, particularly those larger than 10,000 bbl, frequently are designed and erected in accordance with API Standard 650. This standard covers material, design, fabrication, erection, and testing requirements for welded-steel storage tanks. It also includes an alternative basis for shell design, as well as one for calculating tank-shell thickness. The API Standard 650 also may be used to govern the design and fabrication of the smaller shop-welded tanks.

Fixed Roof

Fixed roofs are permanently attached to the tank shell. Welded tanks of 500-bbl capacity and larger may be provided with a frangible roof (designed for safety release of the welded deck-to-shell joint in the event excess internal pressure occurs). In this case, the design pressure should not exceed the equivalent pressure of the dead weight of the roof including rafters, if external.

Floating Roof

Storage tanks may be furnished with floating roofs whereby the tank roof floats on the stored contents. This tank type is used primarily for storage near atmospheric pressure. Floating roofs are designed to move vertically within the tank shell to provide a constant minimum void between the surface of the stored product and the roof. Floating roofs normally are designed to provide a constant seal between the periphery of the floating roof and the tank shell. They can be fabricated in a type that is exposed to the weather or a type that is under a fixed roof. Internal floating-roof tanks, with an external fixed roof, are used in areas of heavy snowfall since accumulations of snow or water on the floating roof affect the operating buoyancy. These can be installed in existing tanks as well as new tanks. Both floating roofs and internal floating roofs are used to reduce vapor losses and to aid in conservation programs. Fig. 11.3 is a schematic of a typical internal floating-roof tank.

Cone-Bottom Tanks

The cone bottom in either the bolted or the welded tank offers a means of draining and removing water, or water-cut oil, from only the bottom of the tank, leaving the marketable oil above. The drain line from a sump-equipped cone bottom must be equipped with a vortex breaker to drain off most of the water without coning oil into the drain. With a flat-bottom tank, some of the marketable oil must be removed if all the water is removed from the tank. Corrosion on the tank bottom is kept to a minimum by keeping all water removed. A cone bottom can be kept clean without having to open the tank if 1 or 2 bbl are drained off once or twice weekly and pumped back through the treating system. If this is not done and the bottom solidifies, the tank must be opened. The cone-bottom tank can be cleaned without entering. A water hose, handled just outside the cleanout opening, can be used to flush the solids to the center of the cone and drain connection.

Pipe Storage

Pipe that is used specifically for storing and handling liquid petroleum components should be designed and constructed in accordance with applicable codes. Pipe storage consists of any number of sections of line pipe laid parallel to each other and interconnected to operate as a single unit. The size and length depend on the capacity required and economics. The exterior of buried-pipe storage should be coated and wrapped for corrosion protection. It also is recommended that any coated, wrapped, and buried carbon steel pipe be protected cathodically against the possibility of eventual holidays (imperfections) in the coating. Aboveground pipe storage should be protected against the

*API specifications for standard bolted tanks were prepared by the API Committee on Standardization of Steel Tanks for Oil Storage. Specifications apply to new material. The specification was designed to provide the industry with a standard series of bolted tanks, comprising an adequate range and variety of sizes to meet oilfield requirements, built in accordance with modern manufacturing practice so that decks and bottom pieces and individual staves as supplied by any manufacturer will be readily interchangeable with those supplied by others. On this page are excerpts from API Std. No. 12-B. The complete specification and latest editions are available from the American Petroleum Inst., Div. of Production, Dallas.

*Nominal ID is considered as 2 in. less than bolt-circle diameter and actual capacity figured on that basis.

**Note that the first ring of staves of the 1,500-bbl tank, which is 21 ft 6½ in. ID by 24 ft 1½ in. high, will consist of 12-gauge material conforming to the usual 60-in. width and on account of the two rows of bolts required for the vertical seams of this particular ring, the net width of each of these staves will be 2 in. less than the standard, so the staves will not match up all the way round the tank, and a fill-in staff will be required.

†NOTE: A narrow fill-in staff may be used in conjunction with regular staves 60 in. wide.

Fig. 11.2—Tank dimensions. See Table 11.2.

elements with paint or other approved coating material. In some cases, pipe storage may require insulation. The individual storage pipes are manifolded together for filling and emptying at pipeline transfer rates. The pipe storage must be protected from overpressure just like any other storage vessel.

Tank Corrosion Protection

Coating Specifications³

The primary use of internal coatings is to protect the inside surface of the tank against corrosion while also protecting the stored contents from contamination.

A coating specification should be a clearly defined list of particulars or instructions. Just as a drawing must give exact dimensions, so must a coating specification state the exact system to be used. In the preparation of such a specification, consideration must be given to such factors as (1) types of coatings available, (2) types of surfaces to be coated, (3) compatibility of coatings, and (4) number of coats required on the various types of surfaces for maximum protection. To secure high-quality coatings, consideration must be given to the following factors.

Compatibility.³ In the broadest sense, any discussion of compatibility should include a consideration of the age-old problem of heredity and environment. Environment calculates the compatibility of coatings when applied to various types of surfaces and the operating conditions to which such coatings will be subjected. Heredity concerns itself with the birth of the coating: formulation. The basic raw materials used in formulating and the art of formulation itself determine whether two paints will be "capable of existing together."

Film Thickness.⁴ Coating film thickness is now widely recognized as one of the most important factors in obtaining desired performance from a coating system. The required thickness of a coating system will vary, depending on (1) generic properties of the coating, (2) the type of substrate to which it is applied, and (3) the severity of the environment to which the coating is exposed. Film thickness for most protective paints and coatings is generally measured in mils; 1 mil is $\frac{1}{1,000}$ in.

TABLE 11.2—PARTIAL API SPECIFICATIONS FOR SHOP-WELDED TANKS—TANK DIMENSIONS

Nominal Capacity (bbl)	Design Pressure (oz/sq in.)		Approximate Working Capacity** (bbl)	OD		Height (ft)
	Pressure	Vacuum		(ft)	(in.)	
90	16	1/2	72	7	11	10
100	16	1/2	79	9	6	8
150	16	1/2	129	9	6	12
200	16	1/2	166	12	0	10
210	16	1/2	200	10	0	15
250	16	1/2	224	11	0	15
300	16	1/2	266	12	0	15
400	16	1/2	366	12	0	20
500	8	1/2	479	15	6	16
Tolerance (all sizes)				± 1/8 in.		± 3/8 in.

Height of Overflow Connection*		Height of Walkway Lugs		Location of Fill-Line Connection (in.)	Size of Connections (in.)	
(ft)	(in.)	(ft)	(in.)		C1,2,3,7	C4,5,6
9	6	7	7	14	3	3
7	6	5	7	14	3	3
11	6	9	7	14	3	3
9	6	7	7	14	3	4
14	6	12	7	14	3	4
14	6	12	7	14	4	4
14	6	12	7	14	4	4
19	6	17	7	14	4	4
15	6	13	7	14	4	4
± 1/8 in.		± 1/8 in.		± 1/8 in.		

*Viscous oil option—when so specified on the purchase order, tanks shall be furnished for viscous oil service. On such tanks, Dimension C of the overflow-line connections shall be 6 in. less than shown in Col. 6, and Dimension E of the fill-line connection shall be 6 in. ± 1/8 in.

**The approximate working capacities shown in Col. 3 apply to flat-bottom tanks.

Type A (unskirted) cone-bottom tanks have 6 in. more working height than the corresponding flat-bottom tanks. The approximate increase is 4 bbl for the 7-ft 11-in.-diameter tanks, 6 bbl for the 9-ft 6-in.-diameter tanks, 7 bbl for the 10-ft-diameter tanks, 8 bbl for the 11-ft-diameter tanks, 10 bbl for the 12-ft-diameter tanks, and 17 bbl for the 15-ft 6-in.-diameter tanks.

Type B (skirted) cone-bottom tanks have 8 in. less working height than the corresponding flat-bottom tanks. The approximate decrease in capacity is 6 bbl for the 7-ft 11-in.-diameter tanks, 8 bbl for the 9-ft 6-in.-diameter tanks, 9 bbl for the 10-ft-diameter tanks, 11 bbl for the 11-ft-diameter tanks, 13 bbl for the 12-ft-diameter tanks, and 15 bbl for the 15-ft 6-in.-diameter tanks.

Surface Preparation.⁵ The importance of surface preparation would seem so fundamental that it would not deserve mention in specifications; however, poor surface preparation is a major contributing factor of many coating failures. Detailed instructions should be given all along the line and steps taken to see that they are carried out properly. Basically, no coating can be better than the surface over which it is applied. If that surface is dirt, grease, moisture, mill scale, rust, concrete dust, or any other foreign or interference material, failure can be expected. These substances, forming a film between the surface and the coating, soon break down and fall away, taking the coating with them. Such failures cannot be called coating failures. The type of surface preparation required on various surfaces is determined by (1) the nature of the surface itself, (2) the operating conditions to which such surfaces will be subjected, and (3) the type of coating to be applied to the surfaces. As a general rule, metal surfaces that are to be submerged require more thorough surface preparation than those areas that will be

nonsubmerged. The more severe the corrosive atmospheric elements will be, the more thoroughly surface preparation must be carried out. Certain coatings have a better bonding quality than others. Once recognition is given to the unequalness of bonding qualities, it is then a relatively simple matter to be certain that the correct type of surface preparation is carried out, as required, for the various coatings.

Coatings Types. Many types of internal coatings are available for numerous protection requirements. Because of the unlimited types and applications, only a few are described here.

Coal Tar. Among the oldest and most reliable coatings, coal tar has extremely low permeability, protects the surface by the mechanical exclusion of moisture and air, is extremely water resistant, and resists weak mineral acids, alkalis, salts, brine solutions, and other aggressive chemicals well.

Fig. 11.3—Typical arrangement of internal floating roof.

Epoxy Resin. Epoxy resin gives excellent adhesion, toughness, abrasion resistance, flexibility, high gloss and durability, and good chemical and moisture resistance. Typical applications include linings for sour-crude tanks, floating roof tanks, solvent storage tanks, drilling mud tanks, and pipelines.

Rubber Lining. Rubber lining is used as internal lining for storage tanks that are subjected to severe service, such as elevated temperatures, or for protection from extremely corrosive contents such as concentrated chlorides, and various acids, such as chromic, sulfuric, hydrochloric, and phosphoric.

Galvanizing. Galvanizing (zinc coating) is highly resistant to most types of corrosion. Bolted steel tanks are ideally suited for galvanizing since all component parts are galvanized by the hot-dip process after fabrication but before erection. Galvanized bolted tanks are recommended where sulfur oil is produced and associated with hydrogen sulfide gas. Galvanizing is also very effective against corrosion in seacoast areas where atmospheric conditions present difficulties in maintaining tank life. Fig. 11.4 shows the expected service life of galvanized coatings in different environments for given thicknesses of galvanizing.⁶

External. The basic needs for external coatings are protection against weathering exposure and appearance. Many types of external coatings are available, ranging from basic one-coat primers to primers with one or more top coats. Environmental conditions usually dictate the extent of coating applied. Offshore and coastal installations require more extensive coatings compared with inland locations.

Cathodic Protection

Cathodic protection can be applied to control corrosion that is electrochemical in nature, whereby direct current is forced to flow onto the entire surface area of the steel structure making it cathodic and thus in a noncorroding state. Self-contained sacrificial anodes are recommended for protecting the interior of tanks and vessels. An impressed-current system is recommended for pipe storage, pipelines, casing in producing wells, etc. In this

Fig. 11.4—Expected service life of galvanized coatings.

system, the current is furnished by an AC power system, then rectified to DC current and fed to the structure by the use of a semipermanent anode.

Appurtenances

Storage tanks can be provided with any number of appurtenances, depending on the appropriate design codes and user requirements. A tank may be fitted with mixers, heaters, pressure/vacuum relief devices, platforms and ladders, gauging devices, manways, and a variety of other connections. Tanks may also be equipped with sumps, inlet and outlet nozzles, temperature gauges, pressure gauges, vents, and blowdowns.

Venting Atmospheric and Low-Pressure Storage Tanks

The many abnormal variables that must be considered in connection with tank venting problems make it impracticable to set forth definite simple rules applicable to all locations and all conditions. Larger vents may be required on tanks in which oil is heated, on tanks that receive oil from wells or traps, and on tanks that are subjected to pipeline surges. Similarly, the use of flame arresters or other restrictions that may build up pressure under certain conditions may require the use of larger vents on tanks. The following recommendations for nonrefrigerated aboveground tanks are from API Standard 2000 and set forth determining factors relative to tank venting and pressure/vacuum release requirements.⁷

Nonrefrigerated Aboveground Tanks

Determination of Venting Requirements. Conditions for which venting requirements have been set forth include (1) inbreathing resulting from maximum outflow of oil from the tank, (2) inbreathing resulting from contraction of vapors caused by maximum decrease in atmospheric temperature, (3) outbreathing resulting from maximum inflow of oil into the tank and maximum evaporation caused by such inflow, (4) outbreathing resulting from expansion and evaporation that result from maximum increase in atmospheric temperature (thermal breathing), and (5) outbreathing resulting from fire exposure.

Requirements for Normal Venting Capacity. The normal venting capacity shall be obtained without exceeding the pressure or vacuum that may be applied intermittently to a tank without causing physical damage or permanent deformation to the tank.

The total normal venting capacity shall be at least the sum of the venting requirements for oil movement and thermal effect.*

Inbreathing (Vacuum Relief). The requirement for venting capacity for maximum oil movement out of a tank should be equivalent to 560 cu ft/hr of free air for each 100 bbl (4,200 gal)/hr of maximum emptying rate, including the gravity flow rate to other tanks, for oils of any flash point.

The requirement for venting capacity for thermal inbreathing for a given tank capacity for oils of any flash point should be at least that shown in Col. 2 of Table 11.3.

Outbreathing (Pressure Relief). The requirement for venting capacity for maximum oil movement into a tank and the resulting evaporation for oil with a flash point of 100°F or above should be equivalent to 600 cu ft/hr of free air for each 100 bbl (4,200 gal)/hr of maximum filling rate.**

The requirement for venting capacity for maximum oil movement into a tank and the resulting evaporation for oil with a flash point below 100°F should be equivalent to 1,200 cu ft/hr of free air for each 100 bbl (4,200 gal)/hr of maximum filling rate.³

The requirement for venting capacity for thermal outbreathing, including thermal evaporation, for a given tank capacity for oil with a flash point of 100°F or above should be at least that shown in Col. 3 of Table 11.3.

The requirement for venting capacity for thermal outbreathing, including thermal evaporation, for a given tank capacity for oil with a flash point below 100°F should be at least that shown in Col. 4 of Table 11.3.

Requirements for Emergency Venting Capacity. When storage tanks are exposed to fire, the venting rate may exceed the rate resulting from a combination of normal thermal effects and oil movement. In such cases, the construction of the tank will determine whether additional venting capacity must be provided.

Tanks With Weak Roof-To-Shell Attachment. On fixed-roof tanks with a roof-to-shell attachment (maximum $\frac{3}{16}$ -in. single-fillet weld) as described in the "Roof Design" section of API Standard 650, *Welded Steel Tanks for Oil Storage*, the roof-to-shell connection will fail preferentially to any other joint, and the excess pressure will be relieved safely if the normal venting capacity should prove inadequate. In tanks built to these specifications, consideration need not be given to any additional requirements for emergency venting.

Tanks Without Weak Roof-To-Shell Attachment. When a tank is not provided with a weak roof-to-shell attachment as previously described, the following procedure shall govern in evaluating the required venting capacity for fire exposure.

*However, the required capacity may be reduced for products whose volatility is such that vapor generation or condensation within the permissible operating range of vessel pressure will provide all or part of the venting requirements. In cases in which non-condensibles are present, this should be taken into account.

**For protection against liquid overfilling, refer to Sec. 6.05 of API Standard 620, *Recommended Rules for Design and Construction of Large, Welded, Low-Pressure Storage Tanks*.

TABLE 11.3—REQUIREMENTS FOR THERMAL VENTING CAPACITY^a

		Thermal Venting Capacity (cubic feet of free air ^b per hour)		
		Outbreathing (Pressure)		
1		2 ^c	3 ^d	4 ^e
Tank Capacity (bbl)	(gal)	Inbreathing (vacuum)	Flash Point ≥ 100°F	Flash Point < 100°F
60	2,500	60	40	60
100	4,200	100	60	100
500	21,000	500	300	500

3,000	126,000	3,000	1,800	3,000
4,000	168,000	4,000	2,400	4,000
5,000	210,000	5,000	3,000	5,000
10,000	420,000	10,000	6,000	10,000
15,000	630,000	15,000	9,000	15,000
20,000	840,000	20,000	12,000	20,000
25,000	1,050,000	24,000	15,000	24,000
30,000	1,260,000	28,000	17,000	28,000
35,000	1,470,000	31,000	19,000	31,000
40,000	1,680,000	34,000	21,000	34,000
45,000	1,890,000	37,000	23,000	37,000
50,000	2,100,000	40,000	24,000	40,000
60,000	2,520,000	44,000	27,000	44,000
70,000	2,940,000	48,000	29,000	48,000
80,000	3,360,000	52,000	31,000	52,000
90,000	3,780,000	56,000	34,000	56,000
100,000	4,200,000	60,000	36,000	60,000
120,000	5,040,000	68,000	41,000	68,000
140,000	5,880,000	75,000	45,000	75,000
160,000	6,720,000	82,000	50,000	82,000
180,000	7,560,000	90,000	54,000	90,000

^aInterpolate for intermediate tank sizes. Tanks with a capacity of more than 180,000 bbl require individual study.

^bAt 14.7 psia and 60°F.

^cFor tanks with a capacity of 20,000 bbl or more, the requirements for the vacuum condition are very close to the theoretically computed value of 2 cu ft of air/hr-sq ft of total shell and roof area. For tanks with a capacity of less than 20,000 bbl, the requirements for the vacuum condition have been based on 1 cu ft free air/hr-bbl of tank capacity. This is substantially equivalent to a mean rate of vapor-space-temperature change of 100°F per hour.

^dFor stocks with a flash point of 100°F or above, the outbreathing requirement has been assumed to be 60% of the inbreathing requirement. The tank roof and shell temperatures cannot rise as rapidly under any condition as they can drop, for example, during a sudden cold rain.

^eFor stocks with a flash point below 100°F, the outbreathing requirement has been assumed to be equal to the inbreathing requirement to allow for vaporization at the liquid surface and for the higher specific gravity of the tank vapors.

For tanks designed for pressures of 1 psig or below, the total rate of venting shall be determined in accordance with Table 11.4. (No increase in venting is required for tanks with more than 2,800 sq ft of wetted surface area.⁴)

For tanks and storage vessels designed for pressures of more than 1 psig, the total rate of venting shall be determined in accordance with Table 11.4. However, when the wetted surface area is more than 2,800 sq ft, the total rate of venting shall be calculated by the equation:

$$q_v = 1,107A^{0.82}, \dots\dots\dots (1)$$

where q_v = venting requirement, cu ft of free air per hour (at 14.7 psia at 60°F), and A = wetted surface area, sq ft.*

*This formula is based on $Q = 21,000A^{0.82}$ as given in API Recommended Practice 520, *Design and Installation of Pressure-Relieving Systems in Refineries, Part I—Design*. The total heat absorbed, Q , is in Btu/hr. The constant 1,107 is derived by converting the heat input value of 21,000 Btu/hr-sq ft to scf of free air by use of the latent heat of vaporization at 60°F and the molecular weight of hexane.

TABLE 11.4—TOTAL RATE OF EMERGENCY VENTING REQUIRED FOR FIRE EXPOSURE VERSUS WETTED SURFACE AREA (NONREFRIGERATED ABOVEGROUND TANKS)*

Wetted Area** (sq ft)	Venting Requirement (cu ft free air [†] /hr)	Wetted Area** (sq ft)	Venting Requirement (cu ft free air [†] /hr)
20	21,000	350	288,000
30	31,600	400	312,000
40	42,100	500	354,000
50	52,700	600	392,000
60	63,200	700	428,000
70	73,700	800	462,000
80	84,200	900	493,000
90	94,800	1000	524,000
100	105,000	1200	557,000
120	126,000	1400	587,000
140	147,000	1600	614,000
160	168,000	1800	639,000
180	190,000	2000	662,000
200	211,000	2400	704,000
250	239,000	2800	742,000
300	265,000	> 2800 [‡]	—

*Interpolate for intermediate values. The total surface area does not include the area of ground plates but does include roof areas less than 30 ft above grade.

**The wetted area of the tank or storage vessel shall be calculated as follows. For spheres and spheroids, the wetted area is equal to 55% of the total surface area or the surface area to a height of 30 ft, whichever is greater. For horizontal tanks, the wetted area is equal to 75% of the total surface area. For vertical tanks, the wetted area is equal to the total surface area of the shell within a maximum height of 30 ft above grade.

[†] At 14.7 psia and 60°F.

[‡] For wetted surfaces larger than 2,800 sq ft, see section on tanks without weak roof-to-shell attachment.

The total venting requirements, in cubic feet of free air, determined from Table 11.4 and Eq. 1 are based on the assumption that the stored liquid will have the characteristics of hexane, since this will provide results within an acceptable degree of accuracy for most liquids encountered. However, if a greater degree of accuracy is desired, the total requirement for emergency venting for any specific liquid may be determined by the following equation for cubic feet of free air per hour:

$$q_v = V \frac{1.337}{L\sqrt{M}} \sqrt{\frac{T}{520}}, \dots\dots\dots (2)$$

where

V = cubic feet of free air per hour from Table 11.4 or from Eq. 1,

L = latent heat of vaporization of the specific liquid, in Btu/lbm,

M = molecular weight of the specific liquid, and

T = temperature of the relief vapor, °R.

Full credit may be taken for the vent capacity provided for normal venting, since the normal thermal effect can be disregarded during a fire. It can also be assumed that there will be no oil movement into the tank.

If normal vents are inadequate, additional emergency vents shall be provided so that the total venting capacity is at least equivalent to that required by Table 11.4.

The vent size may be calculated on the basis of the pressure that the tank can withstand safely.

When additional protection is provided, the total rate of emergency venting determined at the beginning of this section may be multiplied by (1) a factor of 0.5 when

drainage away from the tank or vessel is provided, (2) a factor of 0.3 when a 1-in. thickness of external insulation is provided, (3) a factor of 0.15 when a 2-in. thickness of external insulation is provided, or (4) a factor of 0.075 when a 4-in. thickness of external insulation is provided.*

Water films covering the metal surfaces can, under ideal conditions, absorb substantially all of the incident radiation. However, the reliability of effective water application depends on many factors. Freezing weather, high winds, clogging of the system, unreliability of the water supply, and tank surface conditions are a few factors that may prevent adequate or uniform water coverage. Because of these uncertainties, the use of an environmental factor other than 1.0 for water spray is generally discouraged.

Means of Venting. Normal vents. Normal venting shall be accomplished by a pilot-operated relief valve, a pressure-relief valve, a pressure vacuum valve, or an open vent with or without a flame-arresting device in accordance with the following requirements.

If a pilot-operated relief valve is used, it shall be designed so that the main valve will open automatically and will protect the tank in the event of failure of the pilot valve diaphragm or another essential function device. Relief valves equipped with a weight and lever preferably should not be used.

A pressure-relief valve is applicable on tanks operating above atmospheric pressure; in cases in which a vacuum can be created within a tank, vacuum protection may be required.

Pressure vacuum valves are recommended for use on atmospheric storage tanks in which oil with a flash point

*The values for insulation are based on an arbitrary thermal conductivity of 4 Btu/hr/sq ft/(°F/in. of thickness). The insulation shall resist dislodgment by firehose streams and shall be noncombustible.

below 100°F is stored and for use on tanks containing oil that is heated above its flash point. A flame arrester is not considered necessary for use in conjunction with a pressure vacuum valve because flame speeds are less than vent velocities through pressure vacuum valves. (See API Petroleum Safety Data 2210, *Flame Arresters for Tank Vents*.)

Open vents with a flame-arresting device may be used in place of pressure vacuum valves on tanks in which oil with a flash point below 100°F is stored and on tanks containing oil that is heated above its flash point.

Open vents may be used to provide venting capacity for tanks in which oil with a flash point of 100°F or above is stored, for heated tanks in which the oil's storage temperature is below the oil's flash point, for tanks with a capacity of less than 59.5 bbl (2,500 gal) used for storing any product, and for tanks with a capacity of less than 3,000 bbl (126,000 gal) used for storing crude oil.

In the case of viscous oils, such as cutback and penetration-grade asphalts, where the danger of tank collapse resulting from sticking pallets or from plugging of flame arresters is greater than the possibility of flame transmission into the tank, open vents may be used as an exception to the previously outlined requirements for pressure vacuum valves or flame-arresting devices.

Emergency Vents. Emergency venting may be accomplished by use of (1) larger or additional open vents as limited by normal vent requirements, (2) larger or additional pressure vacuum valves or pressure relief valves, (3) a gauge hatch that permits the cover to lift under abnormal internal pressure, (4) a manhole cover that lifts when exposed to abnormal internal pressure, (5) a connection between the roof and the shell that is weaker than the weakest vertical joint in the shell or the shell-to-bottom connection,* and (6) other forms of construction demonstrably comparable for the purposes of pressure relief.

Vent Discharge. For tanks located inside a building, discharge from the vents shall be to the outside of the building. A weak roof-to-shell connection shall not be used as a means for emergency venting a tank inside a building.

Materials of Construction

Metallic

Shop- and field-welded, and bolted storage tanks are customarily fabricated from mild-quality carbon steel. Most common for welded tanks are A-36 structural steel and A-283 Grade C structural-quality carbon steel. Sheet-gauge steel for bolted tanks is of commercial quality having a minimum tensile strength of 52,000 psi. For hydrogen sulfide crude storage, aluminum bolted tanks or aluminum decks only are often used. Various API codes (listed in General References) to which the storage tank is fabricated set forth the welding procedures, inspection procedures, and testing requirements.

Nonmetallic

Nonmetallic tanks customarily are constructed from plastic materials. These have the advantage of being noncorroding, durable, low-cost, and lightweight. Plastic materials used in the construction are polyvinyl chloride,

polyethylene, polypropylene, and fiberglass-reinforced polyesters (FRP's). The FRP tanks are available in the larger sizes and are the most common.* FRP tanks are suitable for outdoor as well as indoor applications. Aboveground vertical FRP tanks can store 24,000 gal and more, depending on the shell construction.

The temperature limits of plastic tanks are approximately 40 to 150°F. Color must be added to the outer liner for protection against ultraviolet radiation. The inner liner must be selected for compatibility with the product stored. Protection from mechanical abuse such as impact loads is necessary. Good planning dictates that plastic storage should not be located next to flammable storage tanks. Special attention should be given to local codes, ordinances, and provisions for insurance relative to storing a flammable product in a flammable container. All plastic tanks used for storage service should be equipped with pressure-relief devices if designed for relatively low-pressure storage.

Production Equipment

Tank-Battery Connections

The suggested setting and connection plan for a typical tank battery is shown in Figs. 11.5 and 11.6. The pipeline connection in the tank should be located directly below the thief hatch and a minimum of 12 in. above the tank bottom. It should be equipped with a valve and sealing device immediately adjacent to the tank. Pipeline valves should be checked frequently for leaks.

Inlet connections preferably should be located in the deck of the tank and should have a valve located near the inlet capable of closing off against pressure.

Drain connections should be located immediately above the tank bottom in the side of the tank or in the tank bottom immediately adjacent to the side. They should be equipped with a valve and sealing device located next to the tank. Drains from all tanks in a battery should be connected together and piped well away from the tanks.

Equalizer or overflow connections should be installed below the deck in the tank shell. A valve and sealing device should be installed immediately adjacent to the tank if more than two tanks are in the battery and should be connected in such a manner that any two tanks can be equalized together.

Vent connections should be installed in the center of the tank deck and all tanks connected to a common line. This line should have a pressure-vacuum valve installed in the line or on the end of it. The line should be sloped to prevent accumulation of liquids in it or in the valve.

The use of gas to roll stored products is usually considered poor practice, and should be restricted to temporary or emergency use. If a roller line is used, it should enter the tank through the deck and be equipped with a valve next to the tank.

Tank-Battery Installation and Hookup

A tank battery should contain at least two tanks and usually have a capacity equal to 4 days' production. All tanks should be level with each other and have a minimum spacing of 3 ft between tanks. Local codes or specifications may require a firewall and different spacing.

*A tank with a roof-to-shell attachment (maximum 3/4-in. single-fillet weld) as described in the "Roof Design" section of API Standard 650, is recognized as having a weak-seam connection and will therefore not require emergency vents.

*An application for approval of fiberglass tanks was submitted during 1984 and the final draft is now pending approval by the API general membership.

Fig. 11.5—Schematic of lease tank battery installation.

Tank Battery for Hydrogen Sulfide Crude Storage

Constant attention should be given to the hazardous condition created by iron sulfide deposits. These occur most frequently within the vapor space and particularly on the underneath exposed side of the deck. These iron sulfide deposits generate severe corrosion that can go unnoticed when deck conditions are observed from the topside only. When sour crude is stored, all openings on the tanks should be kept closed since hydrogen sulfide is poisonous. This can be accomplished by equipping the tanks with some type of ground-level gauging and thermometers located in the tank shell. Gauges and temperatures then can be read from the ground without the tank being opened. These gauging devices usually require approval by the crude purchaser. Ground-level sampling also can be accomplished by installing pipes that extend into the tank

at any desired level and to any desired distance. Valves are located at a convenient level to permit sampling on the ground without the tanks being opened. If available, a small amount of sweet gas should be fed into the top of the tank continuously to establish a "gas sweep." This will ensure positive pressure within the tank at all times and will prohibit air from entering the tank, thereby greatly reducing corrosion. It is advisable to extend the tank vent line well beyond the tank battery and to use a back-pressure valve and flash arrester in the vent line to burn the vapors.

Maintenance and Operation of Tank Batteries⁸

Steel tanks should be kept clean and free from spilled oil or other material. They should be kept painted and all water or accumulated dirt should be removed from around

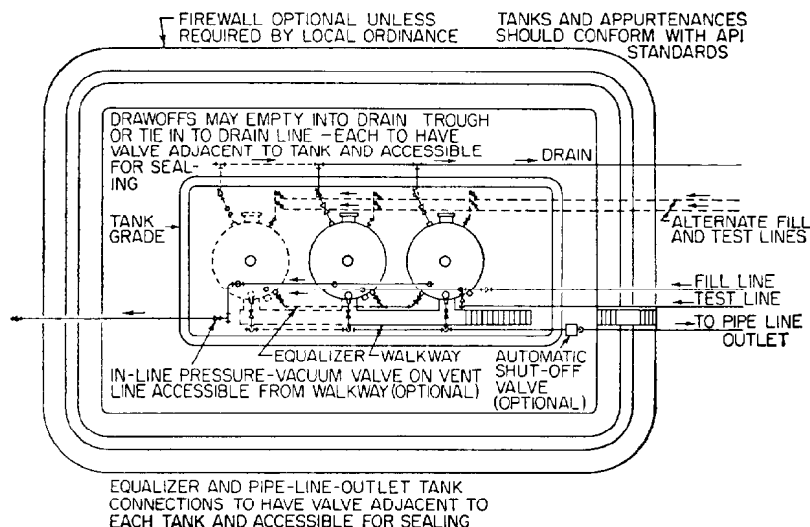

Fig. 11.6—Plan view for lease tank battery installation.

the bottom edge of the tanks. Thief hatches and vent-line valves should be kept closed and inspected periodically for proper operation and gasket condition. Should any leaks occur, they may be repaired temporarily with lead sealing plugs or toggle bolts. These leaks should be repaired permanently as soon as possible.

When a closing gauge is taken, and before the tank is filled again, the pipeline valve should be sealed closed, the drain valve checked to ensure that it is closed and the seal removed, and then the seal from the equalizer-line valve removed. Before the tank is accepted by the crude purchaser, the water should be drained from the tank if necessary and the valve sealed closed. All other valves should be sealed closed except the vapor-recovery-line valve if such a system is in use. The pipeline valve is then unsealed and opened for delivery to the purchaser.

Tank Grades

Selection. Selection of the proper location on the lease for storage tanks is of prime importance. The location should provide good drainage and be on well-packed soil—not a fill—if possible. The tank foundation or grade should be slightly elevated, level, and somewhat larger in diameter than the tank itself. For steel tanks, either bolted or welded, the best grade is one made of small gravel, crushed rock, etc., held in place by steel bands. This type of grade allows no water to stand underneath the tank and provides air circulation. If the tank is to be set directly on the ground, felt tar paper should be applied to the grade first and the tank set on this. If concrete is used for the grade, it should be slightly larger in diameter than the tank and have shallow grooves on the surface to provide air circulation. Many codes, standards, and specifications regulate the location, design, and installation of storage tanks dependent on their end use. Selecting the proper specification and providing adequate fire protection for the installation may lower insurance rates over the life of the installation.

Firewalls or Dikes. Dikes are provided to contain the volume of a certain portion of the tanks enclosed depending on the tank contents. They are used to protect surrounding property from tank spills or fires. In general, the net volume of the enclosed diked area should be the volume of the largest tank enclosed (single-failure concept). The dike walls may be earth, steel, concrete, or solid masonry designed to be watertight with a full hydrostatic head behind them. Local codes and specifications may govern construction. If more than one tank is within the diked area, curbs or preferably drainage channels should be provided to subdivide the area to protect the adjacent tanks from possible spills.

Vapor Losses

Vapors emitted from the vents and/or relief valves of a storage tank are generated in two ways: (1) they are forced out of the tank during filling operations and (2) they are generated by vaporization of the liquid stored in the tank. The total vapor produced in these two instances is the volume that would be available for recovery.

Filling Losses

Vapors that are forced out of the tank are generally called "filling losses." A storage tank generally is not pumped completely dry when emptied. The vapor above the remaining liquid in the tank will expand to fill the void space at the vapor pressure of the liquid stored in the tank at storage temperature. As the tank is filled, the vapors are compressed into a smaller void space until the set pressure on the vent/relief system is reached. There are also some filling losses that are associated with the expansion of the liquid entering the tank. Fig. 11.7 provides a graphical approach to estimating the filling losses as a percentage of the liquid being pumped into the tank.

Fig. 11.7—Filling losses from storage containers.

Fig. 11.8—Gravity loss in degrees API vs. percent loss by volume.

Vaporization Losses

This type of loss is characterized as the vapors generated by heat gain through the shell, bottom, and roof. The total heat input is the sum of the radiant, conductive, and convective energy forces. This type of loss is especially prevalent where light hydrocarbon liquids are stored in full-pressure or refrigerated storage. This is less prevalent but still quite common in crude oil and finished-product storage tanks. These vapors may be recovered by the use of a vapor-recovery system.

Vapor Control and Gravity Conservation With Storage Tanks⁹

Crude oils and condensates are composed of many different paraffin hydrocarbons. Propane is the lightest hydrocarbon found in any measureable amount and the hydrocarbon with the greatest tendency to evaporate or vaporize from the liquid stored. When propane and other hydrocarbons pass into the vapor phase by vaporization, the volume of the liquid stored is decreased, and because these lighter hydrocarbons are not now present in their initial amounts, the API gravity of the crude is decreased. There is a definite relationship between API gravity lost and volume lost, depending on the character of the crude (Fig. 11.8).

Factors Contributing to Vapor and Gravity Losses

Several factors affect and contribute to vapor and gravity losses in storage tanks: (1) vapor pressure of the product stored, (2) temperature of the product stored, (3) surface area of the product stored, (4) agitation of the product stored, (5) pressure on the storage tanks, (6) filling losses from the storage tanks, (7) breathing losses from the storage tanks, (8) size of the storage tanks, and (9) color of outside paint or coating.

Several, if not all, of these factors usually contribute to the total loss from any one tank or battery.

Vapor Pressure. The true vapor pressure (TVP) of a liquid is the actual pressure it exerts on the vapor space in a container at a given temperature. Water, for example, has a TVP of 1 psi at 100°F and a TVP of 14.7 psi at 212°F, yet it must be kept in a closed container to prevent evaporation. The same is true for crude oil if the TVP is below 14.7 psi. Crudes with a TVP of 10 psi and lower are usually relatively stable in closed-atmospheric storage.

Temperature. Temperature of crude is directly related to its vapor pressure. For example, a crude with a TVP of 8 psi at 50°F will have a TVP of 17 psi at 90°F. The vaporization loss is then approximately doubled at the 90°F temperature.

Surface Area. Directly related to the rate of evaporation is the surface area of the crude. Take, for example, two tanks with a capacity of 500 bbl each, one a high 500-bbl tank and the other a low 500-bbl tank. If both are filled one-half full, the high 500 bbl has 0.74 sq ft of surface area exposed per barrel stored, whereas the low 500 bbl has 1.46 sq ft of surface area exposed per barrel stored. The low 500-bbl tank then has twice the evaporation rate of the high 500-bbl tank.

Agitation. Agitation of the stored product is related directly to the vapor pressure. If two crudes under the same conditions receive equal agitation, the one with the higher vapor pressure will show the greatest evaporation loss.

Tank Pressures. The higher the pressure maintained on the storage tank, the less will be the tendency for the crude to evaporate. Pressure storage, considered to be in excess of 1 psig, is required for all stored products with a TVP in excess of 14.7 psi to prevent excessive evaporation losses. High-gravity crudes and distillates or condensates usually require a higher storage pressure than the normal 1 to 4 oz. The crude purchaser often dictates allowable storage pressure.

Filling Losses. When 475 bbl are run from a 500-bbl tank, crude-oil vapors occupy the displaced oil. When the tank is filled again, these vapors are forced from the tank into the atmosphere. These expelled vapors may be equivalent to one or more barrels, depending on the type of crude.

Breathing Losses. Temperature changes between day and night cause vapors to be expelled from the tank and air to be breathed in. These reactions are similar to, but smaller in volume than, the filling and running losses.

Storage Size. A greater vapor space and longer storage time will increase evaporation losses. As an example, consider two tanks with 100 bbl of stored crude each, one a 250-bbl tank and the other a high 500-bbl tank. The 250-bbl tank has 948 cu ft of vapor space while the high 500-bbl tank has 2,457 cu ft or two and one-half times as much. This added vapor space increases the evaporation losses from the larger tank.

Preventing Evaporation and Gravity Losses

Much can be done by the producer to prevent undue losses of crude oil by evaporation. Products should be introduced into storage as cool as possible and kept that way. Some types of heat-exchange equipment should be employed between an emulsion treater, or other heating equipment, and the tanks to cool the oil before it enters storage. If fluid heat exchangers are used, a preventive maintenance program should be employed to guard against buildup of

scale, paraffin, salt, etc., which are common to many produced fluids. Most modern tank batteries are equipped with lease automatic custody-transfer (LACT) units. The run tank should be of sufficient size to allow approximately 12 hours' settling time. Where batteries are equipped with storage for bad oil, this storage should be kept to a minimum and the battery treating capacity should be capable of treating a certain amount of bad oil. Steel tanks should be painted with a reflective or white paint. Tests show the vapor-space temperature of a tank painted with aluminum paint to average $4\frac{1}{2}^{\circ}\text{F}$ above atmospheric temperature, while a red-painted tank averaged 14°F above atmospheric temperature.

Tanks should be selected with smaller diameters, greater heights, and smaller capacities, all other considerations being equal. These factors will allow the stored product to have relatively smaller surface areas and vapor spaces as well as a shorter length of storage time before being sold.

Downcomer pipes prevent undue agitation in the tank. They are usually made by installing a line inside the tank from the inlet connection in the tank deck to 1 ft above the tank bottom. The downcomer must have a vacuum breaker hole at the top to allow gas to escape and thereby prevent agitation, splashing, and accumulation of static electricity.

All tank openings should be maintained closed and pressure on the tank should be as high as practical (at least $\frac{1}{2}$ in. of water column). Tanks in a battery all should be connected together into a common vent line to keep breathing and filling losses to a minimum. Bypass thief hatches are manufactured that will do much to prevent evaporation losses when a tank is gauged through the thief hatch. These special hatches have the tank-battery vent lines connected to them and will close off or isolate all other tanks except the one being gauged. This allows all other tanks in the battery to maintain their pressure while the tank being gauged is depressured.

The producer may install one of several types of ground-level gauging and sampling devices available that will permit gauging and sampling without opening the tank. The tank remaining closed goes far toward eliminating evaporation losses.

Vapor-Recovery System

Vapor-recovery systems are of two basic types. One type connects a vacuum line to the tank and transports the tank vapors to a processing or gasoline plant. The other type consists of a small compressor located by the tank battery, which compresses the tank vapors to a pressure suitable for lease use or sales.

Vacuum-Line System. The vacuum-line system usually is found only in large oil fields, where many tank batteries can be connected together into a relatively short gathering system. This system must employ well-maintained and properly functioning pressure/vacuum relieving devices and dependable control valves to prevent the tanks from collapsing or air from entering the gathering system.

Compression System. The compressor system is usually electrically driven and all components are skid mounted. Some of these systems use a vane-type compressor

and inject a refined oil by way of a lubrication system to seal the vanes against the compressor walls. In these systems an actual liquid recovery is accomplished by the sealing oil absorbing the condensed hydrocarbons from the compressed vapors and transporting them to storage with the returning sealing oil. Applications for this type of system are twofold: (1) compression of the rich stock-tank vapors for sale to a gasoline plant and (2) the recovery of liquids from the rich stock-tank vapors. Liquid hydrocarbons also can be recovered from the compressed vapor-recovery unit (VRU) vapor by either one or both of the following means.

1. A vapor cooling system (air-cooled or water-cooled) heat exchanger can be installed complete with a separator downstream of the hot compressed VRU vapor stream. Multiple vapor cooling systems may be used in between the stages of a multiple-staged compression system.

2. A mechanical refrigeration unit may be installed downstream of the VRU for a higher-yield liquid hydrocarbon recovery.

Underground Storage

Underground storage* is most advantageous when large volumes are to be stored. Underground storage is especially advantageous for high-vapor-pressure products. Solution-mined and conventionally mined caverns are not typically used for underground storage of refrigerated products. Underground storage allows most of the surface area (except for the entry wells) to be used for other purposes. This is especially beneficial in high-value, congested areas.

Type of Construction

Types of underground storage are (1) caverns constructed in salt by solution mining or conventional mining, (2) caverns constructed in nonporous rock by conventional mining, (3) caverns developed by conversion of depleted coal, limestone, or salt mines to storage, and (4) depleted reservoirs.

The solution-mined cavern is constructed by drilling a well or wells into the salt and circulating low-salinity water over the salt interval to dissolve the salt. Fig. 11.9 shows a typical solution-mined cavern.

Conventionally mined caverns can be constructed any place a nonporous rock is available at adequate depth to withstand product pressures. An engineer or geologist experienced in underground storage should evaluate any specific site for the feasibility of constructing underground storage. Most product caverns are constructed in shale, limestone, dolomite, or granite. This type cavern is operated "dry" (the product is recovered by pumping).

Operation

The cavern may be operated by brine displacement of product or pump-out methods (see Figs. 11.9 and 11.10).

Most solution-mined caverns are operated by the brine-displacement technique (Fig. 11.9). A suspended displacement string of casing is installed near the bottom of the cavern, and product is injected into the annulus between the product casing (casing cemented at cavern roof) and the displacement casing, forcing brine up the displace-

Fig. 11.10—Pump-out cavern operation (fracture-connected solution-mined cavern in bedded salt).

ment casing. The procedure is reversed for product recovery. In this type operation, a brine storage reservoir usually is provided.

Some solution-mined caverns are operated "dry" by installing a pump at cavern depth either within the cavern or in a well connected to the cavern by fracturing. Both submersible electrically driven pumps and deep-well vertical multistage pumps are used for this purpose (Fig. 11.10).

Chapter 12

Oil and Gas Separators

H. Vernon Smith, Meridian Corp.

Summary

This chapter is a discussion of the design, use, functions, capacities, classifications, performance, operation, and maintenance of oil and gas separators. Vertical, horizontal, and spherical separators in both two- and three-phase arrangements are discussed. Quality of effluent fluids is approximated. Equations for calculating the sizes and capacities of separators and capacity curves and tables for sizing oil and gas separators are provided. These capacity curves and tables can be used to estimate capacities of separators as well as to determine the size of separator required to handle given volumes of fluids. Sample calculations for sizing separators are included.

Introduction

The term "oil and gas separator" in oilfield terminology designates a pressure vessel used for separating well fluids produced from oil and gas wells into gaseous and liquid components. A separating vessel may be referred to in the following ways:

1. Oil and gas separator.
2. Separator.
3. Stage separator.
4. Trap.
5. Knockout vessel, knockout drum, knockout trap, water knockout, or liquid knockout.
6. Flash chamber, flash vessel, or flash trap.
7. Expansion separator or expansion vessel.
8. Scrubber (gas scrubber), dry or wet type.
9. Filter (gas filter), dry or wet type.
10. Filter/separator.

The terms "oil and gas separator," "separator," "stage separator," and "trap" refer to a conventional oil and gas separator. These separating vessels are normally used on a producing lease or platform near the wellhead, manifold, or tank battery to separate fluids produced from oil and gas wells into oil and gas or liquid and gas. They must be capable of handling "slugs" or "heads" of well

fluids. Therefore, they are usually sized to handle the highest instantaneous rates of flow.

A knockout vessel, drum, or trap may be used to remove only water from the well fluid or to remove all liquid, oil plus water, from the gas. In the case of a water knockout for use near the wellhead, the gas and liquid petroleum are usually discharged together, and the free water is separated and discharged from the bottom of the vessel.

A liquid knockout is used to remove all liquid, oil plus water, from the gas. The water and liquid hydrocarbons are discharged together from the bottom of the vessel, and the gas is discharged from the top.

A flash chamber (trap or vessel) normally refers to a conventional oil and gas separator operated at low pressure, with the liquid from a higher-pressure separator being "flushed" into it. This flash chamber is quite often the second or third stage of separation, with the liquid being discharged from the flash chamber to storage.

An expansion vessel is the first-stage separator vessel on a low-temperature or cold-separation unit. This vessel may be equipped with a heating coil to melt hydrates, or a hydrate-preventive liquid (such as glycol) may be injected into the well fluid just before expansion into this vessel.

A gas scrubber may be similar to an oil and gas separator. Usually it handles fluid that contains less liquid than that produced from oil and gas wells. Gas scrubbers are normally used in gas gathering, sales, and distribution lines where they are not required to handle slugs or heads of liquid, as is often the case with oil and gas separators. The dry-type gas scrubber uses mist extractors and other internals similar to oil and gas separators, with preference shown to the coalescing-type mist extractor. The wet-type gas scrubber passes the stream of gas through a bath of oil or other liquid that washes dust and other impurities from the gas. The gas is flowed through a mist ex-

Fig. 12.1—Typical surface production equipment for handling oil and gas—oil and gas separators and other related equipment.

tractor where all removable liquid is separated from it. A “scrubber” can refer to a vessel used upstream from any gas-processing vessel or unit to protect the downstream vessel or unit from liquid hydrocarbons and/or water.

The “filter” (gas filter or filter/separator) refers to a dry-type gas scrubber, especially if the unit is being used primarily to remove dust from the gas stream. A filtering medium is used in the vessel to remove dust, line scale, rust, and other foreign material from the gas. Such units will normally remove liquid from the gas.

An oil and gas separator generally includes the following essential components and features.

1. A vessel that includes (a) primary separation device and/or section, (b) secondary “gravity” settling (separating) section, (c) mist extractor to remove small liquid particles from the gas, (d) gas outlet, (e) liquid settling (separating) section to remove gas or vapor from oil (on a three-phase unit, this section also separates water from oil), (f) oil outlet, and (g) water outlet (three-phase unit).

2. Adequate volumetric liquid capacity to handle liq-

uid surges (slugs) from the wells and/or flowlines.

3. Adequate vessel diameter and height or length to allow most of the liquid to separate from the gas so that the mist extractor will not be flooded.

4. A means of controlling an oil level in the separator, which usually includes a liquid-level controller and a diaphragm motor valve on the oil outlet. For three-phase operation, the separator must include an oil/water interface liquid-level controller and a water-discharge control valve.

5. A backpressure valve on the gas outlet to maintain a steady pressure in the vessel.

6. Pressure relief devices.

In most oil and gas surface production equipment systems, the oil and gas separator is the first vessel the well fluid flows through after it leaves the producing well. However, other equipment—such as heaters and water knockouts—may be installed upstream of the separator. Fig. 12.1 shows a typical surface production equipment system for handling crude oil using an oil and gas separator along with related equipment.

Well Fluids and Their Characteristics

Some of the physical characteristics of well fluids handled by oil and gas separators are briefly outlined in this section.

Crude Oil. Crude oil is a complex mixture of hydrocarbons produced in liquid form. The API gravity of crude oil can range from 6 to 50°API and viscosity from 5.0 to 90,000 cp at average operating conditions. Color varies through shades of green, yellow, brown, and black. Detailed characteristics of crude oils are given in Chap. 21.

Condensate. This is a hydrocarbon that may exist in the producing formation either as a liquid or as a condensible vapor. Liquefaction of gaseous components of the condensate usually occurs with reduction of well-fluid temperature to surface operating conditions. Gravities of the condensed liquids may range from 50 to 120°API and viscosities from 2.0 to 6.0 cp at standard conditions. Color may be water-white, light yellow, or light blue.

Natural Gas. A gas may be defined as a substance that has no shape or volume of its own. It will completely fill any container in which it is placed and will take the shape of the container. Hydrocarbon gas associated with crude oil is referred to as natural gas and may be found as “free” gas or as “solution” gas. Specific gravity of natural gas may vary from 0.55 to 0.90 and viscosity from 0.011 to 0.024 cp at standard conditions.

Free Gas. Free gas is a hydrocarbon that exists in the gaseous phase at operating pressure and temperature. Free gas may refer to any gas at any pressure that is not in solution or mechanically held in the liquid hydrocarbon.

Solution Gas. Solution gas is homogeneously contained in oil at a given pressure and temperature. A reduction in pressure and/or an increase in temperature may cause the gas to be emitted from the oil, whereupon it assumes the characteristics of free gas.

Condensible Vapors. These hydrocarbons exist as vapor at certain pressures and temperatures and as liquid at other pressures and temperatures. In the vapor phase, they assume the general characteristics of a gas. In the liquid phase, condensible vapors vary in specific gravity from 0.55 to 4.91 (air=1.0), and in viscosity from 0.006 to 0.011 cp at standard conditions.

Water. Water produced with crude oil and natural gas may be in the form of vapor or liquid. The liquid water may be free or emulsified. Free water reaches the surface separated from the liquid hydrocarbon. Emulsified water is dispersed as droplets in the liquid hydrocarbon.

Impurities and Extraneous Materials. Produced well fluids may contain such gaseous impurities as nitrogen, carbon dioxide, hydrogen sulfide, and other gases that are not hydrocarbon in nature or origin. Well fluids may contain liquid or semiliquid impurities, such as water and paraffin. They may also contain solid impurities, such as drilling mud, sand, silt, and salt.

Primary Functions of Oil and Gas Separators

Separation of oil from gas may begin as the fluid flows through the producing formation into the wellbore and may progressively increase through the tubing, flowlines, and surface handling equipment. Under certain conditions, the fluid may be completely separated into liquid and gas before it reaches the oil and gas separator. In such cases, the separator vessel affords only an “enlargement” to permit gas to ascend to one outlet and liquid to descend to another.

Removal of Oil From Gas

Difference in density of the liquid and gaseous hydrocarbons may accomplish acceptable separation in an oil and gas separator. However, in some instances, it is necessary to use mechanical devices commonly referred to as “mist extractors” to remove liquid mist from the gas before it is discharged from the separator. Also, it may be desirable or necessary to use some means to remove non-solution gas from the oil before the oil is discharged from the separator.

Removal of Gas From Oil

The physical and chemical characteristics of the oil and its conditions of pressure and temperature determine the amount of gas it will contain in solution. The rate at which the gas is liberated from a given oil is a function of change in pressure and temperature. The volume of gas that an oil and gas separator will remove from crude oil is dependent on (1) physical and chemical characteristics of the crude, (2) operating pressure, (3) operating temperature, (4) rate of throughput, (5) size and configuration of the separator, and (6) other factors.

Rate of throughput and liquid depth in the separator determine the “retention” or “settling” time of the oil. Retention time of 1 to 3 minutes is generally adequate to obtain satisfactory separation of crude oil and gas unless foaming oil is being handled. When foaming oil is separated, retention time should be increased to 5 to 20 minutes, dependent on the stability of the foam and on the design of the separator. Advancements in field processing systems and production procedures—such as automatic custody transfer—emphasize the need for complete removal of nonsolution gas from the oil. Agitation, heat, special baffling, coalescing packs, and filtering materials can assist in the removal of nonsolution gas that otherwise may be retained in the oil because of the viscosity and surface tension of the oil.

Separation of Water From Oil

In some instances it is preferable to separate and to remove water from the well fluid before it flows through pressure reductions, such as those caused by chokes and valves. Such water removal may prevent difficulties that could be caused downstream by the water—such as corrosion, hydrate formation, and the formation of tight emulsion that may be difficult to resolve into oil and water.

The water can be separated from the oil in a three-phase separator by use of chemicals and gravity separation. If the three-phase separator is not large enough to separate the water adequately, it can be separated in a free-water

Fig. 12.2—Horizontal skid-mounted three-phase well tester on offshore drilling platform off coast of Brazil.

knockout vessel installed upstream or downstream of the separators. If the water is emulsified, it may be necessary to use an emulsion treater to remove it. Figs. 12.2 through 12.5 are illustrations of three-phase separators.

Secondary Functions of Oil and Gas Separators

Maintain Optimum Pressure on Separator

For an oil and gas separator to accomplish its primary functions, pressure must be maintained in the separator so that the liquid and gas can be discharged into their respective processing or gathering systems. Pressure is

maintained on the separator by use of a gas backpressure valve on each separator or with one master backpressure valve that controls the pressure on a battery of two or more separators. Fig. 12.6 shows a typical low-pressure gas backpressure valve, and Fig. 12.7 shows a typical high-pressure gas backpressure valve used to maintain the desired pressure in separators.

The optimum pressure to maintain on a separator is the pressure that will result in the highest economic yield from the sale of the liquid and gaseous hydrocarbons. This optimum pressure can be calculated theoretically or determined by field tests.

Fig. 12.7—High-pressure-gas backpressure valve.

Maintain Liquid Seal in Separator

To maintain pressure on a separator, a liquid seal must be effected in the lower portion of the vessel. This liquid seal prevents loss of gas with the oil and requires the use of a liquid-level controller and a valve similar to those shown in Figs. 12.8 and 12.9. A lever-operated valve similar to the one shown in Fig. 12.10 can be used to

maintain the liquid seal in a separator when the valve is operated by a float that is actuated by the oil level in the separator. The oil discharge control valve shown in Fig. 12.9 can be actuated by a float-operated pilot (not illustrated), by a floatless liquid-level controller similar to the one shown in Fig. 12.11, or by a torque tube-type (displacement) liquid-level controller similar to the one shown in Fig. 12.8.

Fig. 12.8—Torque-tube (displacement)-type liquid-level controller.

Fig. 12.9—Diaphragm-motor-type oil-discharge control valve.

Special Problems in Oil and Gas Separation

Separating Foaming Crude Oil

When pressure is reduced on certain types of crude oil, tiny spheres (bubbles) of gas are encased in a thin film of oil when the gas comes out of solution. This may result in foam, or froth, being dispersed in the oil and creates what is known as “foaming” oil. In other types of crude oil, the viscosity and surface tension of the oil may

mechanically lock gas in the oil and can cause an effect similar to foam. Oil foam will not be stable or long-lasting unless a foaming agent is present in the oil. Crude oil is more likely to foam when (1) the API gravity is less than 40° API, (2) the operating temperature is less than 160°F, and (3) the crude oil is viscous, having a viscosity greater than 5,000 SSU (about 53 cp).

Foaming greatly reduces the capacity of oil and gas separators because a much longer retention time is required to separate adequately a given quantity of foaming crude oil. Foaming crude oil cannot be measured accurately with positive-displacement meters or with conventional volumetric metering vessels. These problems, combined with the potential loss of oil and gas because of improper separation, emphasize the need for special equipment and procedures in handling foaming crude oil.

There are many special designs of separators for handling foaming crude oil. The special horizontal separator for handling foaming oil shown in Fig. 12.12 is one of the simpler, more effective units available for this service. The special degassing element used on the inlet of this separator shown in Section CC of Fig. 12.12 gently agitates the well fluid and assists in removing gas from the oil and in breaking foam bubbles as they flow through the inlet element.

The defoaming plates, which extend from near the inlet end to near the outlet end of the separator, are spaced 4 in. apart and are shaped with an apex at the vertical center of the separator. The plates that are immersed in oil assist in removing nonsolution gas from the oil and in breaking foam in the oil. The plates that are above the oil/gas interface in the gas section of the separator remove

Fig. 12.10—Lever-type valve for controlling oil discharge from oil and gas separators. Valve is float operated.

oil mist from the gas and assist in breaking foam that may exist in the gas section of the vessel.

The 6-in.-thick knitted-wire-mesh mist extractor (located below the gas outlet) removes the remainder of the liquid mist from the gas and breaks or removes the remaining foam bubbles from the gas.

The vertical separator shown in Fig. 12.13 can be used to handle foaming crude oil. As the oil cascades down the plates in this unit, the foam bubbles will be distorted and broken. This design can increase the capacity of the separator to handle foaming oil by 10 to 50%.

The main factors that assist in "breaking" foaming oil are settling, agitation (baffling), heat, chemicals, and centrifugal force. These factors or methods of "reducing" or "breaking" foaming oil are also used to remove entrained gas from oil. They are discussed on Pages 12-13 through 12-15. Many different designs of separators for handling foaming crude oil have evolved. They are available from various manufacturers—some as standard foam-handling units and some designed especially for a specific application.

Paraffin

Paraffin deposition in oil and gas separators reduces their efficiency and may render them inoperable by partially filling the vessel and/or blocking the mist extractor and fluid passages. Paraffin can be effectively removed from separators by use of steam or solvents. However, the best

Fig. 12.11—Floatless liquid-level controller and diaphragm-motor oil-control valve on high-pressure oil and gas separator.

Fig. 12.12—Horizontal oil and gas separator with special internals for separating foaming crude oil.

Fig. 12.13—Vertical oil and gas separator with special baffling to remove gas from oil, especially beneficial in handling foaming oil. Upper left view and Section A-A show inlet separating element that assists in removing gas from oil.

solution is to prevent initial deposition in the vessel by heat or chemical treatment of the fluid upstream of the separator. Another deterrent, successful in most instances, involves the coating of all internal surfaces of the separator with a plastic for which paraffin has little or no affinity. The weight of the paraffin will cause it to slough off of the plastic-coated surface before it builds up to harmful thickness.

Sand, Silt, Mud, Salt, Etc.

If sand and other solids are continuously produced in appreciable quantities with well fluids, they should be removed before the fluids enter the pipelines. Medium-grained sand in small quantities can be removed by settling in an oversized vertical vessel with a conical bottom and by periodically draining the residue from the vessel. Salt may be removed by mixing water with the oil, and after the salt is dissolved, the water can be separated from the oil and drained from the system.

Corrosion

Produced well fluids can be very corrosive and cause early failure of equipment. The two most corrosive elements are hydrogen sulfide and carbon dioxide. These two gases may be present in the well fluids in quantities from a trace up to 40 to 50% of the gas by volume. A discussion of the problems caused by these two corrosive gases is included in Chaps. 14 and 44.

Methods Used To Remove Oil From Gas in Separators

Liquid mist can be effectively removed from the gas stream in an oil and gas separator by a well-designed mist extractor. Condensable vapors in the gas cannot be removed by mist extractors. Condensation of these vapors, caused by reduction of temperature, may occur after the gas has been discharged from the separator. Thus, existence of liquid in the effluent gas from an oil and gas separator in many instances may not necessarily reflect the efficiency of the separator. Because condensable vapors may have the characteristics of natural gas at separator temperature and pressure, condensation of these vapors may occur immediately after being discharged from the separator.

Density difference of liquid and gas may accomplish separation of liquid droplets from a gas stream where the velocity of the stream is slow enough and sufficient time is allowed to accomplish separation. Limiting the gas velocity in a separator may obtain satisfactory separation without a mist extractor. However, mist extractors are generally installed in conventional oil and gas separators to assist in separation and to minimize the amount of liquid (mist) carried out with the gas.

The methods used to remove oil from gas in oil and gas separators are density difference (gravity separation), impingement, change of flow direction, change of flow velocity, centrifugal force, coalescence, and filtering. Mist extractors used in oil and gas separators can be of many different designs using one or more of these methods. Fig. 12.14 shows a vane-type mist extractor, Fig. 12.15 a centrifugal one, and Fig. 12.16 shows a knitted-wire-mesh (coalescing)-type mist extractor.

Density Difference (Gravity Separation)

Natural gas is lighter than liquid hydrocarbon. Minute particles of liquid hydrocarbon that are temporarily suspended in a stream of natural gas will, by density difference or force of gravity, settle out of the stream of gas if the velocity of the gas is sufficiently slow. The larger droplets of hydrocarbon will quickly settle out of the gas, but the smaller ones will take longer.

At standard conditions of pressure and temperature, the droplets of liquid hydrocarbon may have a density 400 to 1,600 times that of natural gas. However, as the operating pressure and temperature increase, the difference in density decreases. At an operating pressure of 800 psig, the liquid hydrocarbon may be only 6 to 10 times as dense as the gas. Thus, operating pressure materially affects the size of the separator and the size and type of mist extractor required to separate adequately the liquid and gas.

The fact that the liquid droplets may have a density 6 to 10 times that of the gas may indicate that droplets of liquid would quickly settle out of and separate from the gas. However, this may not occur because the particles of liquid may be so small that they tend to "float" in the gas and may not settle out of the gas stream in the short period of time the gas is in the oil and gas separator.

Particles of liquid hydrocarbon with diameters of 100 μm and larger will generally settle out of the gas in most average-sized separators. However, mist extractors usually are needed to remove smaller particles from the gas.

As the operating pressure on a separator increases, the density difference between the liquid and gas decreases. For this reason, it is desirable to operate oil and gas separators at as low a pressure as is consistent with other process variables, conditions, and requirements.

Impingement

If a flowing stream of gas containing liquid mist is impinged against a surface, the liquid mist may adhere to and coalesce on the surface. After the mist coalesces into larger droplets, the droplets will gravitate to the liquid section of the vessel. If the liquid content of the gas is high, or if the mist particles are extremely fine, several successive impingement surfaces may be required to effect satisfactory removal of the mist. A mist extractor that provides repeated impingement to remove fine oil mist from the gas is shown in Fig. 12.14a.

Change of Flow Direction

When the direction of flow of a gas stream containing liquid mist is changed abruptly, inertia causes the liquid to continue in the original direction of flow. Separation of liquid mist from the gas thus can be effected because the gas will more readily assume the change of flow direction and will flow away from the liquid mist particles. The liquid thus removed may coalesce on a surface or fall to the liquid section below. The mist extractor shown in Fig. 12.14a uses this method of mist extraction.

Change of Flow Velocity

Separation of liquid and gas can be effected with either a sudden increase or decrease in gas velocity. Both conditions use the difference in inertia of gas and liquid. With a decrease in velocity, the higher inertia of the liquid mist carries it forward and away from the gas. The liquid may then coalesce on some surface and gravitate to the liquid section of the separator. With an increase in gas velocity, the higher inertia of the liquid causes the gas to move away from the liquid, and the liquid may fall to the liquid section of the vessel. Fig. 12.14a shows one version of a vane-type mist extractor that uses change of flow velocity. This mist extractor is used in the typical vertical oil and gas separator shown in Fig. 12.14b.

Centrifugal Force

If a gas stream carrying liquid mist flows in a circular motion at sufficiently high velocity, centrifugal force throws the liquid mist outward against the walls of the container. Here the liquid coalesces into progressively larger droplets and finally gravitates to the liquid section below. Centrifugal force is one of the most effective methods of separating liquid mist from gas. Efficiency of this type of mist extractor increases as the velocity of the gas stream increases. Thus for a given rate of throughput, a smaller centrifugal separator will suffice.

Fig. 12.15 illustrates a horizontal, dual-tube, two-phase oil and gas separator that uses two stages of centrifugal mist extraction to remove liquid mist from the gas. The inlet impingement element is a cone with outwardly spiraling vanes that impart a swirling motion to the well fluid as it enters the separator. The larger droplets of liquid are thrown outward against the shell of the separator and gravitate down to the liquid section of the vessel. The gas

Fig. 12.14—Vertical two-phase oil and gas separator. (a) Illustration of impingement, change of flow direction, and change of flow velocity methods of mist extraction. (b) Separating and degassing element on inlet of vessel shown in detail in Section A-A.

flows to the secondary element, which consists of inward-spiraling vanes that accelerate the gas to around 80 ft/sec at normal capacity. This high velocity forces the particles of the liquid mist to the center of the element where they coalesce and separate from the gas when the velocity reduces to 2 to 8 ft/sec downstream of the secondary element. Oil separated by the primary centrifugal element flows from the upper shell cylinder to the lower one through the downcomer at the left. Oil removed from the gas by the secondary centrifugal element flows from the upper shell cylinder to the lower shell cylinder through the downcomer at the right. The lower cylinder of the separator is divided into two compartments with crude oil being discharged from each by use of two liquid-level controllers and two oil-discharge control valves.

Fig. 12.15—Dual-tube horizontal two-phase oil and gas separator with centrifugal primary and secondary separating elements.

Fig. 12.16—Coalescing-type mist-eliminator pad with drain cylinders.

Separators and scrubbers using centrifugal force for the removal of liquid mist from the gas can handle large volumes of gas. One such unit installed near Princess, Alta., Canada, handles 3.5×10^9 scf/D at 1,000 psig.¹ This type of gas-cleaning unit is generally used in gas gathering, transmission, and distribution systems.

Small-diameter oil and gas separators (below 3 or 4 ft in diameter) using centrifugal force are generally not used as the primary separator on producing leases. This is because of the possibility that the small vessels may be inundated with a "slug" or "head" of liquid that may allow excessive liquid to exit with the gas and excessive gas to exit with the liquid. Therefore, primary separators on oil and gas streams are usually "conventional" units (other than centrifugal) to prevent the possibility of "overloading" the separators with liquid.

Coalescence

Coalescing packs afford an effective means of separating and removing liquid mist from a stream of natural gas. One of their most appropriate uses is the removal of liquid mist from gas in transmission and distribution systems where the amount of liquid in the gas is low.

Coalescing packs can be made of Berl saddles, Raschig rings, knitted wire mesh, and other such tower-packing materials. The packs use a combination of impingement, change of direction, change of velocity, and coalescence to separate and to remove liquid mist from gas. These packs provide a large surface area for collection and coalescence of the liquid mist. Fig. 12.17 is a schematic of a knitted wire mesh coalescing pack-type mist extractor used in some oil and gas separators and gas scrubbers.

A word of caution is appropriate concerning the use of coalescing packs in oil and gas separators for general field use. Coalescing packs may be made of frangible material that can be damaged during transit or installation if they are installed in the separator in the manufacturing shop before shipment to point of use. Knitted wire mesh may foul or plug from paraffin deposition and other foreign material and thus make a separator inoperative after a short period of service. Also, excessive pressure drop across the pack may force the pack out of place and allow channelling around or through the pack.

Even though coalescing packs are very effective in the removal of liquid mist from gas, it is usually preferred to use vane-type mist extractors for most oil and gas separators because they may be used under widely varying field conditions. Because of the "fouling" tendency of coalescing-type mist extractors, their use may appropriately be restricted to gas scrubbers used in gas gathering, transmission, and distribution systems.

Filtering

Porous filters are effective in the removal of liquid mist from gas in certain applications. In effect, the porous material strains or filters the liquid mist from the gas. The porous material may use the principles of impingement, change of flow direction, and change of velocity to assist in separation of liquid mist from gas.

Pressure drop through mist extractors used in separators should be as low as practical while maximum separating efficiency is still maintained. Generally, filter-type mist extractors will have the highest pressure drop per unit volume of capacity and the coalescing type will have the lowest. Pressure drop through the other types of mist extractors will usually range between these two extremes.

Mist Extractors Used in Oil and Gas Separators

Vane-Type Mist Extractors

Vane-type mist extractors are widely used in oil and gas separators to remove the liquid mist from the gas. These mist extractors can be of many designs. One design is shown in Fig. 12.14B. An enlargement of the mist extractor is shown in Fig. 12.14A. This is a simple but effective mist extractor, consisting of four layers of steel angles placed parallel to each other with the apex of the angle pointing upward. The angles are spaced $\frac{1}{2}$ in. apart horizontally; that is, they have a $\frac{1}{2}$ -in. gap between the legs of the angles in the horizontal plane. There is also a $\frac{1}{2}$ -in. space between the apex of the angle and the leg of the angles in the row above.

Gas flowing through the mist extractor follows the path illustrated in Fig. 12.14A. This flow pattern takes advantage of impingement, change of flow direction, change of flow velocity, and coalescence to separate liquid mist from the gas. Literally thousands of these mist extractors have been used, with all of them giving good performance. They are inexpensive to manufacture and usually will not plug or foul with foreign material and paraffin.

Another design of a vane-type mist extractor is shown in Fig. 12.18. As the gas enters the mist extractor, it is divided into many vertical ribbons (A). Each ribbon of gas is subjected to multiple changes of direction of flow

Fig. 12.17—Coalescing-type mist extractor with knitted wire mesh. Used in gas scrubbers and oil and gas separators.

(B) as it flows through the mist extractor. This causes mild turbulence and causes the gas to roll against the vanes, as at (C). The entrained droplets of liquid impinge against the vanes, where they adhere and coalesce (D). The liquid droplets move into the vane pockets (E). The liquid flows downward in these channels to the bottom of the mist extractor and then through the drain to the liquid reservoir in the bottom of the vessel where it can be drained from the separator.² The liquid drainage from this mist extractor occurs with the liquid out of the gas stream and with the movement of the liquid flow at a right angle to the direction of flow of the gas.

The separating efficiency of this mist extractor depends on the (1) number of vanes in the element, (2) distance between the vanes, (3) number of drainage channels, (4)

PRINCIPLE OF OPERATION

Fig. 12.18—Vane-type mist extractor with liquid channels.

Fig. 12.19—Pressure drop and flooding velocity for 6-in.-thick mist-eliminator pad with and without drain cylinders.

width and depth of drainage channels, (5) distance between drainage channels, and (6) size of liquid particles to be removed from the gas.

It is claimed that this mist extractor will remove all entrained liquid droplets that are 8 to 10 μm and larger. If liquid particles smaller than 8 μm in diameter are present in the gas, an agglomerator should be installed upstream of the separator to coalesce the liquid into particles that are large enough for the vane-type mist extractor to remove. Some agglomerators are capable of achieving removal of 99.5% of all particles 1.0 μm and larger. Pressure drop across this vane mist extractor is very low, varying from 2 to 3 in. of water up to 6 to 8 in. of water.²

Fibrous-Type Mist Extractors

Fibrous packing has been used to remove liquid mist from natural gas since the early 1950s. Most of these fibrous packs have been knitted wire mesh. The main use of such mist eliminators has been to remove fine droplets, 10 to 100 μm in diameter, from a stream of gas. Standard mist-eliminator pads made of knitted wire mesh have low pressure drop, high separating efficiency, relatively low initial cost, and low maintenance cost.

In the late 1960's and early 1970's, considerable developmental work was done to improve the separating efficiency of knitted-wire-mesh mist-eliminator pads. It was

found that through use of a combination of filaments of different materials and diameters, the separating capacity of the pads could be greatly increased. It was found that a pad 9 in. thick with one 3-in.-thick pad of cknitted 0.0008-in.-diameter fiberglass filaments and 0.011-in.-diameter stainless steel filaments used as the bottom portion and one 6-in.-thick pad of 0.011-in.-diameter stainless-steel wire mesh as the top portion of the pad would give the highest separating efficiency at the lowest initial cost. In Fig. 12.16, No. 2 is the multifilament bottom portion of the pad, and No. 3 is the coarser monofilament top portion of the pad.

The extra-fine fiberglass filaments (0.0008 in. in diameter) cknitted with the 0.011-in. stainless-steel wire used in the bottom portion of the pad will agglomerate mist particles of 1 to 10 μm into larger particles so that the larger-diameter wire fibers (0.011 in. in diameter) used in the upper 6 in. of the mist eliminator can remove these agglomerated particles from the gas. Even though these combination multifilament pads appreciably increased the separating efficiency, they could not be used widely because they would flood at velocities 50% below those of regular (0.011-in. diameter) wire pads.

U.S. Patent No. 4,022,593³ issued May 10, 1977, solved this flooding problem for fine-wire pads. This patent discloses that the use of liquid drain cylinders installed underneath the mist eliminator pad, No. 4 of Fig. 12.16, will cause liquid to drain from the mist eliminator pad as quickly as it collects so that the mist pads remain free of liquid. This reduces the pressure drop through the pads and increases their separating capacity and efficiency.

These drain cylinders are made of the same material as the bottom portion of the mist eliminator pad, are about 3 in. in diameter, and are spaced underneath the pad on 12-in. centers. The drain cylinders provide a preferential "escape" route from the pad for the liquid. The preferential drain route results from the added gravity head provided by the drain cylinders.⁴ The drain cylinders are generally made of the same material and mesh as the bottom portion of the mist-eliminator pad. The liquid draining from the drain cylinders is shielded from the drag friction of the upflowing gas. Small rivulets or streams of liquid flow down through and across the mist pads down through the drain cylinders. The liquid flows from the drain cylinders in large drops or small streams. Re-entrainment is minimized or eliminated by use of the drain cylinders at the same time the separating efficiency of the pad is increased. Any free liquid anywhere in the pad tends to flow into the drain cylinder and be removed from the pad.

Fig. 12.19 shows the comparative pressure drop and flooding characteristics of a 6-in.-thick knitted-mesh mist-eliminator pad made of high-density polypropylene with and without drain cylinders. The fluids used in this test were air and water. The left curve is for the 6-in.-thick pad without drain cylinders. The middle curve is with the same pad but with drain cylinders installed. The straight line marked "Ref. Dry" represents the pressure drop through the same pad with no water in the pad, i.e., with the pad dry. The two points marked "Flood" indicate the air velocity that caused the pad to flood with water. The flood velocity for the pad without drain cylinders was almost 7 ft/sec. For the pad with drain cylinders, the flood velocity was 11.8 ft/sec.

Methods Used To Remove Gas From Oil In Separators

Because of higher prices for natural gas, the widespread reliance on metering of liquid hydrocarbons, and other reasons, it is important to remove all nonsolution gas from crude oil during field processing.

Methods used to remove gas from crude oil in oil and gas separators are settling, agitation, baffling, heat, chemicals, and centrifugal force.

Settling

Gas contained in crude oil that is not in solution in the oil will usually separate from the oil if allowed to settle a sufficient length of time. An increase in retention time for a given liquid throughput requires an increase in the size of the vessel and/or an increase in the liquid depth in the separator. Increasing the depth of oil in the separator may not result in increased emission of nonsolution gas from the oil because "stacking up" of the oil may prevent the gas from emerging. Optimum removal of gas from the oil is usually obtained when the body of oil in the separator is thin—i.e., when the ratio of surface area to retained oil volume is high.

Agitation

Moderate, controlled agitation is helpful in removing nonsolution gas that may be mechanically locked in the oil by surface tension and oil viscosity. Agitation usually will cause the gas bubbles to coalesce and to separate from the oil in less time than would be required if agitation were not used. Agitation can be obtained by properly designed and placed baffling.

Baffling

An inlet degassing element similar to that shown in Fig. 12.13 can be installed on the inlet of the separator to assist in introducing the well fluid into the separator with minimum turbulence and in removing gas from the oil. This element disperses the oil in such a manner that gas can more readily escape from the oil. This type of element eliminates high-velocity impingement of fluid against the opposite wall of the separator. The baffles placed in the separator (Fig. 12.13) between the inlet and the oil level spread the oil into thin layers as it flows downward from the inlet to the oil section. The oil is rolled over and over as it cascades down the baffles, and the combination of spreading and rolling is effective in releasing entrained gas bubbles. This type of baffling is effective in handling foaming oil.

Special perforated baffles or tower packing can be used to remove nonsolution gas from crude oil. Such baffling or packing provides slight agitation, which allows the gas bubbles to break out of the oil as it flows through the baffles or packing.

Heat

Heat reduces surface tension and viscosity of the oil and thus assists in releasing gas that is hydraulically retained in the oil. The most effective method of heating crude oil is to pass it through a heated-water bath. A spreader plate that disperses the oil into small streams or rivulets increases the effectiveness of the heated-water bath. Upward flow of the oil through the water bath affords slight

agitation, which is helpful in coalescing and separating entrained gas from the oil. A heated-water bath is probably the most effective method of removing foam bubbles from foaming crude oil. A heated-water bath is not practical in most oil and gas separators, but heat can be added to the oil by direct or indirect fired heaters and/or heat exchangers, or heated free-water knockouts or emulsion treaters can be used to obtain a heated-water bath.

Chemicals

Chemicals that reduce the surface tension of crude oil will assist in freeing nonsolution gas from the oil. Such chemicals will appreciably reduce the foaming tendency of the oil and thereby increase the capacity of a separator when foaming oil is handled. In one particular case, the capacity of an oil and gas separator was increased from 3,800 to 9,600 B/D when silicone was injected into and mixed with the oil upstream of the separator with no other change made in the system. Silicone is effective in reducing the foaming tendency of crude oil when it is mixed with the oil in such small quantities as parts per million or parts per billion.

Centrifugal Force

Centrifugal force is effective in separating gas from oil. The heavier oil is thrown outward against the wall of the vortex retainer while the gas occupies the inner portion of the vortex. A properly shaped and sized vortex will allow the gas to ascend while the liquid flows downward to the bottom of the unit. The separators and scrubbers shown in Figs. 12.15 and 12.20 through 12.22 use centrifugal force for separation. Oil from such units will usually contain less nonsolution gas than that from units that do not use centrifugal force.

Estimated Quality of Separated Fluids

Crude Oil

The free (nonsolution) gas content of separated crude oil will vary widely depending on many factors, such as size and configuration of the separator, design and arrangement of the separator internals, operating pressure and temperature, rate of flow, GOR, depth of liquid in the separator, viscosity, and surface tension of the oil. Table 12.1 indicates the estimated free gas and water content of separated crude oil discharged from average oil and gas separators operating under average field conditions. The values shown in this table are only approximate and are intended as an indication of the general range of results that may be expected; they are not intended to be exact and limiting. Table 12.1 indicates that appreciable quantities of free gas and water may be left in the separated crude oil; such undesirable performance may be obtained unless particular attention is given to the controlling factors indicated previously.

The water content of separated crude oil probably will be within the wide range indicated in Table 12.1. The factors listed previously, in addition to the agitation resulting from pressure reduction and flow, well-fluid water content, impurities, and degree of emulsification of the oil and water will determine the water content of the separated crude oil.

The approximate values given in Table 12.1 assume that special chemicals, equipment, procedures, and techniques

*Expressed as a percent of the total oil volume with the gas measured at standard pressure and temperature.

**Volume basis.

have not been used or applied to improve the quality of the separated crude oil. When these are applied, appreciably improved results may be obtained.

Separated Water

It is probable that the effluent water from a three-phase separator will contain oil somewhere within the range indicated in Table 12.2. The quality of the separated water discharged from a three-phase separator depends on the same factors as previously listed for controlling the water content of the effluent oil. It is assumed that special chemicals and separating methods have not been used to improve the estimated quality of the effluent water shown in Table 12.2.

If the difference in the specific gravities of the oil and water at separator operating conditions is less than 0.20, special attention is required because the small difference in the densities of the oil and water will result in limited and incomplete separation. Lower qualities of effluent oil and water may result in such cases.

Gas

The oil (liquid hydrocarbon) content of the gas discharged from an oil and gas separator probably will be in the range shown in Table 12.3. Currently, it is difficult to measure the amount of oil in the separated gas under field operating conditions. With experience and patience, it can be done with a laser liquid particle spectrometer. The range of oil content in the separated gas shown in Table 12.3 has been accepted in recent years as an approximation of the performance of standard commercially available oil and gas separators under normal or average conditions equipped with suitably designed mist extractors.

TABLE 12.2—ESTIMATED QUALITY OF SEPARATED WATER

Water Retention Time (minutes)	Estimated Range of Oil Content of Effluent Water

6 +	40	0.004	200	0.02

*Volume basis.

Gas Quality From Scrubbers

The liquid content of gas discharged from gas scrubbers is usually less than the liquid content of gas discharged from oil and gas separators. Gas scrubbers are normally installed downstream of oil and gas separators or other separating equipment. If there is a separator upstream of the scrubber, the liquid hydrocarbon content of the scrubbed gas should be less than 0.10 gal/MMscf (less than 0.01335 ppm on a volume basis).

Measuring Quality of Separated Fluids

The quality of separated fluids discharged from oil and gas separators and similar equipment can be measured by state-of-the-art instruments currently available from various manufacturers. The measurements of the quality of effluent fluids and the instruments used to make these measurements are presented in Table 12.4

The instruments indicated are delicate. Each must be carefully selected, calibrated, applied, and operated, and

the results must be expertly analyzed and interpreted to obtain reliable and reproducible results.

Classification of Oil and Gas Separators

Classification by Configuration

Oil and gas separators can have three general configurations: vertical, horizontal, and spherical. Vertical separators can vary in size from 10 or 12 in. in diameter and 4 to 5 ft seam to seam (S to S) up to 10 or 12 ft in diameter and 15 to 25 ft S to S. Vertical separators are shown in Figs. 12.4, 12.13, 12.14, and 12.20 through 12.24.

Horizontal oil and gas separators are manufactured with monotube and dual-tube shells. Monotube units have one cylindrical shell, and dual-tube units have two cylindrical parallel shells with one above the other. Both types of units can be used for two-phase and three-phase service. A monotube horizontal oil and gas separator is usually preferred over a dual-tube unit. The monotube unit has a greater area for gas flow as well as a greater oil/gas interface area than is usually available in a dual-tube separator of comparable price. The monotube separator will usually afford a longer retention time because the larger single-tube vessel retains a larger volume of oil than the dual-tube separator. It is also easier to clean than the dual-tube unit.

In cold climates, freezing will likely cause less trouble in the monotube unit because the liquid is usually in close contact with the warm stream of gas flowing through the separator. The monotube design normally has a lower silhouette than the dual-tube unit, and it is easier to stack them for multiple-stage separation on offshore platforms where space is limited.

Horizontal separators may vary in size from 10 or 12 in. in diameter and 4 to 5 ft S to S up to 15 to 16 ft in diameter and 60 to 70 ft S to S. Horizontal separators are shown in Figs. 12.2, 12.3, 12.12, 12.15, and 12.25 through 12.27.

Spherical separators are usually available in 24 or 30 in. up to 66 to 72 in. in diameter. Spherical separators are shown in Figs. 12.5 and 12.28.

Classification by Function

The three configurations of separators are available for two- and three-phase operation. In the two-phase units, gas is separated from the liquid with the gas and liquid being discharged separately. In three-phase separators, well fluid is separated into gas, oil, and water with the three fluids being discharged separately.

Classification by Operating Pressure

Oil and gas separators can operate at pressures ranging from a high vacuum to 4,000 to 5,000 psi. Most oil and gas separators operate in the pressure range of 20 to 1,500 psi.

Separators may be referred to as low pressure, medium pressure, or high pressure. Low-pressure separators usually operate at pressures ranging from 10 to 20 up to 180 to 225 psi. Medium-pressure separators usually operate at pressures ranging from 230 to 250 up to 600 to 700 psi. High-pressure separators generally operate in the wide pressure range from 750 to 1,500 psi.

Classification by Application

Oil and gas separators may be classified according to application as test separator, production separator, low-temperature separator, metering separator, elevated separator, and stage separators (first stage, second stage, etc.).

Test Separator. A test separator is used to separate and to meter the well fluids. The test separator can be referred to as a well tester or well checker. Test separators can be vertical, horizontal, or spherical. They can be two-phase or three-phase. They can be permanently installed or portable (skid or trailer mounted). Test separators can be equipped with various types of meters for measuring the oil, gas, and/or water for potential tests, periodic production tests, marginal well tests, etc.

Production Separator. A production separator is used to separate the produced well fluid from a well, group of wells, or a lease on a daily or continuous basis. Production separators can be vertical, horizontal, or spherical. They can be two phase or three phase. Production separators range in size from 12 in. to 15 ft in diameter, with most units ranging from 30 in. to 10 ft in diameter. They range in length from 6 to 70 ft, with most from 10 to 40 ft long.

Low-Temperature Separator. A low-temperature separator is a special one in which high-pressure well fluid is jetted into the vessel through a choke or pressure-

Fig. 12.25--Schematic of typical horizontal two-phase oil and gas separator.

reducing valve so that the separator temperature is reduced appreciably below the well-fluid temperature. The temperature reduction is obtained by the Joule-Thompson effect of expanding well fluid as it flows through the pressure-reducing choke or valve into the separator. The lower operating temperature in the separator causes condensation of vapors that otherwise would exit the separator in the vapor state. Liquids thus recovered require stabilization to prevent excessive evaporation in the storage tanks.

Metering Separator. The function of separating well fluids into oil, gas, and water and metering the liquids can be accomplished in one vessel. These vessels are commonly referred to as metering separators and are available for two- and three-phase operation. These units are available in special models that make them suitable for accurately metering foaming and heavy viscous oil.

Fig. 12.26--Horizontal monotube two-phase oil and gas separator. Unit is skid mounted with accessories. Operator is checking liquid level in separator.

Fig. 12.27—Typical horizontal dual-tube two-phase oil and gas separator.

Fig. 12.28—Schematic of a typical spherical two-phase oil and gas separator with float-operated lever-type oil control valve.

Fig. 12.29—Schematic of a vertical two-phase metering separator. Liquid is metered in integral metering compartment in lower portion of vessel.

A two-phase metering separator separates well fluids into liquid and gas and measures the liquid in the lower portion of the vessel. A typical two-phase metering separator is shown in Fig. 12.29. A three-phase metering separator separates the oil, water, and gas and measures only the oil or both the oil and water. Metering of the liquid is normally accomplished by accumulation, isolation, and discharge of given volumes in a metering compartment in the lower portion of the vessel.

Fig. 12.30 illustrates a three-phase metering separator in which the free water is measured with a positive-displacement meter. The metering separator shown in Fig. 12.31 is designed especially for separating large volumes of foaming and/or viscous oil. This unit uses hydrostatic-head liquid-level controllers to measure the oil accurately on a weight basis rather than by volume. It uses pressure flow into and out of the dual compartments and does not rely on gravitational flow. The unit shown in Fig. 12.31 is a two-phase vessel with two combination separating and metering compartments operating in parallel on an alternate basis. It is equipped with controls and valves that are arranged to permit constant flow of well fluid into the vessel. With pressure flow into and out of each of the two compartments, this separator can handle much larger volumes than separators with two compartments that rely on gravity flow from upper to lower compartments. These units are furnished with hydrostatic-head liquid-level controls for metering foaming oil or float-operated controls for nonfoaming oil.

Foam Separator. Oil and gas separators that handle foaming crude oil are generally referred to as foam separators. For a discussion of the design and application of separators for handling foaming oil refer to Pages 12-6 and 12-7.

Elevated Separators. Separators can be installed on platforms at or near tank batteries or on offshore platforms so that the liquid can flow from the separator to storage

Fig. 12.30—Schematic of a vertical three-phase metering separator with free water metered with a positive displacement meter.

or to downstream vessels by gravity. This permits the separator to be operated at the lowest possible pressure to capture the maximum amount of liquid and to minimize the loss of gas and vapor to the atmosphere or to the low-pressure gas system.

Stage Separators. When produced well fluid is flowed through more than one separator with the separators in series, the separators are referred to as stage separators. The first separator is referred to as the first-stage separator, the second separator is called the second-stage separator, etc. For a more detailed discussion on stage separation refer to Page 12-32.

Classification by Principle Used for Primary Separation

Separators may be classified according to the method used to accomplish primary separation in the separator. Such a classification is density difference (gravity separation), coalescence and/or impingement, and centrifugal force.

Density Difference (Gravity Separation). This classification includes all units that have no inlet element, deflector, impingement plate, or pack on the inlet to the vessel.

Fig. 12.31—Schematic of vertical two-phase metering separator for separating and metering viscous and/or foaming oil on a weight basis. Pressure flow into and out of the dual separating and metering compartments increases fluid-handling capacity.

Primary separation is obtained solely by the difference in density of the oil and gas or vapor. These units are few in number and most separators will have a mist extractor near the gas outlet to remove oil mist from the gas.

Impingement and/or Coalescence. This type of separator includes all units that use an impingement plate or device or a pack of tower packing on the inlet of the separator to accomplish initial separation of the oil and gas. An infinite number of design arrangements can be used on the inlet of a separator, but one of the simplest and most effective arrangements is illustrated in Fig. 12.14.

Centrifugal Force. Centrifugal force can be used for both primary and secondary separation of oil and gas in a separator. The centrifugal force can be obtained with either a properly sized tangential inlet in the separator (see Figs. 12.20 through 12.22) or a properly sized internal spiral or involute element with the top and bottom of the element open or partially open. These centrifugal elements cause cyclonic flow of the incoming fluid at velocities high enough to separate the fluid into an outer layer or cylinder of liquid and an inner cone or cylinder of gas or vapor. The velocity required for centrifugal separation will vary

from about 40 to about 300 ft/sec. The most common operating velocity range is between about 80 and 120 ft/sec.

Most centrifugal separators are vertical. However, a centrifugal separating element can be used on the inlet of horizontal separators to accomplish the initial separation of oil and gas. A second centrifugal element can be installed in the vessel to remove liquid mist from the exiting gas.

Centrifugal Oil and Gas Separators and Gas Scrubbers

Increased use of oil and gas separators on offshore platforms for handling larger volumes of well fluid has increased efforts to develop more compact separators to reduce space and weight on offshore platforms. Positive results have been achieved from these efforts, resulting in some separators that use centrifugal force to accomplish both initial and final separation of the oil and gas. Three centrifugal-force separators are illustrated in Figs. 12.20 through 12.22.

Centrifugal Separators

The vertical centrifugal oil and gas separator shown in Fig. 12.20 operates as described here.⁵ Well fluid enters the separator through the adjustable tangential slot at high velocity, inducing a cyclone within the vessel. The cyclone, stabilized by the vortex finder, moves down the cyclone cone. High cyclonic velocity ensures that a stable, thin film of liquid is maintained. The cyclone cone provides a long path for well fluid, enabling free gas to break out, a factor that is very effective with foaming oil. Residence time is not critical in gas/liquid separation. When the gas/oil interface is reached, the gas cyclone is reversed with the gas flowing upward and exiting from Nozzle A. The cyclone cone provides a smooth transition for the liquid to flow to the sump, preventing re-entrainment and assisting oil/water separation.

Oil/water separation is accomplished by gravity with the required residence time dependent on the well-fluid properties. Oil and water are drawn off from Nozzles C and D, respectively. Gas Vent B is provided to equalize the pressure and remove any gas that separates in the sump. Gas Vent B is normally connected to Gas Outlet A.

Diverging Vortex Separator

Fig. 12.21 shows a centrifugal gas/liquid separator that has been designed and patented recently.^{6,7} This unit uses centrifugal force to separate the gas and liquids. If the liquid is separated into oil and water, the separation is done by gravity.

The diverging vortex separator (DVS) is a bottom-entry, high-performance cyclone separator. Performance ranges from 99% to 99.99+ % over a flow rate range of 10 to 1. Mist particles are typically removed to below 5 μm and, depending on design specifications, additional condensate can be obtained because of the centrifugal force field. There are no moving parts and no change in gas flow direction. Pressure losses are minimal, ranging from inches of water to a few psi.

The oil-laden gas tangentially enters the bottom of the DVS vortex section, Fig. 12.21. Both the separated oil and gas corotationally spiral outward and up in a constant

vortex flow field. At the top of the vortex section, the oil circumferentially flows over the vortex section lip (Coanda effect), around and down the shroud to the vessel bottom, and out the liquid outlet. The gas continues an upward spiral to the gas outlet. This flow regime minimizes the oil-to-gas relative velocity, thereby minimizing re-entrainment and maximizing vortex-section surface area for coalescing and gathering oil. This surface is flow-wise continuous, allowing the oil to form a nearly uniform film. This film is stable, and the oil movement is consistent with inlet velocity and centrifugal force. Separation performance is independent of inlet liquid loadings up to 10 lbm of liquid per pound of gas.

The shroud extends below the oil level in the annular liquid section. The large annular liquid volume allows the separator to accommodate flow surges and liquid slugs. Performance is not affected by oil level within control range.

The oil and gas equilibrium is affected by centrifugal force in the vortex section. The equilibrium shift favors condensate formation, thereby effecting a dewpoint depression in the outlet gas. This dewpoint depression correlates directly with vortex section centrifugal force and is thus a function of inlet velocity. In-situ condensate formation is greatest at the vortex section inlet. This aids in the coalescing of entrained oil in the inlet stream, which improves separator performance. The outlet gas dewpoint depression means both a drier gas and a slightly higher liquid vapor pressure. If the inlet gas contains water vapor, moisture recovery will be consistent with the dewpoint-depression characteristic. This moisture will collect with the oil and condensate, allowing their final separation in the annulus formed by the vortex wall and the shell of the separator vessel.

Centrifugal Gas Scrubbers

Several different designs of centrifugal gas scrubbers are available from several suppliers. One of the most popular and effective centrifugal gas scrubbers is illustrated in Fig. 12.22. Operation of this unit is as follows.⁸ The centripetal-flow-type recycling separator has two effective stages of separation. The term centripetal flow denotes gas flow converging toward the center of the vessel, as in a whirlpool. In the first stage, all the free liquid and most of the entrained liquid are spun out of the gas by centrifugal force. In the second stage, the small amount of entrained liquid remaining in the gas is spun out under the influence of greatly increased centrifugal force and is collected by a recycling circuit as indicated in Fig. 12.22.

The well fluid enters the separator through the tangential inlet nozzle, which causes the stream to whirl around the inlet chamber. The spinning stream then moves downward between the smoothing sleeve and the separator shell into the vortex chamber. Liquid in the spinning stream is thrown outward by centrifugal force to the wall of the vortex chamber and runs down past the baffle plate into the liquid chamber, from which it is discharged. The gas, still spinning, converges toward the center of the vortex chamber, increasing in velocity, and enters the vortex finder tube. In the vortex finder tube, entrained liquid remaining in the rapidly spinning gas collects on the vortex finder wall and is swept upward by the gas toward the gas outlet. This liquid, together with a sidestream of about

5% of the total gas, is then sucked through a gap in the tube wall, down the recycling line, and through the central hole of the baffle plate into the vortex chamber. The low-pressure area along the axis of the vortex provides the necessary suction. Recycled liquid and sidestream gas thus entering the vortex chamber through the hole in the baffle plate mix with the rapidly spinning gas in the core of the vortex, and the liquid is thrown out to the wall and runs down with the rest of the liquid into the liquid chamber. The mainstream gas, now clean, continues up the vortex finder past the gap to the gas outlet.

The liquid chamber in these separators contains baffles for liquid stilling or for isolation of the level-control float as needed. The liquid chamber may be made oversized to handle very large liquid flows and may be constructed for gravity separation of the oil and water.

Illustrations of Oil and Gas Separators

Typical oil and gas separators are illustrated in Figs. 12.2 through 12.5 and 12.23 through 12.28. Fig. 12.25 is a schematic of a typical horizontal two-phase oil and gas separator. Fig. 12.26 is a photograph of a horizontal monotube two-phase oil and gas separator. Fig. 12.2 shows a horizontal skid-mounted three-phase oil/gas/water well tester on an offshore drilling platform off the coast of Brazil. The well tester is a separator with oil, gas, and water meters piped on it so that the well fluid can be separated into oil, gas, and water and each of the fluids metered before they are recombined or discharged separately.

Fig. 12.23 is a schematic of a typical vertical two-phase oil and gas separator. Fig. 12.24 is a photograph of a typical field installation of a vertical two-phase oil and gas separator. Fig. 12.28 depicts a typical two-phase spherical oil and gas separator with float-operated lever-type oil-control valve.

Fig. 12.3 is a schematic of a typical horizontal three-phase oil/gas/water separator. Fig. 12.4 shows a typical vertical three-phase oil/gas/water separator, and Fig. 12.5 illustrates a typical spherical three-phase oil/gas/water separator. Fig. 12.27 is a photograph of a horizontal dual-tube two-phase oil and gas separator.

Comparison of Oil and Gas Separators

Table 12.5 compares the advantages and disadvantages of two- and three-phase horizontal, vertical, and spherical oil and gas separators. This table is not intended as an "absolute" guide but affords a relative comparison of the various characteristics or features of the different separators over the range of types, sizes, and working pressures. The comparison of oil and gas separators in Table 12.5 assumes that the horizontal oil and gas separators are monotube vessels.

Estimating the Sizes and Capacities of Oil and Gas Separators

The oil and gas capacities of oil and gas separators will vary as the following factors vary.

1. Size (diameter and length) of separator.
2. Design and arrangement of separator internals.
3. Number of stages of separation.
4. Operating pressure and temperature of separator.
5. Physical and chemical characteristics of well fluid (gravity, viscosity, phase equilibrium, etc.)
6. Varying gas/liquid ratio.
7. Size and distribution of liquid particles in gas in the separator upstream of mist extractor.
8. Liquid level maintained in separator.
9. Well-fluid pattern, whether steady or surging.
10. Foreign-material content of well fluid.
11. Foaming tendency of oil.
12. Physical condition of separator and its components.
13. Other factors.

Items 5 and 7 are generally not known with sufficient detail and accuracy to permit accurate calculation of the size or performance of a separator. However, such calculations can be based on empirical data and assumptions for comparative and budgetary purposes. When separators are being sized for maximum performance and when the performance must be guaranteed, Items 5 and 7 become very important and must be available to the designer.

In a vertical separator, the liquid particles to be removed from the gas must settle downward against the upflowing column of gas. Conversely, in a horizontal separator, the

TABLE 12.5—COMPARISON OF ADVANTAGES AND DISADVANTAGES OF HORIZONTAL, VERTICAL, AND SPHERICAL OIL AND GAS SEPARATORS, TWO- AND THREE-PHASE

Considerations	Horizontal (Monotube)*	Vertical (Monotube)*	Spherical (One Compartment)*
Efficiency of separation	1	2	3

Ease of inspection and maintenance	1	3	2

*Ratings: (1) most favorable; (2) intermediate; (3) least favorable.

path of a liquid particle to be separated from the gas as it flows through the vessel resembles the trajectory of a bullet fired from a gun. This difference in the flow pattern of the separated liquid particles indicates that a horizontal separator of a given diameter and length will separate a larger volume of well fluid than a vertical vessel of the same size. This is generally true, but the liquid level that must be carried in a monotube horizontal separator subtracts from this advantage and may cancel it out completely if a high liquid level is maintained in the horizontal separator.

The maximum gas velocity in an oil and gas separator that will allow separation of liquid mist from the gas can be calculated with the following form of Stokes' law:

$$v_g = F_{co} \left(\frac{\rho_L - \rho_g}{\rho_g} \right)^{1/2}, \quad (1)$$

where

- v_g = maximum allowable gas velocity, ft/sec,
- F_{co} = configuration and operating factor
(empirical) (see Fig. 12.32 for values),
- ρ_L = density of liquid at operating conditions,
lbm/cu ft, and
- ρ_g = density of gas at operating conditions,
lbm/cu ft.

The value of F_{co} in Eq. 1 is an empirical independent variable; it includes all factors that affect separation of liquid from gas in an oil and gas separator except (1) the compressibility factor of the gas, (2) base and operating pressure, (3) base and operating temperature, and (4) density of the fluids to be separated. F_{co} does include and varies with the length/diameter (L/D) ratio of the separator, the configuration of the separator vessel, the design of the internals of the separator, the liquid depth in the separator, foaming tendency of the oil, steady or pulsating flow of gas, heading or steady flow of liquid, gas/liquid ratio, presence of foreign materials and impurities,

and the degree of separation required. F_{co} varies in direct proportion to the L/D ratio. Of the variables listed above on which F_{co} is dependent, the L/D ratio of the separator vessel is the most dominant. The use of straightening vanes or cylinders, baffling, and special inlet degassing elements can increase the value of F_{co} and the separating capacity of a separator.

The original values of F_{co} used in Eq. 1 were determined by the assignment of values to F_{co} that would result in a velocity in the separator, expressed in feet per second and calculated by Eq. 1, that would provide the desired degree of separation. Thus the original values of F_{co} were for the customary system of units. To change the velocity calculated by Eq. 1 from customary to SI units, a multiplier of 30.48 must be used. That is, the velocity in feet per second must be multiplied by 30.48 to change it to centimeters per second.

The maximum allowable gas velocity v_g of Eq. 1 is the maximum velocity at which the gas can flow in the separator and still obtain the desired quality of gas/liquid separation. Only the open area of the separator available for gas flow is considered in calculating its capacity. The gas separating capacity of an oil and gas separator can be stated as

$$q_g = A_g v_g, \quad (2)$$

where

- q_g = volume of gas flowing through separator,
cu ft/sec,
- A_g = cross-sectional area of separator for gas
flow, sq ft, and
- v_g = gas velocity, ft/sec, from Eq. 1.

The ρ_g of Eq. 1 is calculated from Eq. 3 as follows:

$$\rho_g = \frac{pM_g}{z_g RT}, \quad (3)$$

Fig. 12.32—Configuration and operation factor F_{co} for oil and gas separators and gas scrubbers (see Eqs. 1 and 4 through 6).

where

- p = separator operating pressure, psia,
 M_g = molecular weight of gas,
 z_g = compressibility factor of gas,
 R = gas constant, 10.732, and
 T = operating temperature, °R.

Substituting in Eq. 2 for v_g and simplifying yields

$$q_g = A_g F_{co} \left(\frac{\rho_L - \rho_g}{\rho_g} \right)^{1/2} \quad (4)$$

Equation for Gas Capacity of Oil and Gas Separator

When Eq. 4 is corrected for compressibility, pressure, and temperature and when units are changed to cubic feet per day, the equation becomes

$$q_g = 86,400 A_g F_{co} \left(\frac{1}{z_g} \right) \left(\frac{p}{p_b} \right) \left(\frac{T_b}{T} \right) \left(\frac{\rho_L - \rho_g}{\rho_g} \right)^{1/2} \quad (5)$$

where

- p_b = base pressure, psia, and
 T_b = base temperature, °R.

Equation for Sizing an Oil and Gas Separator for Gas Capacity

Eq. 5 can be rewritten to solve for A_g .

$$A_g = \frac{q_g}{86,400 F_{co} \left(\frac{1}{z_g} \right) \left(\frac{p}{p_b} \right) \left(\frac{T_b}{T} \right) \left(\frac{\rho_L - \rho_g}{\rho_g} \right)^{1/2}} \quad (6)$$

Eq. 5 can be used to calculate the volume of gas a separator of a given size will handle under given operating conditions. Eq. 6 can be used to calculate the size of separator required to handle a given volume of gas under certain operating conditions.

When Eqs. 5 and 6 are used for horizontal separators, A_g is the area for gas flow. The area occupied by liquid must be excluded. In a vertical separator, A_g is usually the entire internal cross-sectional area of the vessel.

The range of values of F_{co} normally used in Eqs. 5 and 6 is as follows. For vertical separators, the range is 0.10 to 0.167, and for horizontal separators, the range is 0.35 to 0.707. Values of F_{co} can be obtained from Fig. 12.32. The values of F_{co} shown in Fig. 12.32 are in customary units. Multiply these values by 30.48 for SI Units. For the L/D ratio of any given separator, any value of F_{co} indicated in Fig. 12.32 can be used. Experience aids in the selection of the optimum value of F_{co} . The nonideal (conservative) values of F_{co} will result in lower gas velocities, i.e., larger vessels. Use of F_{co} values for ideal (liberal) conditions will result in higher gas velocities, i.e., smaller vessels. Where the oil and gas tend to separate clean and dry and ideal operating conditions prevail, the ideal (liberal) values of F_{co} can be used. Where condi-

tions are less than ideal—such as slugging flow, high operating pressure and temperature, and excessive platform vibration or movement—the nonideal (conservative) values of F_{co} should be used. For estimating purposes for unknown operating conditions, the nonideal (conservative) values of F_{co} should be used. As experience is gained in a particular oil field or producing zone or area, it may be possible and practical to use higher values of F_{co} until the optimum balance between cost and performance is reached.

The values of F_{co} for horizontal separators are higher than for vertical separators. A typical value of F_{co} for vertical separators is 0.167; for horizontal separators a typical value of F_{co} is 0.500.

If the proper F_{co} value is used in Eq. 5, all liquid particles larger than 100 μm should be removed by gravity separation upstream of the mist extractor. If a properly designed and sized mist extractor is used, all liquid particles larger than 10 μm should be removed by the mist extractor.

The value of F_{co} in Eqs. 1 and 4 through 6 varies as the L/D ratio of the separator vessel varies. With a given diameter separator, as the length of the separator increases, the value of F_{co} increases. With a given length separator, as the diameter of the separator increases, the value of F_{co} decreases. This relationship is more pronounced in horizontal separators than it is in vertical separators; in vertical separators, if the L/D is greater than about 2.0, the value of F_{co} will change little, if at all, regardless of how much the L/D is increased. Refer to Fig. 12.32 for an indication of the relationship between L/D and F_{co} for both vertical and horizontal separators.

There is a range of length-to-diameter (L/D) ratios for oil and gas separators that will adequately meet each separator capacity requirement. This range of L/D ratios is minimum at about 1.0 to 2.0 and maximum at about 8.0 to 9.0. There is not just one diameter and length of separator that will satisfy a given capacity requirement; rather, there is a series of sizes (L/D ratios) that can be used for each application.

In a vertical separator, the well-fluid inlet is located about one-third of the length of the shell below the top head-shell weld seam, and the gas flows from the inlet up through the vessel to the gas outlet at the top of the vessel. The oil (liquid) flows downward from the inlet to the bottom of the vessel. Thus either the gas volume (above the inlet) or the liquid oil volume (below the inlet) can determine the required separator diameter.

For vertical separators, if the gas volume determines the size of the vessel, the L/D ratio of the vessel should be from about 2.0 to 3.0; if the liquid volume determines the separator size, the L/D ratio should be from about 2.0 to 6.0.

For horizontal separators, the L/D ratio of the vessel should be from about 2.0 to 6.0. The gas and liquid added together determine the size of a horizontal separator because the two fluids flow concurrently through the vessel from inlet end to outlet end.

For vertical separators similar to the configuration shown in Fig. 12.33, L/D or $1/3 L/D$ can be used to determine the value of F_{co} from Fig. 12.32. From the standpoint of determining the gas separating capacity of a vertical separator, the only pertinent part of the separator is that from the well-fluid inlet to the gas outlet. This

Fig. 12.33—One-third L/D vs. L/D for vertical oil and gas separators.

TABLE 12.6—VALUES FOR EXAMPLE PROBLEM 1

$L/D = 10/2 = 5.0$	$L'/D' = 7.0/1.33 = 5.26$	Difference in Values of F_{co} (%)
$F_{co} = 0.725$ (ideal conditions)	$F_{co} = 0.747$ (ideal conditions)	+ 3.03
$F_{co} = 0.636$ (nonideal conditions)	$F_{co} = 0.655$ (nonideal conditions)	+ 2.99

can include the mist extractor because the mist extractor should be as effective as density-difference separation would be in the space that it occupies. Fig. 12.32 shows both L/D and $\frac{1}{3}L/D$ for vertical separators.

Above an L/D ratio of 2.0 and a $\frac{1}{3}L/D$ ratio of 0.67, additional shell length does not increase the gas capacity of vertical separators. Additional shell length can increase the liquid capacity of the separator when the additional shell length is located between the inlet and the oil outlet.

For configurations of horizontal separators similar to the one shown in Fig. 12.34, L'/D' instead of L/D should be used to determine the value of F_{co} . This usually will result in a smaller separator for a given volume of gas, as indicated in the following three examples.

Example Problem 1. Assume a 24-in.-diameter \times 10-ft (S to S) horizontal separator operating with a liquid depth of 8 in. and with dimensions $A=1.5$ ft and $B=1.5$ ft (Fig. 12.34). The values of F_{co} are from Fig. 12.32. Refer to Table 12.6 for further data.

Example Problem 2. Assume a 48-in.-diameter \times 16 ft S to S horizontal separator operating with a liquid depth of 24 in. and with dimensions $A=2$ ft and $B=2$ ft (Fig. 12.34). Refer to Table 12.7 for more data.

Example Problem 3. Assume a 96-in.-diameter \times 30 ft S to S horizontal separator operating with a liquid depth of 32 in. and with dimensions $A=3$ ft and $B=4$ ft (Fig. 12.34). Refer to Table 12.8 for more data.

For a given horizontal separator, the value of F_{co} obtained by use of L'/D' will vary directly with the liquid depth.

Fig. 12.34— L'/D' vs. L/D for horizontal oil and gas separators.

TABLE 12.7—VALUES FOR EXAMPLE PROBLEM 2

$L/D = 16/4 = 4.00$	$L'/D' = 12/2 = 6.00$	Difference in Values of F_{co} (%)
$F_{co} = 0.640$ (ideal conditions)	$F_{co} = 0.808$ (ideal conditions)	+ 26.25
$F_{co} = 0.560$ (nonideal conditions)	$F_{co} = 0.716$ (nonideal conditions)	+ 15.60

TABLE 12.8—VALUES FOR EXAMPLE PROBLEM 3

$L/D = 30/8 = 3.75$	$L'/D' = 23/5.33 = 4.32$	Difference in Values of F_{co} (%)
$F_{co} = 0.618$ (ideal conditions)	$F_{co} = 0.670$ (ideal conditions)	+ 8.41
$F_{co} = 0.541$ (nonideal conditions)	$F_{co} = 0.582$ (nonideal conditions)	+ 4.10

The use of straightening tubes, cylinders, plates, vanes, and Dixon plates will generally increase the value of F_{co} and increase the capacity of a given separator. The increase in capacity to be obtained by such devices and other design features can be estimated from empirical data that must be verified by field tests.

Computer Sizing of Oil and Gas Separators

Tables 12.9 and 12.10 are printouts of a computer program⁹ for sizing vertical and horizontal separators. The format of the computer printout has been modified.

The L/D for the vertical separator was indicated by the computer to vary from 2.0 to 2.8. The L/D for the horizontal separator was indicated by the computer to vary from 2.0 to 6.0. Fig. 12.32 shows the relation between L/D and the values of F_{co} . The values of F_{co} to be used in Eqs. 5 and 6 can be obtained from Fig. 12.32. Table 12.9 is an example of computer sizing of a vertical oil and gas separator. Table 12.10 is an example of computer sizing of a horizontal separator.

The liquid separating capacity of most oil and gas separators is controlled by retention or residence time, the time liquid is retained in the separator. This time usually var-

Any one of the five separators indicated will satisfy the design capacity requirements.

Fig. 12.35—Gas capacity of vertical oil and gas separators.

ies from 20 seconds to 1 to 2 hours, depending on many factors. For retention time to result in separation of water from oil, the liquid must be relatively quiet and free from agitation. Typical retention time for two-phase separation is 30 seconds to 2 minutes. Typical retention time for three-phase separation is from 2 to 10 minutes, with 2 to 4 minutes the most common.

Separators can be sized for liquid capacity in two ways. One way is to base the sizing on test data on the well fluid to be separated. The other way is to base the sizing on experience in separating fluid from that producing zone or area from neighboring wells or leases. If it is known that a certain retention time will be required to accomplish separation, sizing the separator for liquid becomes a simple volume calculation.

Capacity Curves for Vertical and Horizontal Oil and Gas Separators

The gas and liquid capacities of vertical and horizontal oil and gas separators can be estimated from the curves shown in Figs. 12.35 through 12.38. These capacity curves are based on calculations made with a computer

program developed by George O. Ellis⁹ and the author. Sample printouts of this computer program for vertical and horizontal separators listing the input and output data for each is shown in Tables 12.9 and 12.10.

The oil and gas capacity curves in Figs. 12.35 through 12.38 can be used reversibly to determine (1) the size separator required to separate a given volume of fluid under given operating conditions and (2) the volume of fluid a given separator will handle under given operating conditions.

The gas capacity of vertical separators is shown in Fig. 12.35. The capacities shown are based on the assumptions listed at the lower left side of Fig. 12.35. Conditions other than these will result in different capacities. These capacities are suitable for preliminary sizing and estimating purposes. If accurate sizing or performance data are required, calculations should be made with pertinent data. The gas capacity of a vertical separator does not vary directly with a change in shell length. If a standard length of 10 ft is assumed, an increase in shell length of 100%, to 20 ft, will result in an increase in gas capacity of about 23%.

LIQUID CAPACITIES ARE BASED ON:

1. RETENTION TIME INDICATED.
2. STEADY NON-HEADING FLOW.
3. NON-FOAMING OIL.
4. TEMPERATURE OF OIL MUST BE ABOVE POUR POINT.
5. OIL GRAVITY OF 35° API OR HIGHER.
6. VISCOSITY OF 50 SSU OR LESS.
7. LIQUID DEPTH IN SEPARATOR SHOULD NOT EXCEED APPROX. ONE TO THREE TIMES DIAMETER OF SEPARATOR DEPENDING ON EXACT DESIGN OF SEPARATOR.

EXAMPLE
A 30" X 10' X 1000 PSI SEPARATOR WITH A 30" LIQUID DEPTH WILL HANDLE 2700 BBL/DAY WITH ONE MINUTE RETENTION TIME.

MINIMUM RECOMMENDED RETENTION TIME	
0 — 600 PSI	= 1 MINUTE
600 — 1000 PSI	= 45 SECONDS
OVER 1000 PSI	= 30 SECONDS

NOTE: IF OIL FOAMS, RETENTION TIME MAY NEED TO BE INCREASED TO 5 MINUTES OR MORE.

Fig. 12.36—Liquid capacity of vertical oil and gas separators.

NOTE: THIS CURVE SHOULD NOT BE USED FOR LIQUID DEPTHS GREATER THAN ONE HALF THE DIAMETER OF THE SEPARATOR VESSEL.

GAS CAPACITY IS BASED ON:

1. VOLUME MEASURED AT 60°F AND 14.7 PSIA.
2. FLOW RATES ARE STEADY AND NON-HEADING.
3. OIL IS NON-FOAMING AND 35° API.
4. SHELL LENGTH IS 10 FT.
5. OPERATING TEMPERATURE IS 100°F.
6. GAS IS 0.65 SPECIFIC GRAVITY.
7. LIQUID CARRYOVER WILL BE LESS THAN 1.0 OAL. MMSCF.
8. APPROXIMATE CORRECTIONS FOR SHELL LENGTH OTHER THAN 10 FT.

VESEL LENGTH	MULTIPLIER (1)
5 FT	0.78
8 FT	0.82
7 FT	0.87
4 FT	0.91
9 FT	0.95
10 FT	1.00
12 FT	1.05
15 FT	1.24
18 FT	1.37
20 FT	1.46

(1) BASED ON 48" DIAMETER SEPARATOR

EXAMPLE:

A 30" BY 10' BY 800 PSI HORIZONTAL OIL AND GAS SEPARATOR WITH A LIQUID DEPTH OF 30" IS OPERATING AT 300 PSI WILL HANDLE 24.2 MMSCF/D.

NOTE:

THIS GRAPH IS INTENDED ONLY FOR APPROPRIATE SIZES AND GAS CAPACITIES OF HORIZONTAL SEPARATORS.

Fig. 12.37—Gas capacity of horizontal oil and gas separators.

Fig. 12.38—Liquid capacity of horizontal oil and gas separators.

The liquid (oil) capacity of vertical separators is shown in Fig. 12.36. The liquid capacity of a vertical separator is controlled primarily by the volume of liquid retained in the accumulation (settling) section of the separator. Normal practice is to maintain a liquid depth above the oil outlet connection of from one to three diameters of the vessel. The optimum liquid depth depends on the design of the separator, the rate of throughput, and the characteristics of the fluid being separated.

The gas capacity of horizontal separators is shown in Fig. 12.37. The gas capacity of a horizontal separator is directly proportional to the cross-sectional area of the vessel available for gas flow. Thus, the diameter of a horizontal separator and the depth of liquid maintained in the vessel determine its gas capacity under given conditions. The gas separating capacity of a horizontal separator is proportional to the length but not directly proportional. For instance, if the length of the separator is increased from 10 to 20 ft, the gas separating capacity will increase 46%. Refer to the lower left corner of Fig. 12.37 for the relationship between shell length and gas capacity of a horizontal separator. The indicated multipliers assume that no special internals are used in the separators.

The liquid (oil) capacity of horizontal separators is shown in Fig. 12.38. The liquid capacity of a horizontal separator depends on the volumetric liquid-settling capacity of the accumulation (retention) section of the separator. This volumetric capacity is determined by inside shell diameter, shell length, and liquid depth.

The liquid depth in a horizontal separator for two-phase operation is normally assumed to be one-third of the diameter of the vessel. However, it can vary from 3 to 4 inches up to 60 to 70% of the cross-sectional area of the

separator. The liquid depth in a horizontal separator for three-phase operation is normally assumed to be at the horizontal centerline of the vessel (one-half full of liquid). However, it can vary from 8 to 10 inches up to 80 to 90% of the cross-sectional area of the vessel.

The gas capacities shown in the graphs in Figs. 12.35 and 12.37 are only approximate. These graphs should be used only for approximating the sizes and performance of separators. Calculations are recommended for more precise sizing and performance requirements especially where performance must be guaranteed.

Vertical Separator Sizing

Example Problem 4. See Table 12.11 for the given data. From Fig. 12.32, $F_{co}=0.167$; $M_g=M_{air}\gamma_g=28.97\times 0.7=20.28$.

Gas Sizing. Substituting in Eq. 3 yields

$$\rho_g = \frac{(199.7)(20.28)}{(0.97)(10.73)(575)} = 0.68 \text{ lbm/cu ft.}$$

TABLE 12.11—GIVEN DATA FOR SIZING
VERTICAL SEPARATORS—EXAMPLE PROBLEM 4

Maximum gas flow rate, MMscf/D	50.0
Specific gravity of gas	0.70
Maximum oil rate, B/D	30,000
Specific gravity of oil	0.934
Operating temperature, °F	115
Operating pressure, psig	185
Design pressure, psig	250
Oil retention time, minutes	2.0
Gas compressibility factor	0.97
Two-phase operation	No water

TABLE 12.12—GIVEN DATA FOR SIZING HORIZONTAL SEPARATORS—EXAMPLE PROBLEM 5

Maximum gas flow rate, MMscf/D	100.0
Specific gravity of gas	0.80
Maximum oil rate, B/D	50,000
Specific gravity of oil	0.85
Operating temperature, °F	110
Operating pressure, psig	800
Design pressure, psig	1,000
Oil retention time, minutes	1.5
Gas compressibility factor	0.834
Two-phase operation	No water

Substituting in Eq. 6 gives

$$A_g = \frac{50,000,000}{(86,400)(0.167) \left(\frac{1}{0.97} \right) \left(\frac{199.7}{14.7} \right) \left(\frac{520}{575} \right) \left(\frac{58.28 - 0.68}{0.68} \right)^{1/2}}$$

$$A_g = 29.76 \text{ sq ft for gas flow, and}$$

$$D = (29.76/0.7854)^{1/2} = 6.15 \text{ ft ID.}$$

A 72-in.-ID vessel can be used if the volume of 50.0 MMscf/D includes a small safety margin. If the separator must handle 50.0 MMscf/D with a written guarantee for performance, then a 78-in.-OD or -ID vessel can be used.

Oil Sizing for the Same Separator. Volume required in the separator for oil, V_o , is

$$V_o = \frac{30,000}{1440/2} = 41.67 \text{ bbl} = 233.98 \text{ cu ft.}$$

The height of oil, h_o , in the vertical separator is

$$h_o = \frac{233.98}{28.27} = 8.28 \text{ ft in a 72-in.-ID vessel,}$$

where the cross-sectional area of the 72-in.-ID vessel is 28.27 sq ft. If the separator has a 78-in. ID, the h_o will be

$$h_o = \frac{233.98}{33.18} = 7.05 \text{ ft,}$$

where the cross-sectional area of the 78-in.-ID vessel is 33.18 sq ft.

The length required for this separator shell will be about 16 to 18 ft.

Horizontal Separator Sizing

Example Problem 5. See Table 12.12 for the given data. From Fig. 12.32, $F_{co} = 0.707$; $M_g = M_{air} \gamma_g = 28.97 \times 0.80 = 23.18$.

Gas Sizing. Substituting in Eq. 3 yields

$$\rho_g = \frac{(814.7)(23.18)}{(0.834)(10.73)(570)} = 3.70 \text{ lbm/cu ft.}$$

Substituting in Eq. 6 gives

$$A_g = \frac{100,000,000}{(86,400)(0.707) \left(\frac{1}{0.834} \right) \left(\frac{814.7}{14.7} \right) \left(\frac{520}{570} \right) \left(\frac{53.04 - 3.70}{3.70} \right)^{1/2}}$$

$$A_g = 7.40 \text{ sq ft for gas.}$$

Oil Sizing for the Same Separator. The oil volume required in the vessel is

$$V_o = \frac{50,000 \times 5.615}{24 \times 60} \times 1.5 = 292.4 \text{ cu ft.}$$

Select a vessel length of 30 ft.

The cross-sectional area of oil is

$$A_o = \frac{292.4}{30} = 9.74 \text{ sq ft.}$$

For vessel sizing,

Area for gas = 7.40 sq ft

Area for oil = 9.74 sq ft

Dead space = 2.00 sq ft (about 25% of area for gas)

Total area = 19.14 sq ft

Note that dead space is considered to be "reserve" space between oil and gas and is usually assumed to be about 10 to 30% of the gas space for reserve capacity.

The vessel will be $9.74/19.14 = 51\%$ full of liquid. The area of the vessel's ID = 19.14 sq ft.

$$D = \left(\frac{19.14}{0.7854} \right)^{1/2} = 4.94 \text{ ft} = 59.2 \text{ in.}$$

Use a 60-in.-ID or 66-in.-OD \times 30-ft S to S separator, depending on reserve capacity desired.

The volume of the two heads on horizontal separators is normally not considered in separator-sizing calculations. This volume will compensate for the internals and for other variables.

Capacities of Spherical Separators

Spherical oil and gas separators use the same principles of separation used in horizontal and vertical separators. A spherical separator can be considered as a truncated vertical separator. When the fluid-handling capacity of spherical separators is considered, allowance must be made for the reduced height available for separation above the fluid inlet. The same consideration must be applied to spherical separators that is applied to the trays in a frac-

tionating column: the smaller the tray spacing, the lower the allowable capacity. Fig. 12.28 is a schematic of a typical two-phase spherical oil and gas separator. A typical three-phase spherical separator is shown in Fig. 12.5.

The chief advantage of spherical separators is their relatively low silhouette, which allows all component parts to be readily accessible to operating personnel. However, the horizontal separator offers this same advantage. The spherical separator may be easier and less expensive to install; on smaller units a gin-pole truck or crane may not be required to unload and place it on location.

The oil capacities of spherical oil and gas separators are shown in Table 12.13. The gas capacities of spherical oil and gas separators are shown in Fig. 12.39. The table and curves were originated by Vondy.¹⁰ The gas capacities shown in Fig. 12.39 for spherical separators are conservative and assume that the spherical vessels contain no internals. If a properly designed separating element is used on the inlet of the spherical separators, and if an effective mist extractor is used, the gas capacities shown in Fig. 12.39 can be increased by a multiplier that ranges from 1.0 to 3.0, as shown in Table 12.14.

The amount of increase in spherical separator capacity that can be obtained by vessel design is dependent on several factors: (1) location of inlet connection in the vessel with respect to the liquid level in the separator; (2) size, configuration, and location of the inlet separating and spreading element; (3) vertical distance between the inlet separating and spreading element and the mist extractor; (4) size, design, and location of the mist extractor; (5) physical and chemical characteristics of the well fluid being separated; (6) operating pressure and temperature of the separator; (7) flow pattern into the separator (heading or steady); and (8) other factors.

Fig. 12.39—Gas capacity of spherical oil and gas separators.

The oil (liquid hydrocarbon) capacity of spherical oil and gas separators is shown in Table 12.13. The liquid capacity for each size unit is shown for two different liquid depths in the vessel—with the liquid depth equal to one-third and one-half the ID of the sphere. The first condition is appropriate for two-phase (oil/gas) separation; the second condition is appropriate for three-phase (oil/gas/water) separation.¹⁰

Spherical separators are more appropriately used for two-phase separation than for three-phase separation. This is especially true of sizes smaller than 36 in. in diameter. Field tests should be made on spherical separators to determine and/or to confirm their capacity because, of the three shapes of separator vessels available, they are the most difficult to rate properly for oil and gas capacities.

TABLE 12.13—LIQUID CAPACITIES OF SPHERICAL OIL AND GAS SEPARATORS

TABLE 12.14—MULTIPLIERS FOR GAS CAPACITIES SHOWN IN FIG. 12.39

Type of Separator Service	Design of Vessel Internals	Multipliers for Gas Capacities Shown in Fig. 12.39
Foaming crude oil	Average	0.25 to 0.75
Nonfoaming crude oil	Average	1.0 to 1.5
Nonfoaming crude oil	Superior	1.5 to 2.0
Distillate or condensate	Average	2.0 to 2.5
Distillate or condensate	Superior	2.5 to 3.0

Practical Considerations in Sizing Oil and Gas Separators

To ensure acceptable separation at all times, an oil and gas separator should be sized so that it will never operate above its maximum rated capacity. A separator must be sized for the maximum instantaneous flow rate to which it will be subjected rather than for the total daily production rate. Many wells produce by "heads" or "slugs" as a result of natural causes or intermittent gas lift. Such a well may produce a total of only 200 bbl of liquid in 24 hours. However, if that well "heads" or "intermits" only once each hour, it may produce $\frac{1}{4}$ of its total daily production in a matter of 2 or 3 minutes, which would result in an instantaneous flow rate of about 4,000 to 6,000 B/D. The separator should be sized to handle the maximum instantaneous rate of fluid produced during these short intervals, or it must be of sufficient size to store a portion of these slugs while it separates and discharges the balance.

In addition to serving as a means for separating the well fluid into gas and liquids, the separator vessel, in some instances, must also serve as an accumulation or storage vessel, particularly when the wells flow by "heads," when intermittent gas lift is used, when the tubing string and/or flowlines may unload liquid into the separator at high instantaneous flow rates and when the liquid is transferred from the separator by pump and the separator must serve as the accumulator/reservoir vessel for the pumping operation. In these instances the separator vessel must be large enough to store the extra volume of liquid in addition to performing the function of separating. This consideration of storage may often dictate larger vessels than otherwise would be required if the flow of fluid into and out of the separator were steady and continuous.

It is extravagant to install grossly oversized separators where their excess capacities will never be used. Most pumping wells, continuous-flow gas-lift wells, and some naturally flowing wells always produce at uniform rates. For such wells, separator sizes may be selected on the basis of maximum total daily production.

Field tests should be made on oil and gas separators to determine their oil- and gas-handling capacities under

actual conditions. Manufacturers' rated capacities for separators are intended for "general" or "average" conditions. The only way to determine the exact capacity of a particular separator under a given set of conditions is to actually test the separator under those conditions.

Stage Separation of Oil and Gas

Theoretical Considerations of Stage Separation

Stage separation of oil and gas is accomplished with a series of separators operating at sequentially reduced pressures. Liquid is discharged from a higher-pressure separator into the next-lower-pressure separator. The purpose of stage separation is to obtain maximum recovery of liquid hydrocarbons from the well fluid and to provide maximum stabilization of both the liquid and gas effluent.

Two processes liberate gas (vapor) from liquid hydrocarbon under pressure. They are flash separation (vaporization) and differential separation (vaporization). Flash separation is accomplished when pressure is reduced on the system with the liquid and gas (vapor) remaining in contact; i.e., the gas (vapor) is not removed from contact with the liquid as reduction in pressure allows the gas to come out of solution. This process yields the most gas (vapor) and the least liquid. Differential separation is accomplished when the gas (vapor) is removed from contact with the liquid as reduction in pressure allows the gas (vapor) to come out of solution. This process yields the most liquid and least gas (vapor).

In a multiple-stage-separator installation, both processes of gas liberation are obtained. When the well fluid flows through the formation, tubing, chokes, reducing regulators, and surface lines, pressure reduction occurs with the gas in contact with the liquid. This is flash separation. When the fluid passes through a separator, pressure is reduced; also, the oil and gas are separated and discharged separately. This is differential separation. The more nearly the separation system approaches true differential separation from producing formation to storage, the higher the yield of liquid will be.

An ideal oil and gas separator, from the standpoint of maximum liquid recovery, is one constructed so that it reduces the pressure of the well fluid from the wellhead at the entrance of the separator vessel to, or near, atmospheric pressure at the discharge from the separator. The gas and/or vapor is removed from the separator continuously as soon as it is separated from the liquid. This special application of differential vaporization or separation is not practical and is never used.

Some of the benefits of an ideal separator may be obtained by use of multiple-stage separation. The number of stages does not have to be large to obtain an appreciable benefit, as can be seen from Table 12.15.¹¹ Economics usually limits the number of stages of separation to

TABLE 12.15—NUMBER OF STAGES VS. DIFFERENTIAL SEPARATION

Number of Stages of Separation	Approximate Percent Approach to Differential Vaporization
2	0
3	75
4	90
5	96
6	98½

three or four, but five or six will pay out under favorable conditions. Seven stages have been used on large volumes of oil, but such installations are rare.

Ratios of operating pressures between stages in multiple-stage separation can be approximated from the following equations¹¹:

$$F = \sqrt[n]{\frac{p_1}{p_s}}, \dots\dots\dots (7)$$

$$p_2 = \frac{p_1}{F} = p_s F^{n_i-1}, \dots\dots\dots (8)$$

and

$$p_3 = \frac{p_2}{F} = p_s F^{n_i-2}, \dots\dots\dots (9)$$

where

F = stage pressure ratio $p_1/p_2 = p_2/p_3$

$= \dots p_n/p_s$,

n_i = number of interstages (number of stages - 1),

p_1 = first-stage separator pressure, psia,

p_2 = second-stage separator pressure, psia,

p_3 = third-stage separator pressure, psia, and

p_s = storage-tank pressure, psia.

Equilibrium flash calculations should be made for several assumed conditions of pressures and temperatures to determine the conditions that will yield the most stock-tank liquid. However, the above equations will give a practical approximation that can be used when no other information is available. Fig. 12.40 schematically shows typical two-, three-, and four-stage separation systems.

Two-stage separation is normally considered to be obtained when one oil and gas separator is used in conjunction with a storage tank. Three-stage separation is obtained when two separators are used in a series at different pressures in conjunction with a storage tank. The storage tank is considered a separation stage because of the gas contained in solution in the oil at a pressure below the operating pressure of the low-pressure separator. Some of this gas will not separate from oil immediately upon entry into the tank but will "weather" from the oil for a period of a few minutes up to a few days. Such gas or vapors can be captured with a vapor recovery system (see Chap. 14).

Flash Calculations for Oil and Gas Separators

Flash (equilibrium) calculations can be made to determine accurately the gas and liquid analysis and yield from oil and gas separators if the composition of the well fluid is known. As an example, fluid produced from seven wells is gathered and separated in three stages in such a system as that depicted in Fig. 12.41.

In Fig. 12.41, F1 represents the first-stage separator, F2 represents the second-stage separator, and F3 represents the third stage, the storage tank. The fluid streams are represented by numbers as follows:

- (1) well fluid inlet to first-stage separator,
- (2) gas and vapors from first-stage separator,
- (3) liquid from first-stage separator,

- (4) gas and vapors from second-stage separator,
- (5) liquid from second-stage separator,
- (6) gas and vapors from storage tank (third stage), and
- (7) liquid in storage tank (stock-tank oil) (third stage).

The first-stage separator operates at 850 psia and 90°F; the second-stage separator operates at 250 psia and 76°F; the third stage (storage tank) is maintained at atmospheric pressure (14.7 psia) and is assumed to be at 100°F (summer conditions).

Flash calculations were made on this system with a computer program available from Simulation Sciences, Inc.¹² The results are shown in Table 12.16.

Economic Considerations of Stage Separation

The extent of application of stage separation will depend on two principal considerations: the terms of the gas sales contract and the price structure for the gaseous and liquid hydrocarbons.

If gas is sold on volume only, it will usually be desirable to remove most condensible vapors from it. If, on the other hand, gas is sold on liquid content, it may be desirable to permit condensible vapors to remain in the gas, depending on conditions, facilities, and location.

If the liquid hydrocarbon is sold on the basis of volume and API gravity, it may be desirable to remove the condensible vapors from the gas and add them to the liquid to increase its sales price. If, on the other hand, the liquid is sold on the basis of volume only, it may be desirable to leave the condensible vapors in the gas.

Other considerations in the application of stage separation are (1) physical and chemical characteristics of the well fluid, (2) flowing wellhead pressure and temperature, (3) operating pressures of available gas-gathering systems, (4) conservation features of liquid-storage facilities, and (5) facilities for transporting liquids.

The point of diminishing returns in stage separation is reached when the cost of additional stages of separation is not justified by increased economic gains. The optimum number of stages of separation can be determined by field testing and/or by equilibrium calculations based on laboratory tests of the well fluid. Flash calculations can be made for various numbers of stages of separation to determine the optimum number of stages of separation for each installation.

Stabilization of Separated Liquid Hydrocarbons

If an oil and gas separator is operated under a vacuum and/or at a temperature higher than well-stream temperature, the liquid hydrocarbons flowing through the separator will have more gas and/or vapors removed than otherwise would be removed. This tends to stabilize the liquid and results in loss of less gas and condensible vapors from the storage tanks. By the use of a stabilization unit similar to that shown in Fig. 12.42, the yield of stock-tank liquid has been increased by 10 to 15% over that obtainable with standard two-stage separation.

When a stabilizer of this type is used, a separator installed upstream of the stabilizer removes gas from the liquid, and the liquid is discharged to the stabilizer. The liquid discharged from the stabilizer to the tanks is completely stabilized and has a Reid vapor pressure of 11 to 13 psi, which is less than atmospheric pressure. Therefore, there will be no loss of gas or vapor from the storage

Fig. 12.40—Flow diagrams for two-, three-, and four-stage separation.

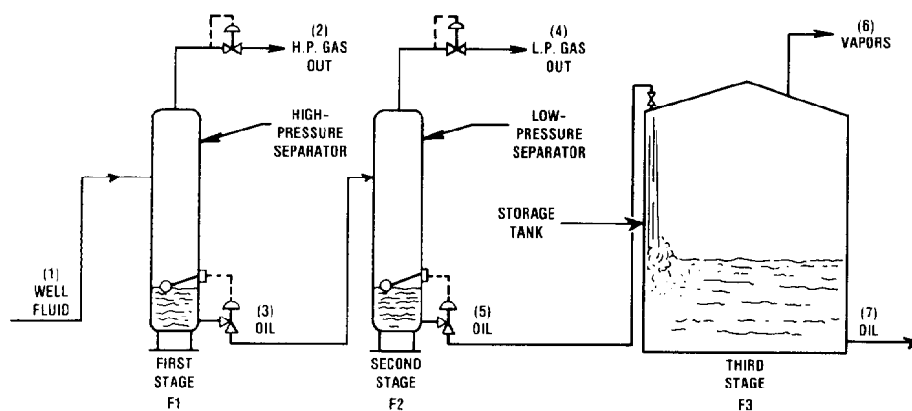

Fig. 12.41—Three-stage separator installation with two separators and storage tank(s). Refer to equilibrium flash calculations on Page 12-33 and Table 12.16.

tanks. In some installations the initial cost of a stabilizer may be less than the initial cost of multiple-stage oil and gas separators. Use of a stabilization unit has resulted in liquid recovery comparable to that from four to six stages of separation. Each new installation should be studied to determine whether a stabilizer should be used. If a highly volatile liquid is being handled, the use of stabilizers may result in increased profit.

Selection and Application of Separators and Scrubbers

Oil and gas separators are manufactured in three basic configurations: vertical, horizontal, and spherical. Gas scrubbers are manufactured in two basic shapes: vertical and horizontal. Each of these units has specific advantages and uses. Selection of the particular unit to use for each application is usually based on which will obtain the desired results at the lowest equipment, installation, and maintenance costs. Table 12.5 gives a comparison of the advantages and disadvantages of vertical, horizontal, and spherical separators.

The following summary indicates the general recommended uses of vertical, horizontal, and spherical oil and gas separators and gas scrubbers.

Vertical Oil and Gas Separators

Applications for vertical oil and gas separators include the following.

1. Well fluids having a high liquid/gas ratio.
2. Well fluids containing appreciable quantities of sand, mud, and similar finely divided solids.
3. Installations with horizontal space limitations but with little or no vertical height limitations, such as crowded tank batteries and/or offshore production platforms.
4. Well fluids where liquid volume may vary widely and instantaneously, such as slugging wells and/or intermittent gas lift wells.
5. Downstream of other production equipment that allows or causes liquid condensation or coalescence.
6. Upstream of other field process equipment that will not perform properly with entrained liquid in the gas.
7. Where economics favors the vertical separator.

Horizontal Oil and Gas Separators

Applications for horizontal oil and gas separators include these situations.

1. Liquid/liquid separation in three-phase separator installations to obtain more efficient oil/water separation.
2. Separating foaming crude oil where the larger liquid/gas contact area of the horizontal vessel will allow and/or cause faster foam breakdown and more efficient gas/liquid separation.
3. Installations where vertical height limitations indicate the use of a horizontal vessel because of its lower silhouette.
4. Well fluids with a high GOR.
5. Well with relatively constant flow rate and with little or no liquid heading or surging.
6. Installations where the operator and/or conditions require or indicate internal water-weir and oil-bucket construction to eliminate the use of oil/water interface liquid level controller.
7. Where portable units (either skid or trailer mounted) are required for either test or production use.

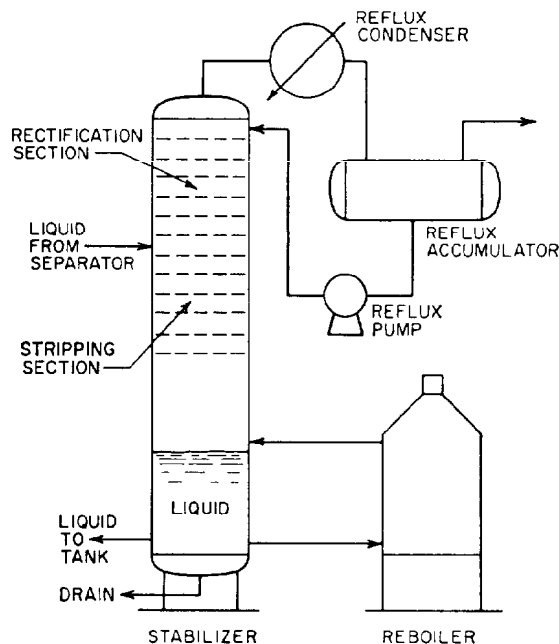

Fig. 12.42—Schematic of typical stabilization unit used for stabilizing and increasing the yield of liquid hydrocarbons at field separation stations.

8. Where multiple units can be stacked to conserve floor space.

9. Upstream of other field process equipment that will not perform satisfactorily with entrained liquid in the gas.

10. Downstream of other production equipment that allows or causes liquid condensation or coalescence.

11. Where economics favors the horizontal separator.

Spherical Oil and Gas Separators

The following is a list of applications for spherical oil and gas separators.

1. Well fluids with high GOR's, constant flow rates, and no liquid slugging or heading.
2. Installations where both vertical and horizontal space and height limitations exist.
3. Downstream of process units—such as glycol dehydrators and gas sweeteners—to scrub and to salvage the expensive process fluids, such as amine and glycol.
4. Installations where economics favors the spherical separator.
5. Installations requiring a small separator where one man can transport the spherical separator to location and install it.
6. Scrubber for fuel and process gas for field and/or plant use.

Gas Scrubbers

Most vertical and horizontal gas scrubbers are used where the gas previously has been separated, cleaned, transported and/or processed with other equipment. That is, most of the impurities—such as entrained liquids, silt, line scale, and dust—have been removed from the gas by other equipment, and the gas scrubber is being used to “polish” the gas. Gas scrubbers generally are used to ensure that the gas contains no materials that will be detrimental to the equipment that the scrubber is installed to protect—such as compressors, dehydrators, sweeteners, meters, and regulators.

Some of the uses for gas scrubbers are to clean gas (1) for fuel for heaters, boilers, steam generators, and engines; (2) for control gas for processing plants and equipment; (3) upstream of compressors; (4) upstream of dehydrators and sweeteners; (5) downstream of dehydrators and sweeteners to conserve processing fluids; (6) upstream of gas distribution systems; (7) upstream of and in gas transmission lines to remove liquid, dust, rust, and scale; (8) upstream and/or downstream of pressure regulation stations; and (9) downstream of gas-transmission-line compressor stations to remove lubricating oil from the line.

Both vertical and horizontal scrubbers can be effective and efficient in the applications listed above. The selection of a vertical or horizontal scrubber may be a matter of personal preference, space limitations, cost consideration, and/or availability.

Gas scrubbers normally are limited to applications where there is little or no liquid to be removed and where liquid slugging seldom or never occurs. A large number of different types, designs, and sizes are available from many manufacturers.

Construction Codes for Oil and Gas Separators

ASME Code for Unfired Pressure Vessels

Most oil and gas separators furnished for field use are designed, constructed, pressure tested, and labelled in accordance with the ASME Code for Unfired Pressure Vessels.¹³ Outside the U.S., other similar codes may be used (Table 12.17). Sec. VIII, Div. I of the ASME code is used for most unfired pressure vessels. Div. II of Sec. VIII may be used for offshore installations because of weight reduction obtained by its use. Div. I design equations are based on a safety factor of 4.0, while Div. II equations are based on a safety factor of 3.0. Quality control is more stringent under Div. II than Div. I.

Use of the ASME or some equivalent code for construction of pressure vessels ensures the purchaser of receiving vessels that are designed, constructed, and pressure-tested in accordance with established standards, inspected by a disinterested party, and certified safe for use at specified design pressures and temperatures. All vessels labeled with ASME code stamp must be constructed in accordance with the ASME code requirements, and written reports verifying this information must be furnished to the purchaser if requested.

The ASME Code for Unfired Pressure Vessels, Sec. VIII, Div. I, is generally preferred in the U.S. Information about and copies of the ASME Code may be obtained from Ref. 13. Information on other codes for construction of pressure vessels can be obtained from the government authorities shown in Table 12.17.¹⁴

Design equations for shell and head thicknesses and working pressures according to ASME Code for Unfired Pressure Vessels, Sec. VIII, Div. I¹³ are as follows.

Cylindrical shells.

$$h_{cs} = \frac{p_{cs} r_i}{\sigma E - 0.6 p_{cs}}$$

and

$$p_{cs} = \frac{\sigma E h_{cs}}{r_i + 0.6 h_{cs}}$$

Spherical shells.

$$h_{ss} = \frac{p_{ss} r_i}{2\sigma E - 0.2 p_{ss}}$$

and

$$p_{ss} = \frac{2\sigma E h_{ss}}{r_i + 0.2 h_{ss}}$$

Ellipsoidal heads.

$$h_{eh} = \frac{p_{eh} d_i}{2\sigma E - 0.2 p_{eh}}$$

and

$$p_{eh} = \frac{2\sigma E h_{eh}}{d_i + 0.2 h_{eh}}$$

Torispherical heads.

$$h_{th} = \frac{0.885 p_{th} r_c}{\sigma E - 0.1 p_{th}}$$

and

$$p_{th} = \frac{\sigma E h_{th}}{0.885 r_c + 0.1 h_{th}}$$

Hemispherical heads.

$$h_{hh} = \frac{p_{hh} r_c}{2\sigma E - 0.2 p_{hh}}$$

and

$$p_{hh} = \frac{2\sigma E h_{hh}}{r_c + 0.2 h_{hh}}$$

where

h = minimum required thickness (exclusive of corrosion allowance), in.,

p = design pressure, psi,

r_i = inside radius of shell course under consideration before corrosion allowance is added, in.,

σ = maximum allowable stress value, psi (use one-quarter of tensile strength listed in Table 12.19 for a safety factor of 4.0),

E = joint efficiency for appropriate joint in cylindrical shells and any joint in spherical shells or the efficiency of ligaments between openings, whichever is less (see Table 12.18),

d_i = inside diameter, in., and

r_c = inside spherical or crown radius, in.

Joint efficiency, E , for the above ASME design equations is shown in Table 12.18.

Materials of Construction for Separator

The most common steels used in the shells, heads, nozzles, and flanges in pressure vessels built under the ASME

Code for Unfired Pressure Vessels, Sec. VIII, Div. I, are listed in Table 12.19, along with the most important information concerning these materials. For more detailed information on these steels refer to the corresponding ASTM specifications indicated in Table 12.19.

Controls, Valves, Accessories, and Safety Features for Oil and Gas Separators

Controls

The controls required for oil and gas separators are liquid-level controllers for oil and oil/water interface (three-phase operation) and gas back-pressure control valve with pressure controller.

Valves

The valves required for oil and gas separators are oil-discharge control valve, water-discharge control valve (three-phase operation), drain valves, block valves, pressure relief valve, and valves for sight glasses.

Accessories

The accessories required for oil and gas separators are pressure gauges, thermometers, pressure-reducing regulators (for control gas), level sight glasses, safety head with rupture disk, piping, and tubing.

Safety Features for Oil and Gas Separators

Oil and gas separators should be installed at a safe distance from other lease equipment. Where they are installed on offshore platforms or in close proximity to other equipment, precautions should be taken to prevent injury to personnel and damage to surrounding equipment in case the separator or its controls or accessories fail.

The following safety features are recommended for most oil and gas separators.

High- and Low-Liquid-Level Controls. High- and low-liquid-level controls normally are float-operated pilots that actuate a valve on the inlet to the separator, open a bypass around the separator, sound a warning alarm, or perform some other pertinent function to prevent damage that might result from high or low liquid levels in the separator.

High- and Low-Pressure Controls. High- and low-pressure controls are installed on separators to prevent excessively high or low pressures from interfering with normal operations. These high- and low-pressure controls can be mechanical, pneumatic, or electric and can sound a warning, actuate a shut-in valve, open a bypass, or perform other pertinent functions to protect personnel, the separator, and surrounding equipment.

TABLE 12.18—JOINT EFFICIENCY, ASME SEC. VIII, DIV. I

Single-welded Butt Joints (back-up strip left in place)		Double-Welded Butt Joints
(%)	(% Radiograph)	(%)
90	100	100
80	Spot	85
65	None	70

High- and Low-Temperature Controls. Temperature controls may be installed on separators to shut in the unit, to open or to close a bypass to a heater, or to sound a warning should the temperature in the separator become too high or too low. Such temperature controls are not normally used on separators, but they may be appropriate in special cases.

Safety Relief Valves. A spring-loaded safety relief valve is usually installed on all oil and gas separators. These valves normally are set at the design pressure of the vessel. Safety relief valves serve primarily as a warning, and in most instances are too small to handle the full rated fluid capacity of the separator. Full-capacity safety relief valves can be used and are particularly recommended when no safety head (rupture disk) is used on the separator.

Safety Heads or Rupture Disks. A safety head or rupture disk is a device containing a thin metal membrane that is designed to rupture when the pressure in the separator exceeds a predetermined value. This is usually from $1\frac{1}{4}$ to $1\frac{1}{2}$ times the design pressure of the separator vessel. The safety head disk is usually selected so that it will not rupture until the safety relief valve has opened and is incapable of preventing excessive pressure buildup in the separator.

Operation and Maintenance Considerations for Oil and Gas Separators

Periodic Inspection

In refineries and processing plants, it is normal practice to inspect all pressure vessels and piping periodically for corrosion and erosion. In the oil fields, this practice is not generally followed, and equipment is replaced only after actual failure. This policy may create hazardous conditions for operating personnel and surrounding equipment. It is recommended that periodic inspection schedules for all pressure equipment be established and followed to protect against undue failures.

Installation of Safety Devices

All safety relief devices should be installed as close to the vessel as possible and in such manner that the reaction force from exhausting fluids will not break off, unscrew, or otherwise dislodge the safety device. The discharge from safety devices should not endanger personnel or other equipment.

Safety Heads (Rupture Disks)

The discharge from a safety head should be open and without restriction. The discharge line from a safety device should be parallel to a vertical separator and perpendicular to a horizontal one; otherwise the separator may be blown over by the reaction force from exhaust-

ing fluids. A valve should not be used between the safety head and the separator because it may inadvertently be closed. Water should not be allowed to accumulate on top of the rupture disk because ice could form and alter the rupture characteristics of the disk. Operation of an oil and gas separator without a properly sized and installed safety head (rupture disk) is not recommended.

Pressure relief valves may corrode and leak or may "freeze" in the closed position. They should be checked periodically and replaced if not in good working condition. Discharge lines, especially those on full-capacity relief valves, should be such that reaction force from discharge will not move the separator. Safety relief valves with "try" handles are recommended for general use. Some operators use pilot-operated relief valves where frequent testing of the relief valves is required.

Mist Extractors

Some mist extractors in oil and gas separators require a drain or liquid downcomer to conduct liquid from the mist extractor to the liquid section of the separator. This drain will be a source of trouble when pressure drop through the mist extractor becomes excessive. If the pressure drop across the mist extractor, measured in inches of oil, exceeds the distance from the oil level in the separator to the mist extractor, the oil will flow from the bottom of the separator up through the mist-extractor drain and out with the gas. This condition may be aggravated by partial plugging of the mist extractor with paraffin or other foreign material. This explains why some separators have definite fixed capacities that cannot be exceeded without liquid carryover through the gas outlet, and it also explains why the capacities of some separators may be lowered with use. In recent years, separators of advanced design have used mist extractors that do not require drains or downcomers. These designs eliminate this source of trouble (see Fig. 12.14).

Low Temperatures

Separators should be operated above hydrate-formation temperatures. Otherwise hydrates may form in the vessel and partially or completely plug it, thereby reducing the capacity of the separator and, in some instances when the liquid or gas outlet is plugged or restricted, causing the safety valve to open or the safety head to rupture. Steam coils can be installed in the liquid section of oil and gas separators to melt hydrates that may form there. This is especially appropriate on low-temperature separators.

Corrosive Fluids

A separator handling corrosive fluid should be checked periodically to determine whether remedial work is required. Extreme cases of corrosion may require a reduction in the rated working pressure of the vessel. Periodic hydrostatic testing is recommended, especially if the fluids being handled are corrosive. Expendable anodes can be used in separators to protect them against electrolytic corrosion. Some operators determine separator shell and head thickness with ultrasonic thickness indicators and calculate the maximum allowable working pressure from the remaining metal thickness. This should be done yearly offshore and every two to four years onshore.

*Data of the most frequently used materials from ASME Code Sec. II and VIII.

**With charpy tests, this steel is used for low-temperature and sour-gas service.

- SA-283 C plate may be used for pressure parts in pressure vessels provided all of the following requirements are met.
 - The vessels are not used to contain lethal substances, either liquid or gaseous;
 - The material is not used in the construction of unfired steam boilers;
 - The design temperature at which the material is used is between -20°F and 650°F;
 - For shells, heads, and nozzles only, the thickness of plates on which strength welding is applied does not exceed ½ in.; and
 - The steel is manufactured by the electric furnace, open-hearth process, or the basic oxygen process.
- For service temperatures above 850°F, it is recommended that killed steels containing not less than 0.10% residual silicon be used. Killed steels that have been deoxidized with large amounts of aluminum and rimmed steels may have creep and stress-rupture properties in the temperature range above 850°F, which are somewhat less than those on which the values in the table are based.
- Upon prolonged exposure to temperatures above about 800°F, the carbide phase of carbon steel may be converted to graphite.
- Only killed steel shall be used above 850°F.
- Not permitted above 450°F; allowable stress value 7,000 psi.
- The material shall not be used in thicknesses above 2 in.
- For welded pipe the maximum allowable stress values are 15% less. No increase in these stress values shall be allowed for the performance of radiography.
- The stress values to be used for temperatures below -20°F when steels are made to conform with Supplement (5) SA-20 shall be those that are given in the column for -20 to 650°F.
- SA-333 pipe is SA-106-B pipe with charpy tests made at the mill by the manufacturer of the pipe.
- For low-temperature and sour-gas service, charpy tests must be made on this steel before fabrication of the vessel.
- Most of the information for this table was taken from Ref. 14.

Paraffin

A separator handling paraffin-based oil may need to be steamed periodically to prevent plugging and a resultant decrease in capacity. This reduction in capacity often results in liquid carryover in the gas or discharge of excessive gas with the liquid.

High-Capacity Operation

Where separators are operating near or at their maximum rated capacity, they should be checked carefully and periodically to determine whether acceptable separation is being accomplished.

Pressure Shock Loads

Wells should be switched in and out of the separator slowly. Fast opening and closing of valves causes damaging shock loads on the vessel, its components, and piping.

Throttling Discharge of Liquid

Throttling discharge of small volumes of liquid from separators normally should be avoided. Throttling may cause erosion or wire drawing of the inner valves and seats of the liquid-dump valves and may erode the dump-valve bodies to the extent that they may burst at or below rated working pressures.

However, throttling discharge may be necessary because processing units, such as lower-pressure separators or stabilization units, downstream of the separator may require relatively steady flow. Liquid-discharge control valves on separators should be sized for the volume of liquid the separator must handle. Such valves usually should be smaller than the lines in which they are installed. Reduced inner valves can be used to size the valve properly to minimize wire drawing during throttling service.

Pressure Gauges

Pressure gauges and other mechanical devices on separators should be tested for accuracy at regular intervals. Isolating valves should be used so that pressure gauges can be easily removed for testing, cleaning, repairs, or replacement.

Gauge Cocks and Glasses

Gauge cocks and gauge glasses should be kept clean so that the liquid level observed in the sight glass indicates at all times the true liquid level in the separator. Periodic flushing of the gauge glass or cleaning with special solvents and swabs is recommended.

Cleaning of Vessels

It is recommended that all separator vessels be equipped with manways, cleanout openings, and/or washout connections so that the vessels can be cleaned periodically. Larger vessels can be equipped with manways to facilitate their cleaning. Smaller vessels can be equipped with handholes and/or washout connections so that they can be easily cleaned or washed out periodically.

SI Metric Unit Conversions

Most conversions from customary units to SI metric units in Chap. 12 can be made directly by using the conversion factors presented in the tables in the publication entitled "The SI Metric System of Units and SPE Metric Standard." The exceptions are listed below.

The values of F_{co} in Fig. 12.32 should be multiplied by 30.48 to change them for use in the SI metric units. F_{co} is used in Eqs. 1, 4, 5, and 6.

In Eq. 3, the gas constant R in customary units has the value 10.732. In SI metric units, the value of R is 0.083145 where the gas volume is in cubic meters, pressure in bars, temperature in degrees Kelvin, and n in kmol.¹⁶

Nomenclature

- A_g = cross-sectional area of separator for gas flow, sq ft
- A_o = cross-sectional area of separator for oil flow, sq ft
- d_i = ID, in.
- D = diameter of separator, in. (see Fig. 12.34 for D')
- E = joint efficiency for appropriate joint in cylindrical shells and any joint in spherical shells or the efficiency of ligaments between openings, whichever is less (Table 12.18)
- F = stage pressure ratio $p_1/p_2 = p_2/p_3 = \dots p_n/p_s$
- F_{co} = configuration and operation factor (empirical) (see Fig. 12.32 for values)
- h = thickness (exclusive of corrosion allowance), in.
- h_o = height (or depth) of oil in separator, ft
- L = length of separator, ft (see Fig. 12.34 for L')
- M_g = molecular weight of gas
- n_i = number of interstages (number of stages - 1)
- p = design pressure or separator operating pressure, psia
- p_b = base pressure, psi
- p_s = storage-tank pressure, psia
- p_1 = first-stage separator pressure, psia
- p_2 = second-stage separator pressure, psia
- p_3 = third-stage separator pressure, psia
- q_g = volume of gas flowing through separator, cu ft/sec
- r_c = inside spherical or crown radius, in.
- r_i = inside radius of shell course under consideration before corrosion allowance is added, in.
- R = gas constant
- T = operating temperature, °R
- T_b = base temperature, °R
- v_g = gas velocity, ft/sec
- V_o = volume required in separator for oil, cu ft
- z_g = gas compressibility factor
- γ_g = specific gravity of gas
- ρ_g = density of gas at operating conditions, lbm/cu ft
- ρ_L = density of liquid at operating conditions, lbm/cu ft

σ = maximum allowable stress value, psi (use
 1/4 of tensile strength listed in Table
 12.19 for a safety factor of 4.0)

Acknowledgments

Appreciation is expressed to George O. Ellis of Ellis Engineering Co., Houston, for allowing the usage of the Comsign Computer Program to calculate the oil and gas capacities for vertical and horizontal separators shown in Figs. 12.35 through 12.38 and for the sample calculations in Tables 12.9 and 12.10.

Chapter 13

Gas Measurement and Regulation

John M. Campbell Sr., The Campbell Companies*

Introduction

Measurement and regulation are an integral part of the production of gas. As the value of gas has increased, the need for more accurate measurement has become apparent. Proper regulation is necessary to prevent unnecessary flaring or production curtailment.

Today the engineer has a choice from among many instruments and controls, some of which are rather sophisticated. The advent of electronic and digital equipment offers many alternatives. Remote metering and control now are more commonly employed to minimize personnel overhead. The net result is a more complex production system than the traditional one.

Many seemingly superior instruments and controls are not suitable for some production systems. They may not be packaged to withstand exposure to the weather and elements in the environment—rain, salt spray, sand, wind, lightning, etc. Some devices are so sensitive that mere vibration may be a problem. Calibration and other like necessities may be inconvenient (or maybe impractical) in remote locations. Also, properly trained personnel may not be available for maintenance.

If transfer of custody is involved, contractual obligation may limit the choice of system. Other factors like spare parts availability and vendor service all influence the proper selection of equipment and vendor.

Gas Measurement

The choice of meter depends on the absolute volume involved and the *rangeability*—the ratio of maximum to minimum flow rate that a given size meter can accommodate. Reliability also is a factor. Both accuracy and precision must be considered. Accuracy is the difference between true and measured rate. Precision is the repeatability of a measurement, however wrong it may be.

*This author also wrote the chapter on this topic in the 1962 edition.

There are a series of volumetric meters that measure volume directly by use of bellows, reciprocating pistons, rotating vanes and cams, etc.¹ These are used primarily for measuring small volumes of low-pressure gas and have little application in production operations.

Velocity Meters

A velocity meter is any device that measures flow by impact kinetic energy or by using the change in pressure that accompanies a controlled change in velocity. However this change is induced, meter performance is governed by an energy balance.

The Energy Balance. Fig. 13.1 illustrates a general flow system on which a general flow equation may be based. Points 1 and 2 represent any two points in a flow system between which an energy balance may be written.

The fluid entering at Point 1 has an internal energy, U_1 , which is the result of previous energy obtained. In addition, a certain amount of pV work must be done to get the fluid past Point 1—i.e., the energy necessary for it to flow. This fluid also possesses potential energy, X_1 , above the datum plane, and kinetic energy $v_1^2/2g$. The fluid leaving at Point 2 possesses the same forms of energy but the amount depends on the work W or heat Q gained or lost by the system between the two points. The general equation may then be written

$$\begin{aligned}
 U_1 + p_1 V_1 + Z_1 + \frac{v_1^2}{2g} + Q - W \\
 = U_2 + p_2 V_2 + Z_2 + \frac{v_2^2}{2g}, \dots\dots\dots (1)
 \end{aligned}$$

Fig. 13.1—General flow system.

where

- U = internal energy, which includes all energy such as heat, electrical, chemical, and surface,
- p = pressure,
- V = volume or specific volume,
- Z = height above an arbitrary datum plane,
- v = velocity in conduit,
- Q = heat gained or lost by system (plus if gained, minus if lost), and
- W = work done by system (plus if done by system, minus if done on system).

The many ramifications of Eq. 1 are developed in any standard text on thermodynamics.

Eq. 1 may be applied to any of the systems shown in Fig. 13.2. When writing it between Points 1 and 2 of any of the three systems shown, it may be reduced to

$$p_1 V_1 - p_2 V_2 = \frac{v_2^2}{2g} - \frac{v_1^2}{2g} \quad \dots \dots \dots (2)$$

Eq. 2 develops on the normally correct premise that Q , W , and ΔU are substantially zero between the two points. These two points are, furthermore, so close together that any change in potential energy is negligible in comparison with the other changes involved. Eq. 2 is the basic equation governing velocity or head meters and expresses the general fact that changes in velocity in such a system must be accompanied by a corresponding change in static pressure.

Forms of Meter. Fig. 13.2 shows several common ways in which a velocity change may be imposed on the system. In each instance, a constriction is supplied for increasing the velocity (decreasing static pressure), following which the velocity returns to normal. The amount of *permanent* pressure loss across the device is small and depends largely on the amount of turbulence and friction loss involved.

The Venturi tube shown in Part a is designed so that a high-pressure differential can be induced and still minimize the permanent pressure loss due to turbulence and eddy currents. In general, it will restore at least 90% of the pressure drop at the throat. The sections involved, though, are expensive to manufacture and bulky to handle, especially at elevated pressures. Consequently, their

Fig. 13.2—Diagrammatic representation of fluid flow through a flat-plate orifice showing relative positions of the pressure taps in common use and the change in static pressures (flow is from left to right). (a) Venturi tube, cross section; (b) flow nozzle, cross section; (c) location of taps; (d) schematic view of pitot tube.

use is usually limited to low-pressure applications where high-pressure recovery is essential. The flow nozzle is essentially a cross between the three devices shown and represents an attempt to incorporate the best features of each. General usage is limited.

The flat-plate orifice is used in the majority of all gas-production and transportation facilities. It is simple, inexpensive, handy to change and stock, and gives reproducible results. Although the pressure recovery is seldom higher than 65%, this is not a critical fault, for most systems are designed to operate with a low differential pressure.

Derivation of an Orifice Equation. Eq. 2 may be simplified by assuming that $V_1 = V_2 = V$, an assumption that is approximately true and is later corrected by a term called the expansion factor. Then

$$v_1^2 - v_2^2 = 2gV(p_2 - p_1) = 2gh \quad \dots \dots \dots (3)$$

The term h is the differential head loss between Points 1 and 2 expressed as "feet of fluid" (that fluid flowing in the system).

The velocities may be expressed in terms of volume rate of flow q_g and diameters d_i and d_o (internal diameter of pipe and orifice opening, respectively). This substitution yields an intermediate equation

$$q_g = A_2 \frac{1}{\sqrt{1 - F_d^4}} \sqrt{2gh} \quad \dots \dots \dots (4)$$

where A_2 = area of orifice plate opening, and $F_d = d_o/d_i$. The second term on the right side of Eq. 4 is often referred to as the approach factor.

Further modification of our theoretical equation is necessary. Part c of Fig. 13.2 shows that the diameter of the flowing stream becomes smaller than that of the orifice opening. This point, known as the *vena contracta*, is really the limiting diameter, and some correction must be made when using the orifice-opening diameter in the equation. There is also an energy loss due to turbulence and friction not yet accounted for. Both of these considerations are easily handled by use of an efficiency factor, K_o , that must be determined experimentally.

For convenience we furthermore like to express h in terms of inches of water, h_w . If all these corrections and conversions are superimposed on Eq. 4 the equation reads

$$q_g = 218.44 K_o d_o^2 \frac{p_f}{p_{sc}} \frac{T_{sc}}{T_f} \sqrt{\frac{h_w T_f}{p_f \gamma_g}}, \dots \dots \dots (5)$$

where

- q_g = gas-flow rate, std cu ft/hr measured at p_b and T_b ,
- d_i = internal diameter, in.,
- d_o = orifice-opening diameter, in.,
- p_f = flowing pressure, psia,
- p_{sc} = base pressure, psia,
- T_f = flowing temperature, °R,
- T_{sc} = base temperature, °R,
- h_w = differential across orifice, in. H₂O,
- γ_g = specific gravity of gas (air=1.0), and
- K_o = efficiency factor, which includes the approach factor.

Eq. 5 may be modified to a more standard form by (1) combining terms, (2) writing it for a gas whose specific gravity=1.0, and (3) assuming that $p_{sc}=14.73$ psia and $T_{sc}=T_f=520^\circ\text{R}$.

This yields the two basic orifice equations

$$q_g = C' \sqrt{h_w p_f} \dots \dots \dots (6)$$

and

$$C' = F_b F_{pb} F_{tb} F_g F_{tf} F_r Y F_{pv} F_m F_v F_a \dots \dots \dots (7)$$

The value C' is known as the orifice constant. It is determined primarily from F_b , the basic orifice flow factor, which is equal to $338.17 K_o d_o^2$. The other multipliers shown in Eq. 7 are correction factors to correct for the basic assumptions necessary to arrive at Eq. 6. Only the first five are usually used in routine lease operations, in measuring gas for proration records and the like. The last six correction factors are relatively small and are used to obtain accurate records in the sale or purchase of gas. The last two apply only to meters with mercury manometers.

Table 13.1 summarizes these constants except for F_{pv} , which is calculated from compressibility factor, and F_a , calculated from the expansibility of metals used for orifice construction.^{2,3}

The comparable metric standard for the orifice equations and constants is ANSI/API 2530.² At the time this material was being prepared, the conversion effort to SI units had not been completed. Until it is, calculations may be made in English units and converted.

$$q_g (\text{m}^3) = (0.02833) (\text{cu ft}),$$

where $q_g = \text{m}^3$ measured at 101.315 kPa and 15°C and cu ft=volume measured at 14.73 psia and 60°F.

Orifice Constants

The value of the constants in Eq. 7 depends in many cases on the points between which the differential head loss, h_w , is measured. Two standards are provided in gas measurement—flange taps and pipe taps. With the former, the flange or orifice holder is so tapped that the center of the upstream and downstream taps is 1 in. from the respective orifice-plate surfaces. For standard pipe taps, the upstream tap is located two and one-half pipe diameters upstream and eight pipe diameters downstream. The location of Sec. 1 (Tables 13.1a, g, i, and l) of the orifice tables is for *flange taps* and Sec. 3 (Tables 13.1b, h, j, and m) is for *pipe taps*. Sec. 2 (the remaining parts of Table 13.1) shows the fluid-condition factors common to both types.

Basic Orifice Factor F_b . This factor, as noted above, is based on those assumptions necessary to go from Eq. 5 to 6. These are $T_{sc}=520^\circ\text{R}$, $\gamma_g=1.00$, and $T_f=520^\circ\text{R}$. It is a function of the experimental constant K_o , which means that it depends on the location of the differential pressure taps and the internal pipe diameter, in addition to the orifice diameter.

The value of F_b may be found from tables of F_b shown in Table 13.1a for flange taps and Table 13.1b for pipe taps if the meter run is of standard internal diameter. For gas-measurement work involving sale and purchase by a gas-transmission or distribution company, corrections are provided for values of F_b not fitting the standard tables. These are not shown here, for they are not normally used in production operations.

Pressure-Base Factor F_{pb} . Values of this factor are shown in Sec. 2 (Table 13.1c) of the charts. It corrects the value of F_b for the case where the pressure base used is not 14.73 psia. It may be determined by the equation $F_{pb}=14.73 p_{sc}$.

Temperature-Base Factor F_{tb} . This is shown in Table 13.1d and corrects for any contract wherein the base temperature is not 520°R (60°F). This factor may be computed by the equation $F_{tb}=T_{sc}/520$.

Specific-Gravity Factor F_g . This factor, shown in Table 13.1e, is to correct the basic orifice equation for those cases where the specific gravity of the gas is other than 1.00. The equation is $F_g=(1/\gamma_g)^{0.5}$.

Flowing-Temperature Factor F_{tf} . This factor corrects for those cases where the flowing temperature of the gas is other than 60°F. The equation is $F_{tf}=(520/T_f)^{0.5}$. Values are given in Table 13.1f.

Reynolds-Number Factor F_r . This takes into account the variation of the discharge coefficient with Reynolds number. In gas measurement, the variation is slight and is often ignored in production operations. Values are shown in Tables 13.1g and 13.1h. It has been assumed in preparation of these tables that gas viscosity is substantially constant. The constant b shown in the tables is then primarily a function of pipe diameter, orifice diameter, and the location of the differential-pressure taps.

Expansion Factor Y . This factor accounts for the change in gas density as the pressure changes across the orifice. Inasmuch as the differential involved is usually small, this correction is small and often ignored. The value used depends on which one of the differential-pressure taps is used to measure static pressure and the location of the tap. The additional primary variables involved are (1) F_d , (2) ratio of differential pressure to absolute pressure, and (3) the specific-heat ratio C_p/C_v . In the standard table the last variable is taken as constant and equal to 1.3. This factor is shown in Tables 13.1i through 13.1m.

Supercompressibility Factor F_{pv} . The variation from the ideal-gas laws by an actual gas is the function of this factor. The factor may be measured experimentally or determined by detailed methods outlined in AGA Committee Report 3.² The correction is usually small and is often ignored. It may be estimated from the equation $F_{pv} = (1/z)^{0.5}$, where z is equal to the compressibility factor obtained from standard correlations.

Manometer Factor F_m . This is used only with mercury-type meters to correct for the slight error in measurement caused by having different heads of gas above the two legs of the manometer. For all practical purposes it is insignificant. Table 13.1n lists this factor vs. gas specific gravity.

Gauge Location Factor, F_ℓ . This corrects the manometer factor, F_m , for elevation and latitudes other than sea level and 45° latitude (see Table 13.1o).

Thermal Expansion Factor, F_a . This corrects for expansion or contraction of the orifice opening when operating at temperatures substantially different from that at which the orifice was made. Normally, it is applied only at temperatures above 120°F or below 0°F.

Example Problem 1. A 0.7-specific-gravity natural gas is measured in an orifice meter having flange taps. Determine the flow rate in scf/hr at 14.4 psia and 60°F if the following data apply:

$$\begin{aligned}\bar{h}_w &= 40 \text{ in. H}_2\text{O}, \\ \bar{p}_f &= 143 \text{ psig (measured} \\ &\quad \text{downstream),}\end{aligned}$$

$$\text{avg flowing temp} = 84^\circ\text{F},$$

$$\text{line size} = 4.026 \text{ in., and}$$

$$\text{orifice-plate opening} = 1.50 \text{ in.}$$

Solution.

The respective factors are

$$F_b = 460.79,$$

$$F_{pb} = 1.0229,$$

$$F_{tb} = 1.0000,$$

$$F_g = 1.1952,$$

$$F_{ff} = 0.9777,$$

$$F_r = 1.0004,$$

$$Y = 1.0016, \text{ and}$$

$$C' = 551.89 \text{ (the product of the above numbers).}$$

Then, $q_g = 551.89 [(40)(143 + 14.73)]^{0.5} = 43,810$ scf/hr.

As a practical matter, the accuracy of the meter device itself does not justify the number of significant figures shown in the charts. Consequently, in most production operations and engineering calculations the values of the coefficients may be rounded off and sometimes ignored with no practical loss of accuracy.

Fig. 13.3—Proper installation of a meter run for an orifice meter.

Physical Setup of System

Inasmuch as standard tables are used, careful attention must be paid to the physical setup of the metering system. Otherwise the results would vary with the installation.

Straightening Vanes. The purpose of these vanes is to minimize the effect of swirls, eddy currents, or irregular velocity distribution on meter accuracy. These vanes are built into a nipple and consist of a bundle of small pipe or tubing as shown in Fig. 13.3. The dimension of each tube d should not exceed one-fourth of the inside pipe diameter d_i . The length should be at least $10d$.

Unless necessary, vanes should not be used because they are susceptible to erosion, introduce additional pressure loss, and clog easily.

Orifice Location. Fig. 13.3 shows the minimum distance the orifice should be from valves and fittings in order that proper metering might result.

Size of Orifice and Meter Run. The meter run should be sized so that the anticipated maximum and minimum flow rates may be handled within the satisfactory ratio of orifice to pipe diameter. In doing this, it should be kept in mind that (1) the differential h_w should not exceed the static pressure p_s (based on numerical values only, not units); (2) the meter run ID should be at least one-third larger than the orifice opening; and (3) both the differential- and static-pressure pens should preferably operate within the middle 60% of the recording-chart range.

As a practical matter, the meter run ID should not be less than 3 in. in nominal diameter regardless of the small quantity of gas flowing. As a first approximation, Eq. 6 should be solved for C' at the flow rate h_w and p_f desired. Then

$$d_o = \left(\frac{C'}{250} \right)^{0.5} \quad (8)$$

If the maximum anticipated flow rate is used to find C' , multiplying the orifice size found in Eq. 8 by 1.5 gives the approximate minimum pipe diameter needed. Once this has been established, it is a relatively simple matter to change orifice plates as the flow varies to keep the values of h_w , and p_f in the desired range. If flow is small and fairly constant (e.g. fuel meter) and/or a 1/4-in. orifice is used, a 2-in. run should be used to avoid low F_d (below 0.10).

Standard sharp-edged orifice plates should be used, the thickness of which is at least 1/16 in. For pipes larger than 4 in., thickness is at least 1/8 in. The thickness should not exceed one-eighth the orifice opening.

Recorder. The normal orifice meter is equipped with a two-pen recorder for measuring both static and differential pressure. The differential pen is normally actuated through a mechanical system using either a mercury manometer or a bellows. Both types are shown in Fig. 13.4.

With the former, a slight change in flow rate changes the level in the mercury manometer. A large float resting on the mercury changes level correspondingly and transmits this movement to the chart pen through a system of levers.

The bellows-type or mercuryless meter consists of two bellows filled with fluid such as glycol. As the pressure differential changes, this fluid moves between the bellows through a damping device, causing the bellows to expand or contract. The pen is actuated by a center rod, which is connected to the free ends of the bellows. The small liquid-filled bellows located on the high-pressure side serves as an expansion device to correct for changes in ambient temperature.

Both types of instruments are equipped with check valves to protect them from differential pressures that exceed the range of the instrument. This is more of a problem with the mercury meter, for excessive differential pressure can blow mercury out of the meter, which destroys its calibration. In the bellows meter, soft-seated check valves prevent the flow of fluid between the bellows. The bellows are then not likely to rupture for they are supported internally by the fluid contained within them.

The bellows meter has gained increasing popularity, particularly in field operations. Even though the initial cost is higher, many operators feel that this is compensated for by decreased maintenance. It also offers the advantage of operating either properly or not at all, with little range in between. Eliminated are the problems of mercury loss, worrying about the change in calibration with the amount of mercury, and the like. Until it fails, experience has shown that this meter needs little routine calibration.

With both types, the static pressure is read from a pen actuated by a bourdon tube. The lead for this may come off either the upstream or downstream tap. In most installations, it is good practice to order a bourdon tube having about twice the maximum pressure anticipated. This minimizes the problem of distortion, which destroys the original calibration of the tube. These tubes are available in many materials, the type depending on the service and the pressure rating desired.

Most meters are hooked up using a standard five-valve manifold of the type shown just above the bellows meter in Fig. 13.4. One valve is placed on each of the leads to the pressure taps, two valves on the bypass, plus a vent valve. When the meter is placed in operation the bypass valves would be open, as would the two main valves, with the vent valve closed. The meter is then placed in service by slowly closing the bypass valves, followed by opening of the vent valve. This procedure prevents momentary pressure surges that might damage the meter or upset the calibration. The reverse procedure would be used in taking the meter out of service. When the leads are bypassed, the vent valve is an excellent place to obtain a gas sample. A slightly more complex manifold is shown above the mercury meter, with drip pots for removing any liquid in the gas.

Standard calibration procedure on the differential pen calls for connecting one side of a water manometer into the high-pressure side of the meter. The low-pressure side of the meter is then opened to the atmosphere. This gives two manometers in parallel. By superimposing pressure on the high-pressure cell with a hand pump or similar device, one may compare the meter reading with that of the manometer. If they are different, the meter must be adjusted accordingly.

The bourdon tube may be calibrated simply by placing a dead-weight tester (preferred) or a calibrated pressure gauge in the lead line to the bourdon tube. By proper manipulation of the valves, the vent valve may be used to make this connection.

The circular charts used usually cover a time period of 24 hours or 7 days. Many meters have clocks that may be easily adjusted for either time period. In most production operations, 7-day periods are preferred, because this minimizes the cost of changing charts and the number of charts to be handled.

Other Forms of Metering Systems

For well-test purposes, other forms of velocity meters are used—orifice well testers, critical-flow provers, pitot tubes, and side-static methods. These methods are not so accurate as the meters discussed previously but are convenient and often yield results accurate enough for the purpose.

Orifice Well Tester. This consists of a 2-in. nipple with provision for attaching different sharp-edged orifice plates on the end. The static pressure just upstream from this plate may then be measured. Tables 13.2a and b show various applicable charts for measuring flow.⁴

The accuracy of this device is limited but it is suitable for measuring the amount of gas being produced where the pressures are relatively low and the production is to the atmosphere.

Fig. 13.4—Views showing construction of meters.

Critical-Flow Prover. The critical-flow prover is a similar device that exhausts the gas to the atmosphere. It is also a special pipe nipple with a flange for holding special plates to the end. It is based on the principle that the velocity of sound represents the maximum speed at which a pressure effect may be propagated through a gas—i.e., once this velocity is reached, further increase in the pressure differential will not increase the pressure at the throat. This means that the mass rate of flow would not increase as the pressure differential p_2/p_1 was decreased below this critical value. With ideal gases, the critical ratio is 0.49 for monatomic gases and 0.53 for diatomic gases, with slightly higher values for complex gases. Saturated steam, for example, shows a critical pressure ratio of 0.55. The range of these values is the source of the common rule of thumb that, once the pressure reduction is twofold, critical-flow phenomena limit the mass rate of flow.

When metering gas under such conditions, the volume rate of flow will be a function of upstream pressure, gas gravity, and gas temperature, since it is a compressible fluid.
