On the other hand, experimental data of Gregory⁵⁰ in Fig. 51.18 indicate that for some rocks, shear-wave velocity behavior upon the change of saturation from gas to brine is opposite to the predictions of the Biot theory. This may be due to the presence of isolated microcracks in these rocks, whereas the Biot/Gassmann theories assume the pore structure to be open and interconnected.

Texture

Texture in this context is the structural framework of the rock consisting of solid matrix and pore structure. Its importance in elastic wave propagation has been dramatically illustrated in Fig. 51.19. The data in this figure are the compressional and shear-wave velocities in dry and water-saturated Troy granite with a porosity of 0.3%.⁵¹ Velocities were measured as functions of confining pressure by maintaining pore fluid pressure (p_f) at 1 bar. Compressional-wave velocities are higher when the rock is water-saturated, whereas the shear-wave velocities are unchanged between the two states. What is most interesting, however, is that a porosity of only 0.3% is affecting the velocities by 20% or more.

Classical bounding theories⁵²⁻⁵⁵ obviously cannot account for these large changes in the respective moduli because of large differences between the properties of rock matrix and fluid in the pores. This is because they used the total porosity without considering how it is distributed.

Scanning electron micrographs (SEM's) shown in Fig. 51.20 show pore space in Troy granite to consist mainly of thin cracks, typical of most granites.⁵⁶

The effects of these cracks on elastic wave propagation properties have been investigated extensively, and many theoretical models have been developed.^{14,57} The theoretical curves shown in Fig. 51.19 were obtained by fitting the velocity data with the noninteractive scattering theory.¹⁴ For these theoretical formulations, the rock is

Fig. 51.17—Observed and theoretical compressional- and shear-wave velocities in Boise sandstone as a function of pressure for three saturation fluids. The circles, triangles, and squares are laboratory data from King for brine-, kerosene- and air-saturated (dry) samples.

assumed to consist of a solid matrix and pores of spherical and oblate spheroidal shapes. Using the SEM's as a guide and the porosity as a constraint, the pore space was modeled by a spectrum of pore shapes ranging from spheres to very fine cracks. Theoretical velocities were calculated as a function of pressure by first determining the ranges in pore shapes at each pressure condition. Depending on the fit, the pore aspect ratio (ratio of minor to major axis of an ellipsoid) spectra were adjusted and calculations were repeated until good fits were obtained to all velocities. Theoretical curves plotted on Fig. 51.19 are based on the final model.

Effects of various pore shapes on acoustic velocities as predicted by the noninteractive scattering theory are illustrated in Fig. 51.21. The effects shown in this figure are for a rock with matrix properties of $K_m=0.44$ megabar, $G=0.37$ megabar, and $\rho_m=2.7$ g/cm³; for water with $K_w=23.2$ kilobar and $\rho_w=1$ g/cm³; and for gas with $K_g=1.5 \times 10^{-3}$ kilobar and $\rho_g=10^{-3}$ g/cm³. As indicated, for a given porosity, the thinner (smaller aspect ratio) pores affect the velocities much more than the spherical pores.

Fig. 51.18—S-wave velocity ratio vs. porosity for dry, $(v_s)_g$, and fully water-saturated, $(v_s)_w$, rocks.

Fig. 51.19—Observed and theoretical compressional (v_p) and shear (v_s) velocities in dry and water-saturated Troy granite as a function of differential pressure. The data (points) are from Ref. 51.

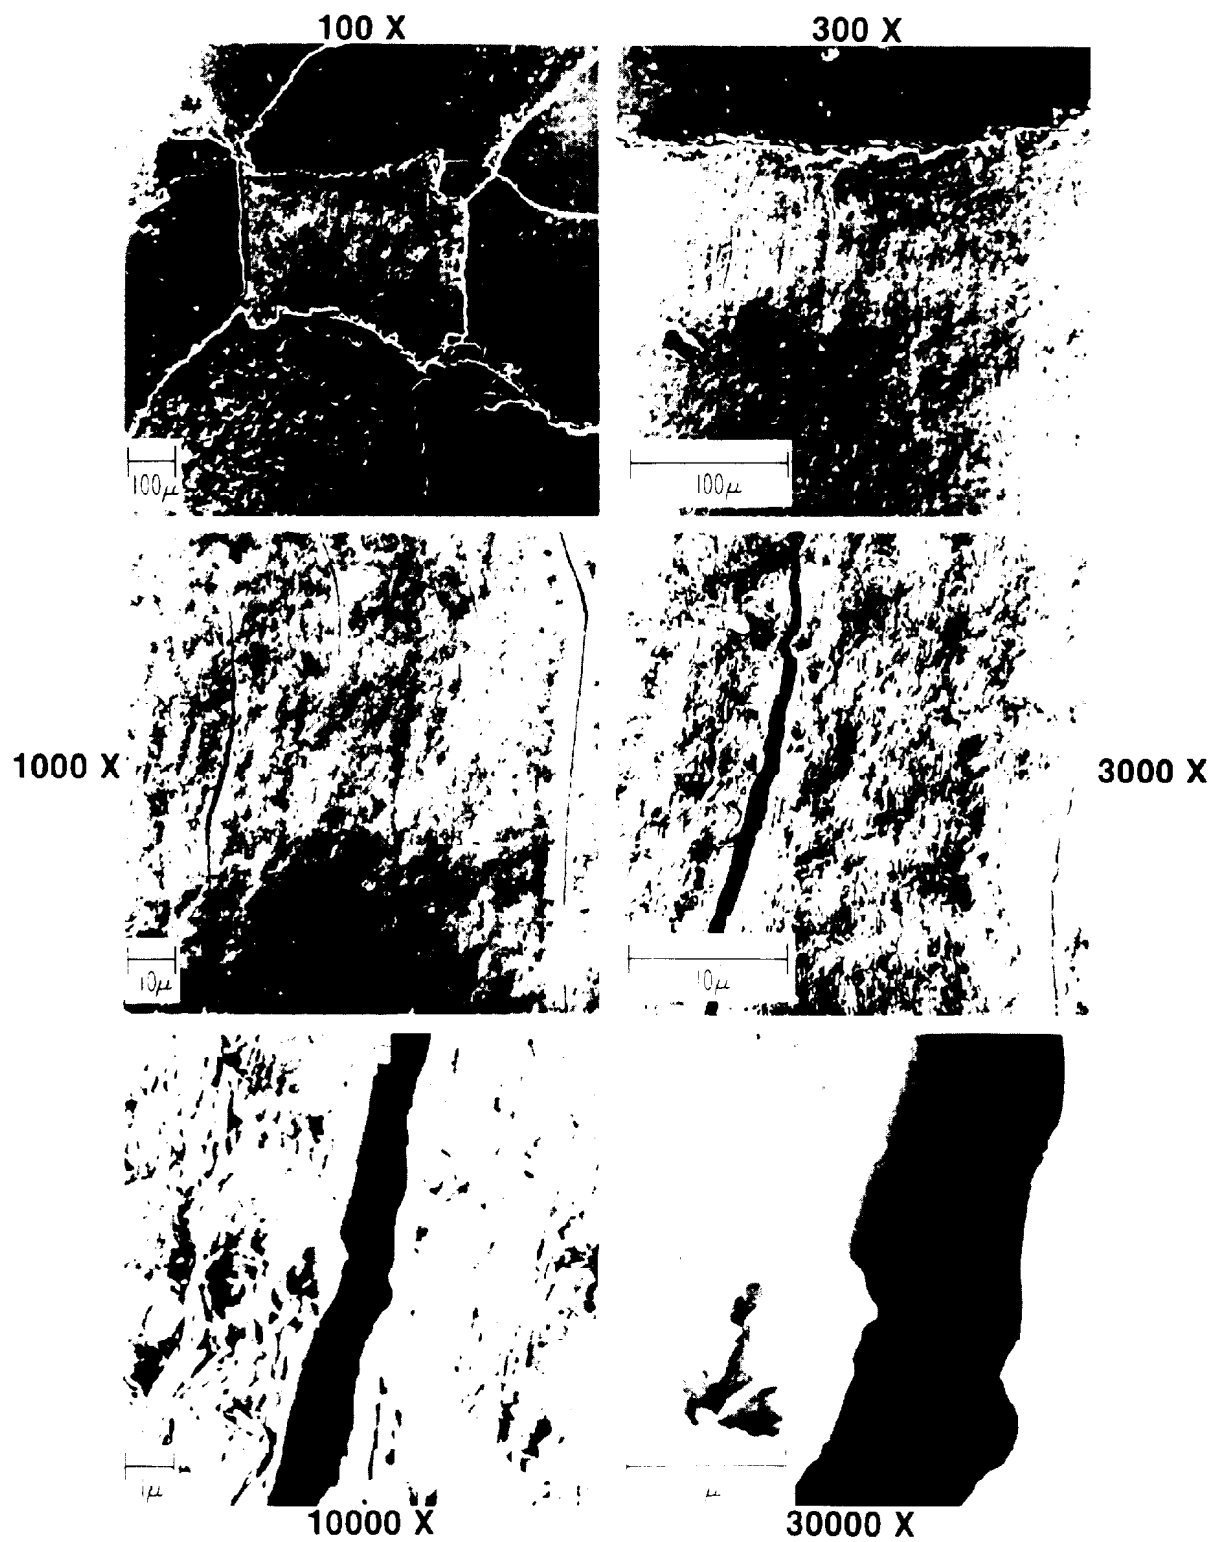

Fig. 51.20—Scanning electron micrographs of pore system in Troy granite.

This theory also was used to analyze the "well-behaved" (according to Biot/Gassmann) experimental data of Fig. 51.17, where the results are plotted as solid and long- and short-dashed curves. Additionally, however, it also can explain the "unexpected" behavior of the experimental data of Fig. 51.18, as illustrated in Fig. 51.21 by its predictions for the S-wave velocities in rocks with pores of various shapes.

Modeling of the real rock can be achieved by approximating the regular pores by spheres and rounded spheroids and by approximating the grain boundary spaces and flat pores by low-aspect-ratio cracks. However, there is no practical way to measure a pore aspect-ratio spectrum independently. An extensive study by Hadley⁵⁸ involved counting hundreds of cracks on three SEM's, each covering about 1 mm² of rock surface. These results are being used for testing "crack" theories. So far, these theories have added much to our understanding of acoustic wave propagation; their practical applications, however, have not yet materialized.

Summary

Factors affecting acoustic wave propagation properties of rocks were illustrated in a qualitative fashion with emphasis on compressional and shear-wave velocities, mostly because attenuation properties are much less understood. Among the factors influencing velocities, porosity, lithology (mineral composition and structural framework), saturation and differential pressure are considered primary, and the others, with certain qualifications, secondary. As the previous discussion indicates, significant advances have been made in understanding the properties of acoustic wave propagation in rocks. Further advances will be made because of the significance of this work, not only in formation evaluation, but also in seismic exploration.

Acoustic Wave Propagation Methods

Introduction

Acoustic wave propagation methods used in well logging can be classified into two groups: transmission and reflection (Table 51.1). In the transmission method, one or more transmitters emit acoustic energy, which is transmitted by formation and/or casing and is detected by one or more receivers. In the reflection method, one or more transducers emit acoustic energy, part of which is reflected by the borehole wall and/or casing and is detected by the same transducer.

In this section, both the transmission and reflection methods will be described, starting with a description of acoustic wave propagation in a borehole and followed by various methods of recording acoustic data.

Fig. 51.22—Compressional, P, and shear, S, wave propagation in or around a fluid-filled borehole.

Fig. 51.23—Acoustic waveform.

Acoustic Wave Propagation in a Fluid-Filled Borehole

The propagation of elastic waves in a borehole filled with liquid has been studied extensively.⁶⁰⁻⁷⁰ Only a qualitative description of the phenomenon will be given here for identifying the components of an acoustic pulse recorded in a borehole.

The general geometry for the transmission method is illustrated in Fig. 51.22, which shows a single receiver logging sonde. Two pressure transducers are spaced on an acoustically insulated body, the upper one to generate compressional waves in the borehole fluid and the lower one to detect compressional waves reaching it. The receiver converts these waves to electrical signals. These are transmitted to the surface and displayed on an oscilloscope as a record of received-signal amplitude vs. time and recorded either in analog form on film or digitally on magnetic tape.

This received signal, which is referred to as the acoustic waveform, represents several acoustic waves and is illustrated by the synthetic waveform trace shown in Fig. 51.23. For the usual case of a liquid-filled borehole in a formation with both the compressional- and shear-wave velocities higher than borehole fluid velocity, two body (or head) waves and two guided waves are propagated. These waves are shown in Fig. 51.23 in the order of their arrival time at the receiver: (1) compressional wave, (2) shear wave, (3) pseudo-Rayleigh waves, and (4) Stoneley waves.

Compressional and shear waves, which are also called P, primary, and S, secondary waves, respectively, are head or body waves because they travel in the body of the formation. Pseudo-Rayleigh and Stoneley waves, which also are called reflected conical (or normal mode) and tube wave (or water arrival), respectively, are guided waves because they require the presence of the borehole for their existence.

A description of the various ray paths of these waves may help further in understanding elastic wave propagation in and around the borehole. The acoustic transmitter shown in Fig. 51.22 generates compressional waves

traveling with a velocity, v_f , in the mud. When these waves reach the borehole face, they are both reflected and refracted. For angles of incidence less than the P-wave critical angle θ_p ,

$$\theta_p = \sin^{-1} \left(\frac{v_f}{v_p} \right),$$

part of the energy is transmitted into the formation in the form of compressional wave and another part as a shear wave, and the remainder is reflected back into the mud as a compressional wave, all according to Snell's law.

At or near the P-wave critical angle, a shear wave is still transmitted into the formation and P-wave reflected back into the mud, but a P-wave is critically refracted and travels with the v_p in the formation, close and parallel to the borehole wall, while continuously radiating P-wave energy back into the mud at the same P-wave critical angle (Fig. 51.22).

At the S-wave critical angle (θ_s),

$$\theta_s = \sin^{-1} \left(\frac{v_f}{v_s} \right),$$

the S-wave is critically refracted and travels with the v_s in the formation along a path similar to that of the refracted P-wave. It also continuously radiates P-wave energy back into the mud at the S-wave critical angle (Fig. 51.22). Beyond the S-wave critical angle, all the incident energy is reflected back into the mud to form the guided pseudo-Rayleigh waves (Fig. 51.24).

To summarize, the compressional wave travels as a P-wave between the transmitter and the formation, in the formation, and also between the formation and the receiver (PPP); the shear wave travels as a P-wave between the transmitter and the formation, an S-wave in the formation, and again as a P-wave between the formation and the receiver (PSP). If the formation shear-wave velocity is slower than borehole fluid velocity, shear waves cannot be refracted along the borehole wall; therefore, no shear head wave is generated.

As described earlier, compressional and shear waves travel at velocities determined by the elastic moduli and the density of the formation:

$$v_p = \frac{1}{t_p} = \frac{1}{\rho_b^{1/2}} \left(K + \frac{4}{3} G \right)^{1/2} \dots \dots \dots (7)$$

and

$$v_s = \frac{1}{t_s} = \left(\frac{G}{\rho_b} \right)^{1/2} \dots \dots \dots (8)$$

ρ_b is the bulk density of formation, and t_p and t_s are compressional- and shear-wave transit times.

The body waves travel at all frequencies at speeds given by Eqs. 8 and 9. They are nondispersive (variation of velocity with frequency is negligible), and undergo attenuation and geometric spreading. Attenuation, α , of the body waves is proportional to the logarithmic ratio of the amplitudes, A_1 and A_2 , at distances s_1 and s_2 from the source^{15,16}:

$$\alpha = \frac{20}{s_2 - s_1} \log \left[\frac{A_1}{A_2} \cdot \frac{F_{gs2}}{F_{gs1}} \right],$$

where α is in decibel/ft and F_{gs} is a geometrical spreading factor.

The ringy packet shown between the compressional and shear waves is called the leaky or PL mode.⁶⁶ It is a guided wave generated by the interaction of the formation with totally reflected compressional waves between the compressional and shear critical angles. Paillet and White⁶⁹ have shown that the leaky mode propagates at a velocity close to that of compressional waves in the formation and its phase velocity decreases with increasing frequency. They also have shown that the leaky mode amplitude, and hence the shape of the compressional wave train, varies with a change of Poisson's ratio.

Pseudo-Rayleigh and Stoneley waves are the two main guided waves. They both arrive after the shear wave, have larger amplitudes and longer durations than either the compressional or the shear wave, and are dispersive.⁶⁷ The pseudo-Rayleigh wave is generated by the total internal reflection of the acoustic energy at the borehole face beyond the shear critical angle. It travels within the borehole by multiple internal reflections without loss of energy into the formation; therefore, it is a guided wave. Its amplitude decays exponentially in the formation away from the borehole face, but is oscillatory in the fluid. A pseudo-Rayleigh wave is not generated unless $v_s > v_f$ and it travels with a velocity v_r such that $v_f < v_r \leq v_s$ with an Airy phase traveling slower than v_f .

Fig. 51.25 shows the dispersion characteristics for the phase and group velocities of the guided waves in a fluid-filled borehole.⁶⁷ The parameters used are (1) for the formation, P-wave velocity = 15×10^3 ft/sec, S-wave velocity = 9×10^3 ft/sec, density = 2.3 g/cm^3 , and (2) for the borehole fluid, P-wave velocity = 6×10^3 ft/sec, density = 1.2 g/cm^3 ; the borehole diameter is 8 in. The phase and group velocities plotted are normalized to the P-wave velocity of the borehole fluid.

As shown in this figure, the pseudo-Rayleigh waves are very dispersive. At the low-frequency end, there is a cutoff frequency below which these waves are not generated. At this frequency, the pseudo-Rayleigh wave phase velocity is equal to the shear-wave velocity of the formation and it steeply decreases with increasing frequency and asymptotically approaches at high frequencies the velocity of the fluid in the mud. Group velocity of pseudo-Rayleigh wave has an Airy phase that travels more slowly than the borehole fluid velocity (Fig. 51.25). Pseudo-Rayleigh waves have large amplitudes and arrive after the refracted shear wave, often making identification of the smaller-amplitude S-wave arrival difficult. However, only a small error is made if the velocity estimates are made by using the pseudo-Rayleigh arrivals.

The second type of guided waves is the Stoneley wave, which is the true surface wave coupled between the borehole fluid and the formation. The particular motion of these waves is shown in Fig. 51.26,⁷¹ where r is the borehole radius. Their amplitudes decay exponentially both in the fluid and in the formation away from the borehole face. As shown in Fig. 51.24, they are slightly dispersive, have no geometric spreading, and travel at

Fig. 51.24—Two-receiver sonde and the ray paths of body and guided waves.

Fig. 51.25—Dispersion characteristics of the pseudo-Rayleigh and Stoneley waves.

Fig. 51.26—Stoneley (or tube) wave particle motions.

Fig. 51.27—Transit time measurement by a single-receiver tool.

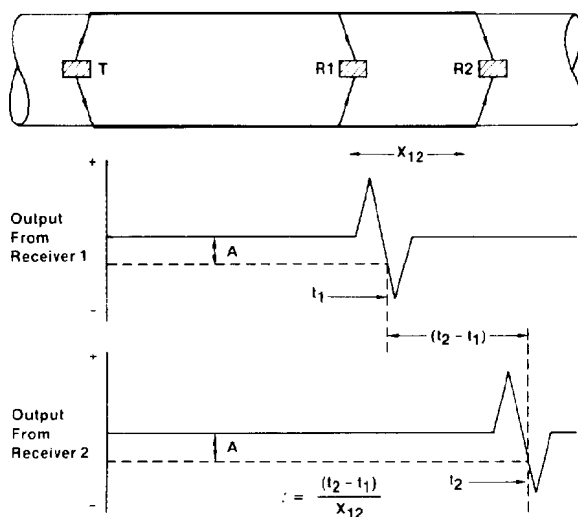

Fig. 51.28—Transit time measurement by a two-receiver tool.

velocities slightly slower than that of the borehole fluid or formation shear wave velocity, whichever is less.

Unlike the formation shear wave or pseudo-Rayleigh waves, Stoneley waves always are present, whether or not v_s is greater than v_f . They arrive as a compact pulse slightly later than that for a direct fluid arrival or shear arrival if $v_s < v_f$. Stoneley wave amplitudes are high at low frequencies and decay rapidly with increasing frequency.⁷² In the low-frequency end, the Stoneley waves are called tube waves and travel with a velocity, v_t , given by⁸

$$v_t = \frac{v_f}{\left(1 + \frac{K_f}{G}\right)^{1/2}}, \quad \dots \dots \dots (9)$$

where K_f is the bulk modulus of the fluid, given by

$$K_f = \rho_f v_f^2,$$

and

$$G = \rho_b v_s^2.$$

Therefore, in formations with $v_s < v_f$, so that neither shear nor pseudo-Rayleigh waves are present, the Stoneley wave can be used to estimate formation shear-wave velocity if formation bulk density is available from a density log.

The dispersion characteristics described so far (of the pseudo-Rayleigh and the Stoneley waves) are for a borehole containing a point source. The effects of the logging sonde on dispersion behavior also have been investigated by Cheng and Toksöz.⁶⁷ Their study indicated, first, that the dispersion curves for the pseudo-Rayleigh wave are shifted to lower frequencies as the borehole radius increases. They further found that for a relatively rigid tool, presence of a logging sonde simply makes the borehole diameter appear smaller, thus shifting the dispersion curves to higher frequencies.

As stated at the beginning of this section, only a qualitative description was given of the elastic wave propagation in a fluid-filled borehole. Ray theory is only an approximation when describing elastic wave properties in a cylindrical geometry. Accurate description of this phenomenon requires solution of the wave equation for cylindrical boundary conditions. The reader is referred to the references given at the beginning of this section for a more quantitative treatment.

Methods of Recording Acoustic Data

As described in the previous section, an acoustic waveform is rich in information. It may have four component waves: compressional, shear, pseudo-Rayleigh, and Stoneley. Each of these, in turn, has four measurable properties: velocity, amplitude, amplitude attenuation, and frequency.²⁷

Various methods of logging were developed to record one or more of these properties. A brief description of some of these logging techniques, with emphasis on those in more common use, follows.

Fig. 51.29—The effect of hole enlargement on the response of acoustic velocity logging tools: (a) one-receiver type and (b) two-receiver type.

Conventional Acoustic Logging

The most commonly used property of acoustic waves in a borehole is the velocity of compressional waves. In conventional acoustic logging, the time, t , required for a compressional wave to travel through 1 ft of formation is recorded as a function of depth. This parameter, t , referred to as the interval transit time, transit time, or travel time, is the reciprocal of the velocity of the compressional waves:

$$t = t_p = \frac{1}{v_p}$$

Transit time also is referred to as compressional-wave slowness and is identified as t_p to differentiate it from shear wave transit time:

$$t_s = \frac{1}{v_s}$$

Velocities observed in acoustic logging vary from 4,000 to 25,000 ft/sec; hence, the travel times range from 40 to 250 μ s/ft.

Tool Characteristics. The original acoustic logging tool, as mentioned earlier, used one transmitter and one receiver (Fig. 51.27). Values of t recorded in this arrangement, however, also include travel time of sound in mud in the borehole.⁷³ To remove this component, a dual-receiver commercial tool was introduced⁷⁴ to measure the time difference between the arrival of the signal at the first receiver and at the second receiver (Fig. 51.28).

Two-receiver systems, however, also were found to be unsatisfactory, especially at boundaries of hole irregularity,⁷⁵ as illustrated in Fig. 51.29.

To improve accuracy of t measurement further, a borehole-compensated sonde (Fig. 51.30) with two

Fig. 51.30—Borehole-compensated acoustic log.

Fig. 51.31—Travel time measurement with the borehole-compensated acoustic log.

transmitters and four receivers was developed.⁷⁶ This borehole-compensated tool may be considered to be composed of two separate two-receiver systems. As illustrated by the measurement scheme in Fig. 51.31, perturbations caused by hole irregularities are oppositely directed; therefore, they cancel. These sondes usually have a 2-ft span between the receivers with a 3-ft spacing between each transmitter and its near receiver.

Fig. 51.33—The effect of bed thickness on the response of an acoustic velocity logging device: (a) bed thinner than the span and (b) bed thicker than the span.

Fig. 51.32—Presentation of acoustic log.

Log Presentation. Transit time t measured by acoustic velocity logs is recorded as a function of depth across Tracks 2 and 3 in units of microseconds per foot ($\mu\text{sec/ft}$). The typical example shown in Fig. 51.32 also has the integrated travel time recorded at the left edge of Track 2 as a series of pips, placed at 1-millisecond intervals.

Additional Curves Recorded. A three-arm caliper and a gamma ray curve can be recorded simultaneously in Track 1 of the conventional acoustic logs (Fig. 51.32). The gamma ray curve can be replaced or supplemented by a spontaneous-potential (SP) curve; however, this SP should be used only for qualitative interpretation because of proximity of the electrode to the metal in the sonde.

Tool Span. The usual span for the acoustic log receivers is 2 ft; however, tools with receiver spacings of 3 in.⁷⁷ to 1 m⁷⁸ or longer also have been developed for special applications.

The shorter the span, of course, the more detail given by the tool. The relative effects of bed thickness, h , and tool span on measured transit times are illustrated in Fig. 51.33. The log measures only the formation between the receivers. The measured transit time is the weighted average of transit times in formations between the receivers.

Cycle Skipping and Triggering on the Noise. In transit time logging, the first arrival of the acoustic pulse must trigger both receivers of the sonde to yield correct values

Fig. 51.34—Cycle skip and triggering on the noise.

of t . Under certain conditions, even though the first arrival is strong enough to trigger the first receiver, it may be attenuated to such an extent that by the time it reaches the far receiver it may be too weak to trigger it (Fig. 51.34). Instead, the far receiver may be triggered by a later arrival in the same acoustic pulse. This causes large and abrupt increases in the recorded transit time values. This phenomenon, known as "cycle skipping," may occur when the signal is strongly attenuated by (1) gas sands, especially if they cause gas in the mud; (2) poorly consolidated formations; (3) recently drillstem-tested intervals, because of the release of gas; (4) fractured formations; and (5) aerated mud.

If the detection levels are set too low, however, either one or both receivers may be triggered by noise, which is always present as the tool is being dragged up the hole. Depending on the receivers involved, triggering may cause t spikes either too short or too long. Examples of cycle skipping and triggering by noise are illustrated in Figs. 51.35 and 51.36.⁷⁹

Calibration. The precision of measurement of acoustic transit time with the acoustic log is determined by the precision of the timing circuitry, which, in turn, is controlled by the frequency of the quartz crystal used. For the usual crystals of 2.5 MHz, the potential resolution of the transit time measurement is $\pm 0.4 \mu\text{sec}/\text{ft}$.

The accuracy of the transit time measurement, however, depends on many other factors in addition to the precision of the timing circuitry. A discussion of some of the factors affecting the measurement of transit time is given by Thomas.⁷³

Fig. 51.35—Sonic log run in Edwards limestone: (a) 1-ft span, (b) 3-ft span, and (c) 3-ft span with intentionally accentuated cycle-skipping.

An essential factor is to ensure the proper calibration of the logging system. Calibration procedures of each commercially available acoustic velocity system are described in respective service company manuals. These should be required before and after logging to ensure the accuracy of the surface equipment. It is important to emphasize, however, that most calibration procedures do

Fig. 51.36—Cycle skip and noise on acoustic log.

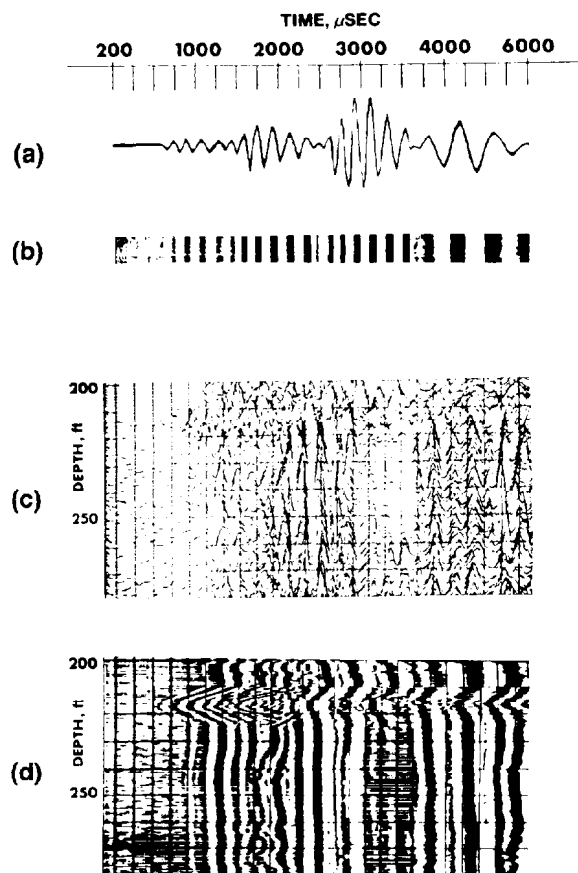

Fig. 51.37—Acoustic waveform recording.

Fig. 51.38—Approximate volume of investigation of conventional acoustic logs.

just that. They merely check linearity of some of the circuitry in the surface instrumentation without any input from the downhole sonde.

A true calibration requires measuring the response of the complete system, surface instrumentation, and sonde in a standard environment. For this purpose, the tool is placed in a fluid-filled steel sleeve and transit time is checked against the known value of $57 \mu\text{sec}/\text{ft}$. In addition, some free pipe in the surface casing should be logged while going in and coming out of the hole, and checked against the value for steel of $57 \mu\text{sec}/\text{ft}$. Anhydrite beds, with a transit time of $50 \mu\text{sec}/\text{ft}$, and other formations with known transit times sometimes can be used to check the accuracy of the log; however, these methods are useful only if the downhole velocities in naturally occurring rocks are known not to vary from location to location or with depth of burial.

Amplitude/Time Recording

As described earlier, the acoustic wave (Fig. 51.37a) contains information other than compressional wave velocity. One of the methods developed to record some of this formation is the amplitude/time recording. In this method, which is also called the "X-Y mode," the amplitude of acoustic energy is recorded as a function of time at preassigned depths along the wellbore (Fig. 51.37c). Usually, this is achieved by analog recording of the output of one of the receivers on film.

Within the last few years, however, the introduction of wellsite and downhole computers has made possible the digital recording of waveforms from an array of acoustic receivers. For example, with one of these tools, a waveform is digitized at every $\frac{1}{2}$ -in. depth interval of the borehole to obtain more than 500 data points. Processing of this wealth of new information is a current area of research that is expected to increase significantly the usefulness of borehole acoustic measurements.

Intensity/Time Recording

For most applications, analog recordings of waveforms at $\frac{1}{2}$ -in. depth intervals are rather cumbersome to use. Hence, for routine use, to obtain a continuous recording or a log, waveforms are recorded in the intensity/time mode. In this presentation, each waveform is reduced to a series of dashes of varying width and intensity, depending on its frequency and amplitude (Fig. 51.37b). The process can be visualized by rotating the acoustic waveform of Fig. 51.37b by 90° on its horizontal axis and then recording the positive-going portions of the wave train as series of dashes and leaving the negative-going portions as blank spaces, as shown in Fig. 51.37c. The intensity/time log (Fig. 51.37d) is obtained by stacking these dashed lines from each depth interval.

Unfortunately, this process has not been standardized. Some service companies have the negative part of the waveform as the dark dashes and the positive part as the light blanks; other companies, vice versa. Also, some service companies have the time increasing from left to right, while other companies increase in the opposite direction. The various trade names for this presentation are Variable Density LogTM (VDL) by Schlumberger and Dresser, 3-D LogTM by Birdwell, and Micro-Seismogram LogTM by Welex.

Long-Spaced Acoustic Logging

Introduction. Conventional acoustic logs have a relatively shallow depth of investigation, D_i . The approximate bulk volume of the rock investigated by conventional acoustic logs is illustrated in Fig. 51.38.⁸⁰

This region is most subject to alterations because of stress relief, mechanical damage caused by drilling, and chemical alteration (clay hydration) caused by drilling fluid. An important early study by Hicks⁸¹ clearly demonstrated that acoustic velocities in certain formations sensitive to damage were significantly lower when measured near the borehole face than when measured deeper in the formation. Hicks⁸¹ clearly demonstrated that these borehole effects on acoustic velocities diminish with increased transmitter-to-receiver spacing. Since then, many investigators have observed drastically poor logging data caused by borehole enlargement and formation alteration around the borehole.

Borehole Size. Effects of borehole geometry on log measurements can be considered in terms of hole rugosity and hole enlargement. Borehole rugosity, which can cause significant errors in pad-type tools (such as density, sidewall neutron porosity, microresistivity, and high-frequency dielectric measurements) can produce diffractions in acoustic waves propagating along the borehole. In general, these should not affect the first-arrival compressional transit time measurements but can affect the

Fig. 51.39—Maximum detectable formation transit time, various transmitter-to-near-receiver spacing.

Fig. 51.40—Effects of cavity on density, sidewall neutron, and acoustic logs.

Fig. 51.41—Comparison of depth of investigations of conventional and long-spacing acoustic logs.

amplitudes. The hole size, however, can have a significant effect on the transit time measurements if the hole is large enough and the tool is centralized because the acoustic energy traveling directly down the hole in the mud might arrive at the receiver before the formation compressional wave.

Hole size effects on acoustic measurements have been investigated extensively.^{73,82} For a centralized tool, Goetz *et al.*⁸² computed the travel times along the direct mud path and the refracted path in the formation, for various hole sizes. Some of their results are illustrated in Fig. 51.39 in terms of t vs. borehole diameter. Below the line labeled conventional 3- to 5-ft sonde, a centered tool will read the formation transit time. Between this line and the dashed line (computed for a receiver with a 5-ft spacing from the transmitter), a centered tool will record a value intermediate between formation and mud transit times. Above the dashed line, a conventional acoustic log measures the velocity of compressional waves in the mud. The upper solid line is for a longer-spacing acoustic log with 8- to 10-ft receiver spacing. Below this

Fig. 51.42—Effects of formation alteration on measurements with conventional (3 to 5 ft) and long-spacing (8 to 10 ft) acoustic sondes.

line, the long-spaced tool measures high formation transit times in larger-diameter holes in the range where conventional tools would record incorrectly low formation travel times.

Even though these borehole size effects are important, conventional borehole-compensated acoustic logs can record reliable measurements under much more adverse borehole conditions than other porosity tools, such as density and neutron tools. The influence of a cavity on the density, sidewall neutron, and conventional acoustic tools is compared in Fig. 51.40.⁸³ In this figure, over the elliptical cavity indicated by the calipers on the density and acoustic logs, both the density and sidewall neutron curves are useless, whereas the acoustic log provides reliable data. This feature of the acoustic log is used to complement density and neutron porosity that are not reliable because of poor hole conditions.

Formation Alteration. A more important factor affecting the borehole acoustic measurements is formation alteration or damage around the borehole (Fig. 51.41). This can occur because of stress relaxation near the borehole wall, mechanical damage caused by prolonged exposure to drilling, or chemical alteration of the formation by interaction of drilling fluid with sensitive clays in the formation. Under these conditions, accurate measurements of acoustic velocities depend on hole size and transmitter receiver spacing, as well as velocities of both altered and unaltered zones around the borehole.

Formation alteration was investigated by Goetz *et al.*⁸² by assuming a step profile transit time around the borehole, with the altered or damaged zone having a transit time t_d that is greater than the undisturbed formation t and a mud transit time of 200 $\mu\text{sec/ft}$. They computed the depths of investigation of conventional acoustic (3- to 5-ft) and long-spacing (8- to 10-ft) acoustic logs in a 10-in.-diameter borehole. They also

Fig. 51.43—Schlumberger long-spacing sonic log.

calculated formation alteration ($t_d - t$) as a function of alteration depth for unaltered formation transit times of 100, 120, and 150 $\mu\text{sec}/\text{ft}$. Their results, plotted in Fig. 51.42, illustrate the ability of the longer-spacing tool to overcome the effects of formation damage. In this figure, the area to the left of each curve represents the conditions for reliable measurements. For example, at an alteration of 20 $\mu\text{sec}/\text{ft}$, a conventional tool can handle an alteration of 5 in. if the formation transit time, t , is 100 $\mu\text{sec}/\text{ft}$, but only 3 in. if $t = 150 \mu\text{sec}/\text{ft}$.

Long-Spacing Acoustic Logging Tool. Both the borehole enlargement and the formation alteration effects can be accommodated by acoustic tools with longer transmitter-to-receiver spacings. A schematic diagram of one such tool, the Long Spacing Sonic™ by Schlumberger,⁸⁴ is shown in Fig. 51.43. Two transmitters, 2 ft apart, are at the bottom, and two receivers, 2 ft apart, are at the top, with 8-ft spacing between the two sections. Two long-spacing logs are recorded concurrently, one with 8- to 10-ft spacing and the other with 10-

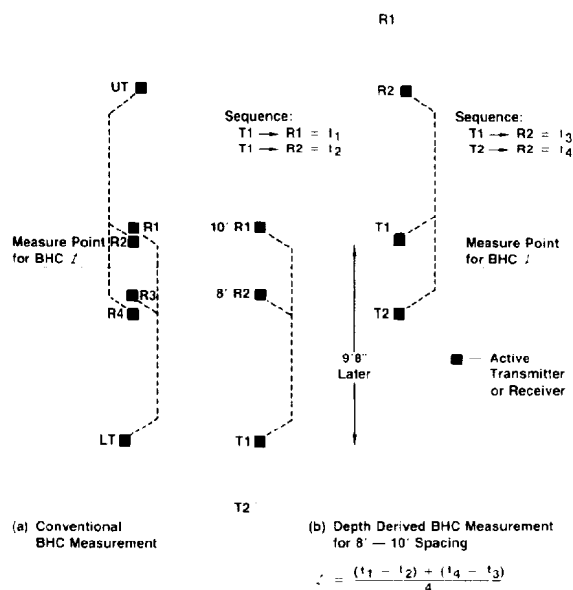

Fig. 51.44—Borehole-compensated transit time measurements: (a) conventional and (b) depth derived.

to 12-ft spacing. Borehole compensation is accomplished by a depth-derived measurement scheme illustrated in Fig. 51.44b, rather than the inverted array technique shown in Fig. 51.44a, which was described earlier (Fig. 51.31). To obtain the transit time at depth level, first the transmitter T_1 is pulsed twice and the respective times $t_1 = T_1 \rightarrow R_1$, $t_2 = T_1 \rightarrow R_2$ are recorded. The transit time for this case is given by

$$t_1 = \frac{t_1 - t_2}{2} \mu\text{sec}/\text{ft},$$

which is subject to errors discussed earlier if the hole size is different at the two receiver positions.

After the tool has moved 9 ft 8 in. up hole, the transmitters will be spanning the same depth interval between the points of refraction. This time they are each pulsed, and the travel times, $t_3 = T_1 \rightarrow R_2$ and $t_4 = T_2 \rightarrow R_2$ are recorded by the second receiver (R_2). For this second case, the transit time is given by

$$t_2 = \frac{t_4 - t_3}{2} \mu\text{sec}/\text{ft},$$

which is subject to the same errors as t_1 but in an opposite direction. The depth-derived transit time for the 8- to 10-ft spacing is obtained by averaging these two measurements:

$$t = \frac{t_1 + t_2}{2}.$$

A similar borehole compensation is obtained for the 10- to 12-ft spacing by using the second transmitter T_2 in the first position, instead of T_1 , and the first receiver R_1 in the second position, instead of R_2 .

Fig. 51.45—Formation alteration caused by exposure to mud; bit size 12¼ in.

Effects of prolonged exposure to drilling and drilling mud on acoustic velocities measured with a conventional borehole-compensated acoustic log are illustrated in example logs in Fig. 51.45 taken from the reference by Misk *et al.*⁸⁵ The dashed curve is obtained after the hole has been exposed to drilling for 4 days with the borehole relatively undamaged; the solid curve is after 79 days of exposure. During this period, the formation over much of the interval has been damaged enough to increase the t by 30 $\mu\text{sec}/\text{ft}$ or more.

As described previously, long-spacing acoustic logs are less affected by altered zones. A comparison of conventional and long-spaced acoustic logs is shown in Fig. 51.46 for a sand/shale section.⁷³ In the upper section, the conventional log is reading higher values of t than those by the long-spacing tool, probably because of shale alteration. In Sand Z, both logs are in agreement, whereas in sections directly above and below Sand Z, the conventional log is reading significantly higher values of t , probably because of hole washouts.

Fig. 51.46—Conventional and long-spacing acoustic logs in a sand/shale section.

The example in Fig. 51.47 is a comparison of the two acoustic tools in shallow and deeper Louisiana gulf coast sand/shale sequences.⁸⁶ Physical characteristics of both the shale at 3,470 ft and the sand at 3,500 ft have been altered by drilling and interaction with mud filtrate. The conventional spaced tool is reading 15 $\mu\text{sec}/\text{ft}$ higher because of this alteration. This is also reflected by a 10-millisecond difference between the respective transit time integration curves shown in the depth tract. In the deeper section, as the formations become more compacted, the formation alteration is reduced; hence, the conventional and long-spacing measurements are in agreement within the interval 8,500 to 8,600 ft.

Even though, in most instances, the t values from 8- to 10-ft and 10- to 12-ft spaced receivers are in agreement, very deep formation alteration can sometimes affect the t values recorded by the 8- to 10-ft receivers. The example in Fig. 51.48 is from a shallow well with modified depths.⁸⁴ In the upper zone, the 8- to 10-ft spacing is reading values higher by 10 $\mu\text{sec}/\text{ft}$ than those given by

Fig. 51.47—Conventional (BHC) and long-spacing (LSS) acoustic logs in a Louisiana gulf coast sand/shale sequence.

Fig. 51.48—Very deep formation alteration.

the 10- to 12-ft spacing, because of very deep formation alteration. In the lower section, the 8- to 10-ft spacing still reads a few microseconds higher down to the compacted formations below depth 227 ft.

In the final example shown in Fig. 51.49, the better response of the long-spaced logs in enlarged boreholes is illustrated. In the upper section, the conventional spaced tool is reading the mud transit time in a hole washed out

to 20 in. In the lower section, the borehole is not washed out but the conventional tool is reading up to 60 $\mu\text{sec}/\text{ft}$ too high because of formation alteration. Below 8,700 ft, all three curves (i.e., the 3- to 5-ft, 8- to 10-ft, and 10- to 12-ft curves), are in agreement.

Summary. Borehole size and formation alteration can significantly affect the properties of acoustic waves

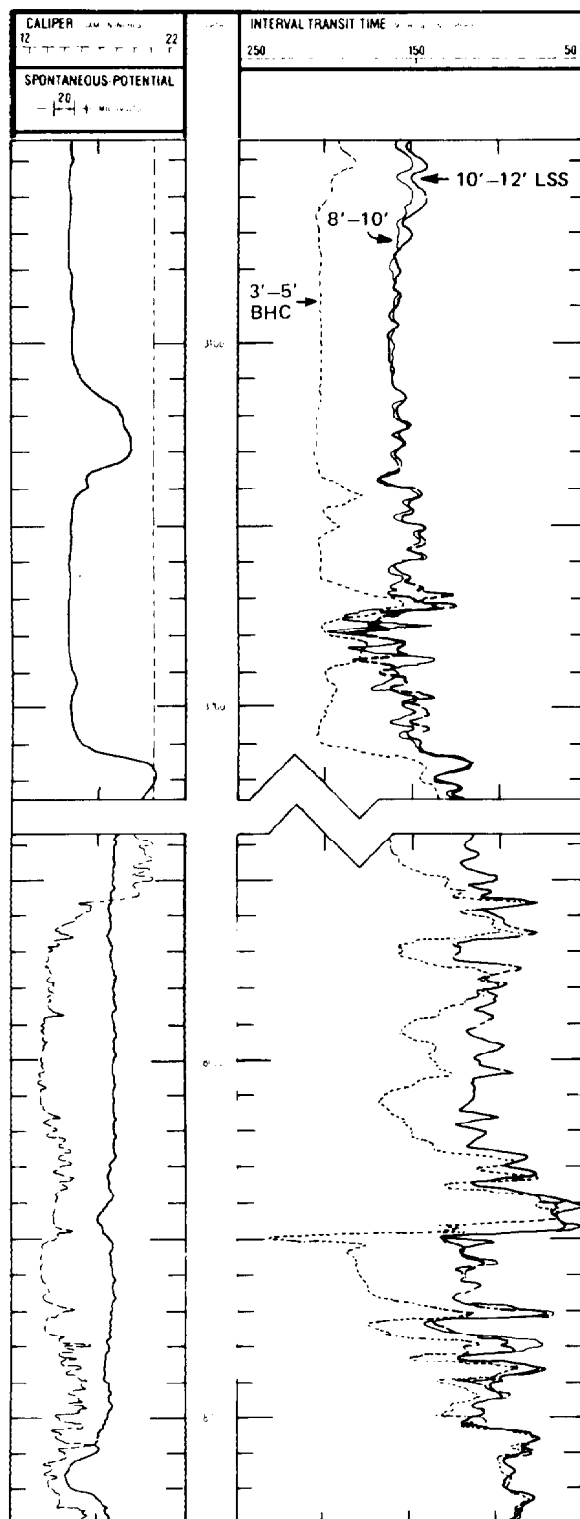

Fig. 51.49—Response of conventional and long-spacing acoustic logs in an enlarged borehole.

Fig. 51.50—Identification of shear arrivals on analog recording of (a) acoustic waveforms and (b) variable-density (3D) presentations.

traveling in a borehole. The long-spaced acoustic tools are much less affected by borehole conditions and yield more reliable values of compressional-wave transit times under borehole conditions in which conventional tools would be grossly in error. The vertical bed boundary resolution of the long-spaced tool is the same as that of the conventional tool since the receiver spacing is 2 ft for both. Because of the longer transmitter-to-receiver spacing, the acoustic energy has to travel farther; therefore, it is attenuated more. This has caused more frequent spiking and cycle skipping on the long-spaced acoustic logs; however, this technology is improving through the introduction of more powerful transmitters, more sensitive receivers, downhole digitizing, and surface processing of waveforms.

Shear-Wave Logging

The borehole acoustic measurement methods described so far have been for obtaining compressional wave velocities. The desirability of obtaining other information contained in the acoustic waveform has long been recognized.²⁷ Most of the effort has been directed toward obtaining the velocity of shear waves.

Early attempts involved hand-picking the shear-wave arrivals on the analog recording of either waveforms or variable-density—microseismogram or three-dimensional (3-D)—presentations as illustrated in Fig. 51.50⁶³

Another method involves automatic recording of shear-wave travel times by a bias technique.⁸⁷⁻⁹⁰ In this method, a high-amplitude event following the compressional-wave arrivals is assumed to be the shear wave arrival. The transit time of these waves is measured by setting the voltage bias level higher than the compressional-wave amplitudes.

A thorough investigation of conventional methods for determining shear-wave velocities from long- and short-spaced acoustic logs was conducted by Koerperich.⁹¹ In this study, borehole experiments were conducted by using a conventional Schlumberger Borehole Compensated Sonic Log® (BHC) with two transmitters and four receivers at 3- and 5-ft spacing and a Schlumberger experimental long-spaced tool with a single transmitter and four receivers located at 10, 12, 14, and 16 ft from the

transmitter. Waveforms recorded with these tools in a carbonate section are shown in Fig. 51.51 for several transmitter-to-receiver spacings. As indicated in this figure, it is easier to identify the later arrivals on the longer-spacing waveforms because of the greater separation in arrival times.

Some measurement results from this study are shown in Figs. 51.52 and 51.53 for a carbonate and a sand/shale section, respectively. For both compressional and shear waves, long spacings generally yield slightly lower travel times (higher velocities) than short spacings. Another important aspect of this study involved laboratory measurements of acoustic velocities on core samples. Compressional and shear-wave velocities were measured on core plugs subjected to simulated subsurface overburden and pore pressure conditions. These results are plotted as circles in Figs. 51.52 and 51.53. Koerperich⁹¹ states that average agreement between the laboratory and log shear velocities (for both the long- and short-spaced tools) is within 2% for carbonates and 8% in sandstones, and that it is slightly better for the compressional waves. He states further that these differences between the laboratory and the log values are nonsystematic.

The foregoing discussion demonstrates that determination of shear transit times in a borehole by hand-picking the arrival times from waveforms or from variable-density presentations is at best a tedious and not very accurate process. Further, attempts to automate this process by threshold detection have been subject to errors when using an axial transmitter/receiver logging technology designed primarily for measurement of compressional-wave travel times. The reasons for these errors are explained by some of the recent modeling studies of acoustic wave propagation in a fluid-filled borehole.⁶⁵⁻⁶⁷ These studies demonstrate that the shear-wave arrival is indistinguishable from the onset of the reflected conical waves on the synthetic acoustic waveforms. However, the phase and group velocities of the reflected conical wave at its low-frequency cutoff are equal to the formation shear-wave velocity (see Fig. 51.25). Hence, if the onset of the reflected conical wave is measured in error, the transit time will be close to that of the shear wave. This might be the case in some of the previously discussed studies.

Acoustic Array Logging

Borehole modeling of acoustic wave propagation has demonstrated the need for a new generation of acoustic logging technology to extract more information from acoustic waveforms. Acoustic logging tools having arrays of transmitters and receivers, and complex digital signal processing capabilities have been developed to analyze the data obtained.

One such tool is shown in Fig. 51.54.⁹² It has a lower-frequency transmitter (11 kHz vs. the conventional 20 kHz), an array of four receivers placed at a longer spacing from the transmitter, and a downhole digitizer to record waveforms without cable distortions. Surface instrumentation records the signals digitally. The processing method, using a four-fold correlation algorithm, analyzes waveforms from the four receivers simultaneously to obtain compressional and shear-wave transit times (Fig. 51.55).

Fig. 51.51—Acoustic waveforms recorded at various transmitter-to-receiver spacings in a carbonate section.

Another acoustic array log is a 12-receiver experimental sonde developed by Schlumberger.⁷⁷ It has a single 10 kHz transmitter and an array of 12 receivers. The receivers have been arranged both in a nonuniform array spanning 4 ft with spacings of 0, 6, 9, 12, 15, 18, 21, 24, 27, 30, 36, 42, and 48 in. and in a uniform array spanning 5.5 ft with 6 in. between the receivers. The spacing between the transmitter and a receiver array is adjustable between 5 and 25 ft.

An experimental tool developed by Elf Aquitaine uses an array of transmitters and an array of receivers.⁷⁸ The transmitting array has five transmitters uniformly spaced at 0.25 m apart; hence, it has a span of 1 m. The receiving array has 12 receivers uniformly spaced at 1-m intervals. The distance between the receiving and the transmitting arrays is set at 1 m.

Finally, the prototype sonde by Schlumberger (shown in Fig. 51.56) has an eight-receiver array and two transmitters.⁹³ In addition, it has two additional receivers spaced at 3 and 5 ft from the transmitter to simulate conventional tools. It also has the capability to measure the compressional-wave velocity of the borehole fluid. Again, waveforms are digitized downhole and transmitted to the surface for recording and analysis.

As apparent from the previous discussion, this is a very active area of development. Tools are constantly being developed to explore the extraction of additional information, such as pseudo-Rayleigh and Stoneley wave velocities, from acoustic waveforms. Capabilities are being developed to record large amounts of data. For example, more data are obtained with one of these array tools in a 1-mile-deep well than are recovered in a 1-mile seismic section.

A parallel and complementary area of development is signal processing methods for analyzing these data. Processing methods such as direct phase determination,⁹⁴ slowness time coherence,⁹³ and semblance^{77,95} have been developed to permit automated analysis of shear-wave transit times. Array processors are being added to wellsite data acquisition systems to permit real-time signal processing.

Fig. 51.52—Borehole and laboratory measurements of compressional- and shear-wave transit times in a carbonate section.

Fig. 51.53—Borehole and laboratory measurements of compressional- and shear-wave transit times in a sand/shale section.

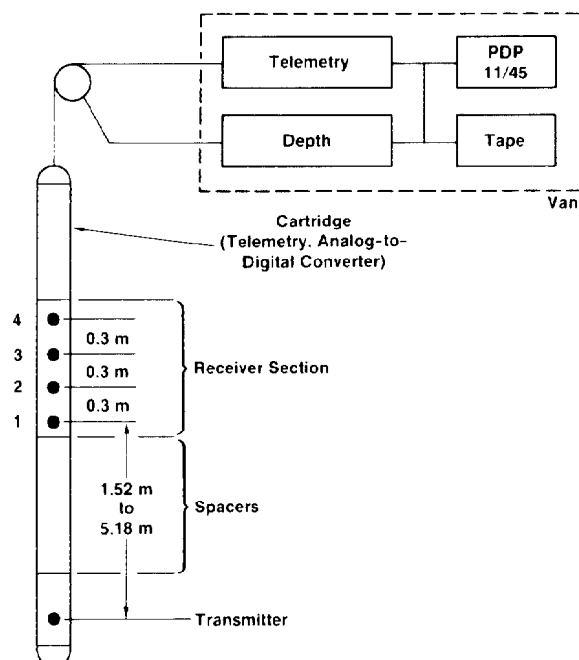

Fig. 51.54—A four-receiver acoustic array log with a downhole digitizer.

So far, emphasis has been on extraction of shear-wave velocity from acoustic waveforms. With continued improvement in tool design and signal processing, it is expected that in the not too distant future, acoustic logs will record not only the velocities of compressional, shear, pseudo-Rayleigh and Stoneley waves, but their attenuations as well.

Reflection Method

The reflection method of acoustic wave propagation logging is basically similar to sonar. A single transducer rotates at constant speed, emitting acoustic pulses in the megahertz range and recording their echoes from the borehole face (Fig. 51.57). As in the transmission method, both travel times and amplitudes are used. The azimuth of the beam also is recorded.

The first such logging tool, the borehole televiewer,⁹⁶ used only the amplitude of the reflected signals to

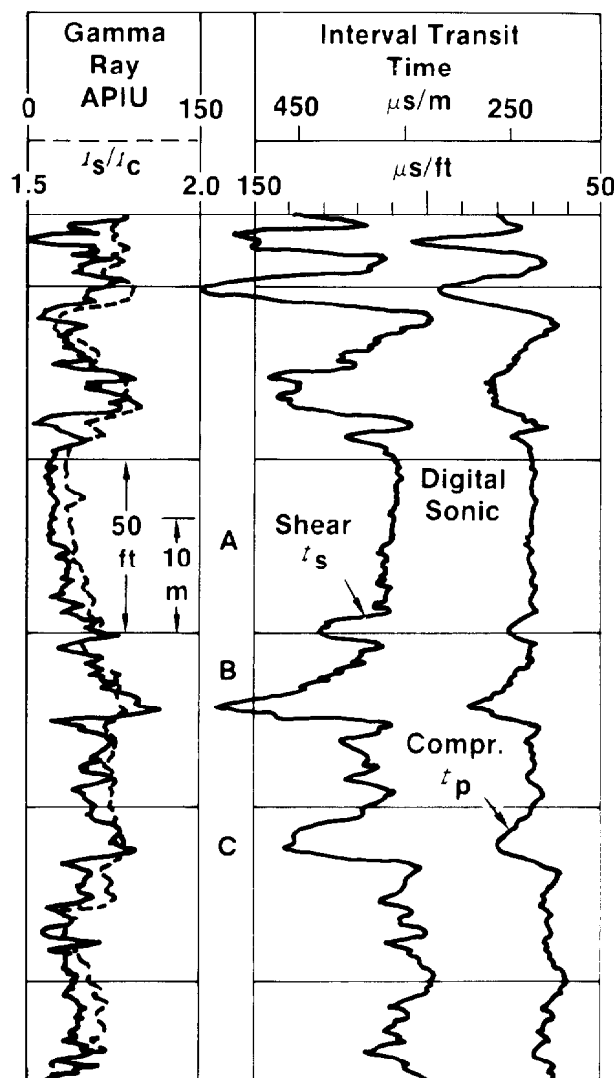

Fig. 51.55—Compressional- and shear-wave transit time log obtained by analysis of the waveforms recorded with the sonde in Fig. 51.54.

generate a picture of the borehole wall. When the borehole wall is smooth, the amplitude of the reflected signal is high; it is recorded as a light spot. Low-amplitude reflections from fractured or vuggy walls are recorded as dark spots. The resulting log is essentially a black and white picture of the borehole wall, split vertically along magnetic north and flattened (Figs. 51.58 through 51.60).

For the borehole televiewer (BHTV) log, the vertical scale is depth and the horizontal scale corresponds to azimuth of the borehole wall. An isometric view of a vertical fracture intersecting the wellbore in an east-west direction is shown on the left in Fig. 51.58.⁹⁷ The corresponding BHTV log on the right shows the fracture as two vertical dark lines 180° apart. Similarly, an isometric of a south-dipping fracture or bedding plane is shown with the corresponding BHTV log in Fig. 51.59.

An example of a BHTV log (Seisviewer® by Birdwell⁹⁸) based on amplitude imaging is shown in Fig.

Fig. 51.56—An eight-receiver acoustic array sonde.

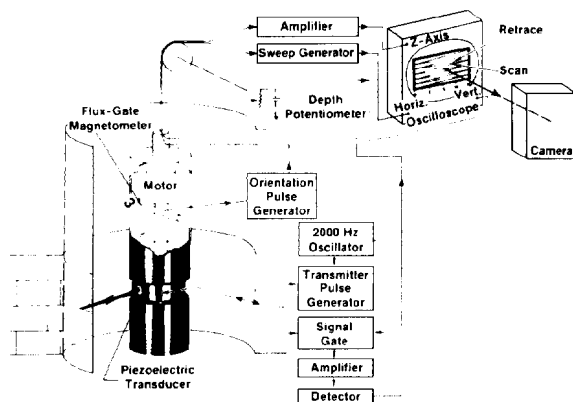

Fig. 51.57—Block diagram of BHTV logging system.

Fig. 51.58—Isometric of a vertical fracture intersecting a borehole and corresponding BHTV log.

51.60 for a borehole intersected by two fractures. The corresponding isometric on the right describes the two different dips and strikes.

Significant hardware and signal processing improvements have been made to early BHTV technology.^{97,99-101} Current technology uses transit time information to obtain an image, in addition to the image obtained from the amplitudes of the reflected signals. Transit time images complement amplitude images in many ways. Transit time measurement is essentially a near-perfect borehole geometry tool with a resolution of 0.05 in. BHTV images developed from the transit time measurements can be considered as two-dimensional (2D) relief maps of the borehole.

Further use of transit time measurements is made in generating tilted polar scan displays.⁹⁹ These are essentially 3D casts of the borehole, which can be viewed from all directions. The tilted polar scan of Fig. 51.61 shows a damaged section of a casing viewed from two angles, which also can be viewed from any desired angle.

Applications

Introduction

Some present and possible future applications of acoustic logging will be presented to illustrate the use of borehole acoustic measurements described earlier and listed in Table 51.1. Discussion here will emphasize the more important uses, and only references will be given to more routine and less significant ones.

Seismic and Geological Interpretation

Borehole measurements of acoustic properties were developed originally to obtain time/depth curves to use in seismic interpretation.¹⁰² In addition to recording transit times of the compressional waves as functions of depth, acoustic logs also integrate these data and record a tick mark on the log for each millisecond of elapsed time. These marks are then used in conjunction with check-shot surveys for seismic interpretation.^{79,103}

Recent advances in borehole shear-wave velocity recording also have allowed this technology to be used with surface seismic shear surveys in a way similar to the compressional-wave velocity log use with the seismic compressional surveys.¹⁰⁴

An important geological application of acoustic logs has been for correlating geologic sections. As described earlier (see Fig. 51.39), acoustic log response is much less affected by borehole irregularities than are some of the other porosity logs. As a result, acoustic logs provide valid data over a large proportion of the borehole.

Further, acoustic logs usually show much character and detail. Therefore, they have been useful for locating bed boundaries, identifying gas/oil interfaces, and determining subsurface geology. An example of geological correlation is shown in Fig. 51.62; even though the two wells in this figure are 10 miles apart, the character of the compressional transit time curves is quite similar.

Porosity

Borehole measurements of acoustic velocities were instrumental in the development of quantitative formation evaluation in the 1950's, although they were developed initially to aid seismic interpretation. Over the years, the primary use of acoustic logs in formation evaluation has been the determination of porosity from measurements of compressional-wave transit time ($t = 1/v_p$). Earlier in this chapter, factors affecting acoustic properties were described through both theoretical and experimental studies of elastic wave propagation in porous media. On the basis of these discussions, it would be at best naive to expect a simple linear relationship between porosity and compressional-wave transit time. However, empirical observations have indeed demonstrated the validity of such a relationship under certain special conditions.

Consolidated Rocks. A commonly used linear relationship for estimating porosity from acoustic measurements (based on laboratory measurements of acoustic velocity and porosity in porous rocks and other materials) was proposed by Wyllie *et al.*^{18,19} Commonly referred to as the Wyllie time-average equation, it is expressed as

$$\frac{1}{v_p} = \frac{\phi}{v_L} + \frac{(1-\phi)}{v_m}, \quad \dots \dots \dots (10)$$

or in terms of transit times, as

$$t = \phi t_L + (1-\phi)t_m, \quad \dots \dots \dots (11)$$

where

- $t (=1/v_p)$ = transit time of the compressional waves for the liquid-saturated porous medium,
- $t_L (=1/v_L)$ = transit time for saturant liquid that forms the solid frame of the porous medium,
- $t_m (=1/v_m)$ = transit time for rock matrix that forms the solid frame of the porous medium, and
- ϕ = porosity.

This relationship can be rearranged as

$$t = (t_L - t_m)\phi + t_m \quad \dots \dots \dots (12)$$

Fig. 51.59—Isometric of fracture or bedding plane intersecting borehole at moderate dip angle, and corresponding BHTV log.

Fig. 51.60—BHTV indicating two fractures of different dips and strikes.

Fig. 51.61—BHTV tilted polar image of a section of a damaged casing.

Fig. 51.62—Acoustic log correlation between two wells.

Fig. 51.63—Porosity evaluation from acoustic log.

or

$$t = m\phi + b, \quad (13)$$

where the slope is $m = t_L - t_m$ and the intercept is $b = t_m$.

The most attractive feature of Eq. 12 is its simplicity. It states that the transit time of an acoustic wave in a porous rock is the porosity-weighted average of its transit times in the matrix and the liquid in its pores. Also, it extrapolates to correct values for 0 and 100% porosities—i.e., t_m and t_L , respectively.

This simplicity coupled with pedagogically pleasing qualities made Eq. 12 popular and, more importantly, established acoustic logging as an important tool in formation evaluation. As stated, however, there is no theoretical justification for such a simple relationship. In the Appendix, the linear relationship, Eq. 13, is shown to be a second-order approximation of a comprehensive relationship, Eq. A-9, with the intercept b approximately equal to the matrix transit time and the slope m strongly dependent on elastic properties of the porous rock frame and the compressibility of pore fluid. Nevertheless, under the right conditions, a linear dependence of transit time on porosity has been established through literally hundreds of empirical observations.

A graphical representation of the time-average equation, Eq. 11, is given in Fig. 51.63.¹⁰⁵ This is a good beginning for determining porosity from acoustic log measurements when no other information is available. It provides acceptable values of porosity for well-compacted rocks with uniform pore size distribution and under effective stress (difference between the overburden stress and pore fluid pressure) of at least 4,000 psi.

In most applications, the linear relationship of Eq. 13 has been found to be more useful than the time-average equation, Eq. 11, provided that the values of b and m can be determined. As indicated in the Appendix, the parameter b is approximately equal to $(1/v_m)$; therefore, it depends on rock matrix properties. Published values for b range from 50 to 60 $\mu\text{sec}/\text{ft}$ for sandstones, from 45 to 50 for limestones, and from 40 to 48 for dolomites.

Velocities of compressional and shear waves for a large number of materials are given in handbooks by Clark¹⁰⁶ and by Simmons and Wang.¹⁰⁷ An extensive list of compressional and shear transit times have been compiled by Wells *et al.*¹⁰⁸ for minerals and rocks encountered in oil and mineral exploration. Probably the most comprehensive compilation of compressional and shear-wave velocities for marine sediments, rock-forming minerals, and rocks is given, for various pressures and temperatures, in a recent handbook by Carnichael.¹⁰⁹ A set of compressional and shear-wave velocity data from the literature is listed in Table 51.3¹¹ for selected materials, to illustrate the range of velocities encountered in and around the borehole.

The values of m depend on the elastic moduli of the rock frame, which in turn are controlled by the effective stress and pore structure and by the compressibility of the pore fluid. Changes in velocities have been observed to become smaller with increasing effective stress. Therefore, pressure dependence of m may be small enough to be neglected in normally pressured sections below 7,000 ft. Effects of pore structure might be

TABLE 51.3—ACOUSTIC VELOCITIES

Material		v_p (ft/sec)	v_s (ft/sec)
Nonporous solids

described qualitatively by stating that the magnitude of m increases with decreasing grain contact areas. Thus, m is small for crystalline rocks and larger for granular and shalier rocks, ranging from 0.5 to 1.5 $\mu\text{sec}/\text{ft}$ for carbonates and from 1 to 3 $\mu\text{sec}/\text{ft}$ for sandstones.

Compressibility of the pore fluid depends on whether it is gas, oil, or water and becomes significant in poorly consolidated rocks (see Eq. A-7). In well-consolidated rocks under high effective stress, the relative contribution of pore fluid compressibility to the overall rock elastic moduli is small; therefore, variations of m because of pore fluid content may be neglected.

The large range in values of b and m necessitates the use of core analysis data to calibrate the acoustic log for estimating porosity. For this purpose, porosities and travel times are measured on core samples under the equivalent subsurface pressure conditions, and the linear relationship between the two is established by statistical analysis. If laboratory measurements of t are not available, restored pressure measurements of porosity, or porosity corrected for equivalent subsurface conditions can be correlated to t from the acoustic log to establish the linear relationship, provided that adequate depth correspondence between core and log data can be established.

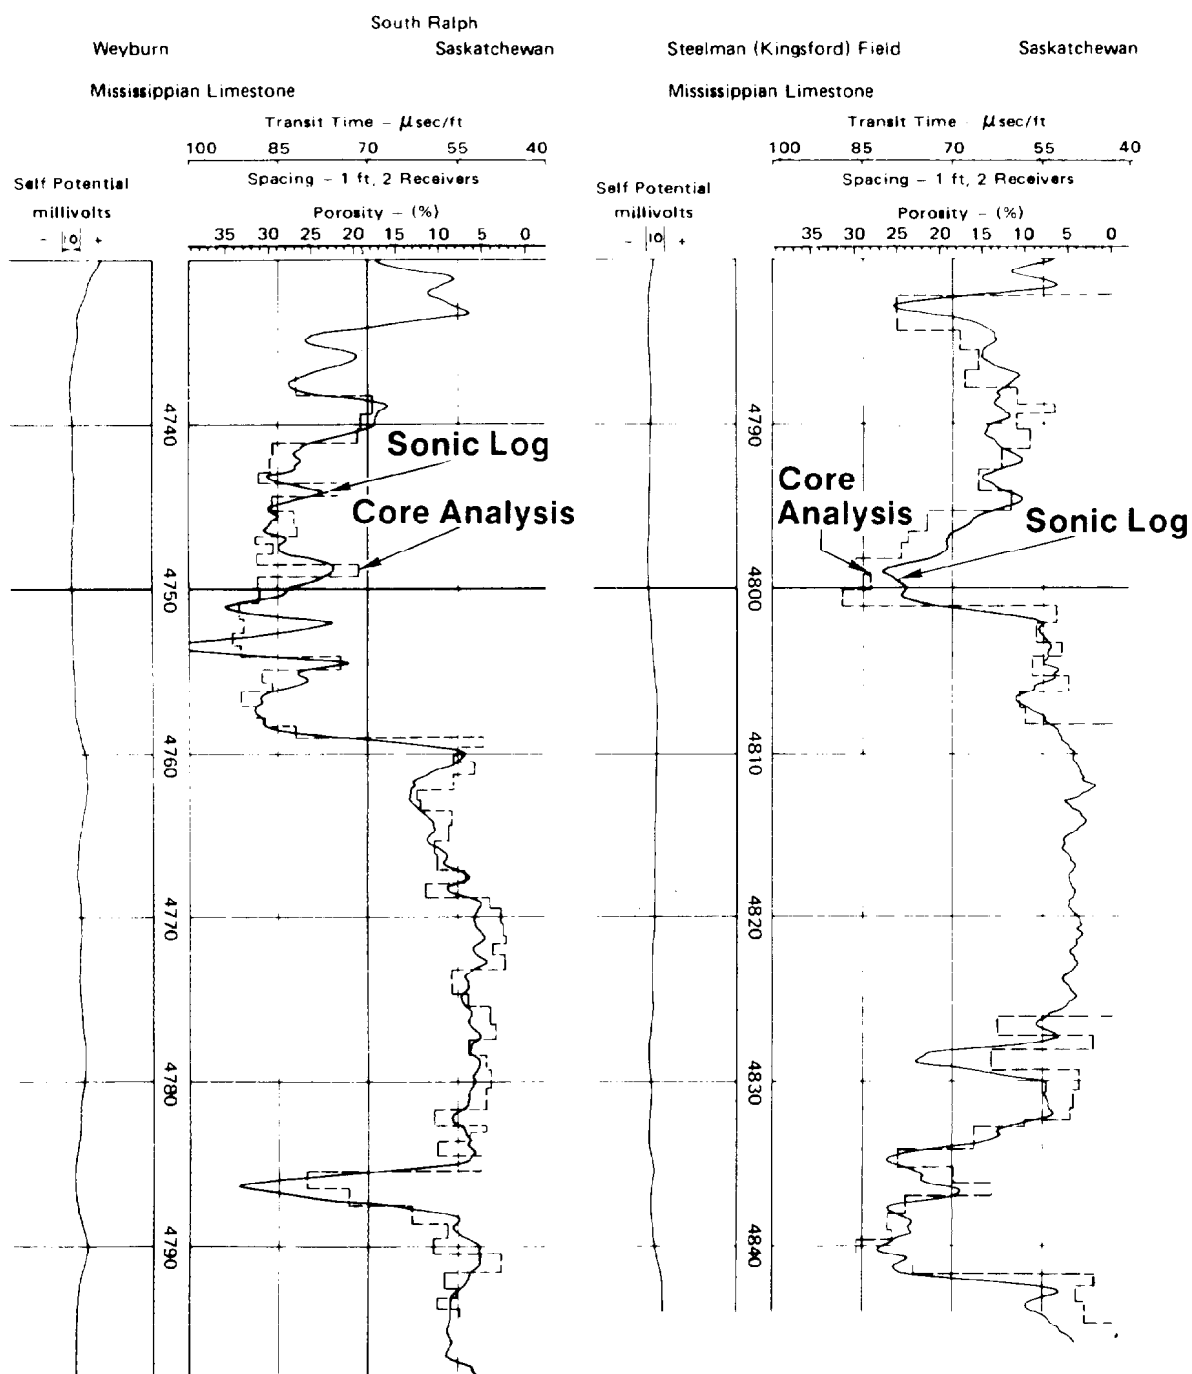

There are numerous field examples of acoustic log measurements yielding reliable estimates of porosity in well-compacted, clean sandstones and carbonates, provided that the lithology is known. Fig. 51.64 illustrates

the close agreement between acoustic-log-measured transit times and core-measured porosities for carbonate sections in two wells.

In fact, the acoustic log in certain areas is the most consistently reliable porosity device. To reiterate, the conditions required are (1) lithology is accurately known, (2) porosity is largely intergranular, and (3) rocks are well compacted and subjected to a differential stress of at least 4,000 psi.

As with other conventional porosity logs, variations in lithology make porosity estimates from compressional-wave transit times unreliable. To overcome this, acoustic logs are used with density and/or neutron logs, or with measurements of shear-wave transit times described in the next section.

Secondary Porosity. Another application of the acoustic log is for estimation of "secondary porosity" in vugular and/or fractured rocks. For this, it is assumed that compressional wave velocity is affected only by the primary or intergranular porosity. The density and neutron logs are assumed to respond to total porosity. Hence, any difference between these is assumed to be secondary porosity consisting of vugs and/or fractures. An example of this is shown in Fig. 51.65, where the section contains anhydrite with fracture porosity.¹¹⁰ Notice that while the transit time t remains approximately constant over the entire section, density ρ_b decreases from 2.97 to 2.83

Note: Porosity Scale Based on Matrix Velocity, $v_m = 23,000$ ft/sec

Fig. 51.64—Acoustic log vs. core analysis porosity.

g/cm^3 , and the neutron porosity ϕ_N increases from 0 to 4%, thereby indicating a secondary porosity of 4%.

Poorly Consolidated Rocks. In poorly consolidated sandstones, reliability of porosity estimates from acoustic logs is rather poor. In these cases, usually a combination of density and neutron logs is preferred. One significant advantage of the acoustic log is that it is much less affected by the hole conditions, such as washouts and rugosity. This was illustrated in Fig. 51.39 where the density and sidewall neutron logs were responding to hole conditions whereas the acoustic log was found to yield reliable estimates of porosity.

Several methods have been developed to obtain porosity information from acoustic logs in poorly compacted sands.^{21,111} One approach²¹ involves adjustment of porosity calculated from the time-average equation using a compaction correction factor F_{cp} . First, the apparent porosity ϕ_a is computed from

$$\phi_a = \frac{t - t_m}{t_L - t_m} \quad (14)$$

Then this value is corrected by F_{cp} to obtain the corrected porosity, ϕ_c , from

$$\phi_c = \frac{\phi_a}{F_{cp}} \quad (15)$$

The values of F_{cp} (Fig. 51.63) range from 1 to 1.6 or higher. One method used to estimate F_{cp} is based on estimating the compaction of sands from the compaction of adjacent shales. If the transit time of adjacent shales is 100 $\mu\text{sec}/\text{ft}$ or less, they are assumed to be compacted. Hence, to obtain the correction factor, the transit time t_{sh} observed in the nearby shales is divided by 100.

$$F_{cp} = \frac{t_{sh}}{100} \quad (16)$$

Other methods for determining F_{cp} include determination of porosity either from a resistivity log in a water-bearing sand or from other porosity logs such as density and/or neutron, and then comparing the value with ϕ_a obtained from the acoustic log.

More recently another empirical relationship for estimating porosity from compressional-wave velocity was developed by Raymer *et al.*¹¹¹ on the basis of extensive field observations of transit time vs. porosity. The relationship reported is for the full porosity range from 0 to 100%; however, for the porosity range of interest, 0 to 37%, it is expressed as

$$v = \phi v_f + (1 - \phi)^2 v_m,$$

where v_m is 17,850 ft/sec for sandstone, 20,500 ft/sec for limestone, and 22,750 ft/sec for dolomite, respectively; and v_f is velocity of sound in the pore fluid.

Fig. 51.65—Secondary porosity in the Auquilco formation, Neuquen basin, Argentina.

Fig. 51.66—An empirical relationship for estimating porosity in sandstone, limestone, and dolomite.

Fig. 51.67—Velocity/porosity correlations for moderately consolidated to unconsolidated sands.

Fig. 51.68—Shaly sand models for acoustic wave propagation studies.

Fig. 51.69—Estimated shale effects on compressional and shear velocities.

A graphical representation of this empirical relationship is given in Fig. 51.66. Raymer *et al.*¹¹¹ found this relationship to be a better estimator of porosity than the time-average equation. They also reported that it is applicable to both consolidated and unconsolidated rocks.

Predictions from this relationship and from the time-average equations were investigated by Hartley¹¹² for the moderately consolidated to unconsolidated sands of the Gulf of Mexico. The lack of agreement indicated in Fig. 51.67 led Hartley to the universally applicable conclusion that empirical relationships "may provide erroneous porosities if they are applied outside of the data set from which they were developed."

Shaly Sands. Another aspect of Hartley's study¹¹² considers the effects of shaliness in porosity interpretation. In Fig. 51.67, porosity predictions from the empirical relations are worse for the shaly sands. Effects of shales on acoustic velocities are not very well understood; as a result, they are difficult to account for. A recent theoretical study by Minear¹¹³ shed much light on this problem by relating clay effects to their distribution within the rock framework. Minear used the Kuster-Toksöz¹¹⁴ model of porous media and divided clay distributions into four groups. As illustrated in Fig. 51.68, these four groups are (1) the laminated model (Fig. 51.68a), in which clay-mineral-rich and shaly layers alternate with clean sandstone layers, (2) the framework structural model (Fig. 51.68b), in which shale grains substitute for quartz grains randomly, (3) the grain boundary structural model (Fig. 51.68c), in which shale grains occur at some, but not all, boundaries between the quartz grains, and (4) the dispersed clay model (Fig. 51.68d), in which clays occur dispersed in the pore fluid or lining the pores but not between the grain contacts.

Fig. 51.70—Compressional-wave transit time vs. shear-wave transit time.

Fig. 51.71—Compressional- to shear-wave velocity ratio vs. compressional-wave velocity. Data from Fig. 51.70.

One of the obvious conclusions in this study is that the time-average equation is applicable to the laminated model. A more interesting conclusion, however, states that the framework (Fig. 51.68b) and grain-boundary (Fig. 51.68c) shales seem to have the same effect on acoustic velocities. Further results of this study are summarized in Fig. 51.69. The differences, $t_{\text{shaly}} - t_{\text{clean}}$, between the transit times of the shaly and clean formation for both the compressional and shear waves are plotted vs. the clay or shale fraction for a sandstone with a porosity of 30%. Structural and laminated shales have approximately the same effect on t_p and t_s but increase t_s more than t_p . Dispersed clay, if it has a density close to that for sandstone, has about the same effect on t_s as the structural and the laminated clays; however, its effect on t_p is only about one-third of that by the other two.

Lithology

Estimation of lithology from conventional acoustic log measurements may be made by solving for the matrix travel time from the time-average equation if the porosity is known from another source. Even though this technique has been used under certain conditions, matrix transit times of the most common rock types determined in this fashion are not distinct enough to make this a very useful method.

A more deterministic method for establishing lithology from acoustic log measurements is based on the relationships shown in Fig. 51.70. In this figure, laboratory- and borehole-measured values of compressional-wave transit times are plotted against shear-wave transit times. Laboratory data cover a porosity range of 5 to 30% for sandstones and 5 to 25% for carbonates, and an effective stress range of 0 to 6,000 psi.²⁷ As indicated, each lithology has a well-defined trend, regardless of porosity or effective stress (depth). Lines of equal velocity ratio

(v_p/v_s) are closely spaced for dolomites and limestones—1.8 and 1.9, respectively. The sandstones range from 1.6 for low-porosity sands to 1.75 for high-porosity sands under low effective stress.

Lithology identification is also illustrated in Fig. 51.71 by replotting the velocity ratio data of Fig. 51.70 vs. compressional wave velocities.

Use of borehole measurements of compressional and shear transit times is described by Nations⁸⁸ for determining porosity and lithology in mixed-lithology rocks. He assumes that velocity ratio is a constant for a "pure" rock type: 1.6 for sandstones, 1.8 for dolomites, and 1.9 for limestones. He further assumes that mixed-lithology rocks will exhibit a ratio that is directly proportional to the content of the two minerals and that porosity is distributed equally between the two. From the velocity ratio, he first determines the mineralogical composition; then, on the basis of this information, assigns the appropriate matrix transit time for calculating porosity. An example of the results of this technique is illustrated in Fig. 51.72 for dolomite/sandstone and dolomite/limestone mixtures.

Hydrocarbon Content

Acoustic signals on microseismogram or variable-density logs are known to disappear sometimes in oil and gas zones in unconsolidated formations. This property is used to locate oil/water contacts, as well as gas caps, but is not completely reliable. Sometimes, even within the same zone, signal disappearance may or may not be indicative of presence of hydrocarbons.

Laboratory studies conducted by Gardner and Harris¹¹⁵ on sandpacks indicate that shear-wave velocities decrease when liquid is added to sandpacks, whereas the compressional-wave velocity increases (Fig. 51.73).

Fig. 51.72—Porosity from compressional-wave transit time corrected for lithology by the velocity ratio vs. porosity from density/neutron crossplot for complex lithologies.

Fig. 51.74—Ratio of compressional-wave to shear-wave velocity for sands and consolidated rock.

Fig. 51.73—Variation of compressional-wave and shear-wave velocities of wet and dry sands with porosity at 5,000 psig differential pressure.

These observed differences between compressional and shear-wave velocities are illustrated by plotting velocity ratio as a function of porosity and pressure (Fig. 51.74). Also shown in this figure is the velocity ratio range of 1.75 ± 0.20 for the consolidated sedimentary rocks. A velocity ratio greater than two indicates an unconsolidated sand saturated with liquid. Below this value it may be either an unconsolidated sand containing gas or a consolidated rock.

For the consolidated rocks, the ranges of velocity ratios for liquid and gas saturation were obtained by Gregory⁵⁰ through laboratory measurements. The results of his study are summarized in Fig. 51.75.

Additional experimental data obtained on a sandpack are shown in Fig. 51.76.¹¹⁶ Laboratory measurements of compressional- and shear-wave velocities are measured as a function of water saturation and plotted on this figure together with measured values of density.

These data and the previous observations may be interpreted in general terms through use of the Gassmann-Biot theory described in the Appendix. Taking the square roots of Eqs. A-1 and A-2 gives, respectively,

$$v_p = \frac{1}{\rho_b^{1/2}} \left[P_d + f(K_f) \right]^{1/2}$$

and

$$v_s = \left(\frac{G}{\rho_b} \right)^{1/2}.$$

Predictions of these equations also are plotted on Fig. 51.76 as dashed lines. One of the predictions of Eq. A-1 is that for 100% gas saturation, incompressibility of pore

Fig. 51.75—Variations of velocity ratio with porosity for water-saturated and gas-saturated rocks.

fluid (K_f) is much smaller than that of the rock matrix (K_m); hence, $f(K_f)$ becomes negligibly small (see Eq. A-4). Therefore, P-wave velocities calculated from this equation for the gas-saturated rocks are smaller than those for the liquid-saturated rocks.

The S-wave velocity, however, becomes the function of gas saturation through dependence on the bulk density because the shear modulus G is the same for the rock whether it contains gas or liquid. Hence, as indicated in Eq. A-2, shear-wave velocity increases upon introduction of gas to the extent that the bulk density decreases.

Returning to the P-wave velocities, since the compressibility of gas is much larger than that of water, a small amount of gas reduces pore fluid compressibility essentially to that of gas as predicted by Eq. A-7 (see Appendix).

$$c_f = S_w c_w + (1 - S_w) c_g,$$

where c_g is gas compressibility. Hence, a small amount of gas reduces compressional-wave velocities significantly, but additional gas saturation has little further effect. This was illustrated by the laboratory data and theoretical prediction plotted in Fig. 51.76. A field example shown in Fig. 51.77 confirms this by demonstrating that compressional-wave transit time does not differentiate the upper zone at 90% gas saturation from the lower one containing 20% gas, because the t curve essentially is responding to the velocity of the mud in both intervals.

Effects of gas saturation on the compressional to shear-wave velocity ratio is illustrated in Fig. 51.78 for a deep dolomite reservoir.¹¹⁷ Over the 18,500 to 18,520-ft interval the v_p/v_s ratio is 1.8; this is as expected for a dolomite lithology. Over the gas zone below 18,520 ft, however, this ratio is reduced to 1.6, and clearly differentiates the gas zone. A similar gas effect is shown in Fig. 51.79 for a sandstone reservoir. In this case, the v_p/v_s ratio is reduced from 1.67 to 1.51, again clearly delineating the gas zone.

Fig. 51.76—Compressional- and shear-wave velocity and bulk density vs. saturation for a sand pack.

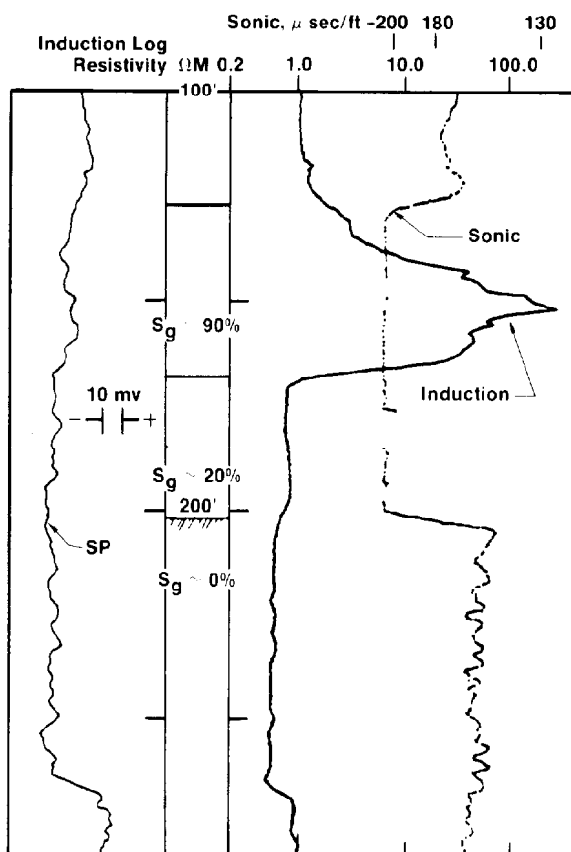

Fig. 51.77—Gas effect on acoustic log.

Fig. 51.78—Gas effect on compressional- to shear-wave velocity ratio in a dolomite reservoir.

Fig. 51.79—Gas effect on compressional- to shear-wave velocity ratio in sandstone reservoir.

Fig. 51.80—Typical gulf coast induction log indicating two gas sands.

Fig. 51.81—Scope pictures from selected levels in the log on Fig. 51.80.

In general, the effects of gas saturation on acoustic velocities in rock may be summarized as follows.

1. Compressional-wave velocity is greater in liquid-saturated rocks than in comparable gas-saturated rocks, whereas the reverse is true for shear-wave velocities.

2. The difference in compressional-wave velocity for the liquid- and gas-saturated states becomes negligibly small with increasing depth, whereas the equivalent difference for the shear-wave velocities remains constant.

3. Under equivalent pressure conditions, compressional-wave velocity decrease upon gas saturation (in poorly consolidated rocks) is much greater than that in well-consolidated rocks.

Attenuations of elastic waves are also used to identify gas zones.¹¹⁸ This is illustrated in the typical Gulf Coast sands shown in Figs. 51.80 and 51.81. In Fig. 51.80, the induction log indicates two gas zones: one in a thin stringer at 5,476 ft and the other in a massive sand at 5,520 ft underlain by water. Scope pictures in Fig. 51.81 were recorded with a single-transmitter, dual-receiver acoustic log while going into the hole described in the previous figure. In Fig. 51.81a, the lower-receiver signal is just becoming affected as it moves very close to the gas stringer. One foot lower, at 5,477 ft, the lower receiver is in the top of the gas zone. In Fig. 51.81c, the lower receiver is in the gas sand and the upper receiver is being affected. In the massive gas sand at 5,540 ft, both receivers are showing almost total compressional wave loss, whereas in the water sand at 5,580 ft, a strong signal is apparent at both receivers. For comparison, a typical shale response at 5,462 ft is given in Fig. 51.81f.

Geopressure Detection

Geopressure refers to a buried rock/fluid system in which the fluid pressure is greater than the hydrostatic pressure of a full column of formation water. Geopressure also is called abnormal pressure or overpressure. Abnormally high fluid pressures are found worldwide. Such pressures occur when fluid in the pore space begins to support more overburden than just fluids—i.e., not all the compressional forces are transmitted by the rock matrix only.

The ability to predict the occurrence and magnitude of abnormal pressures is a requirement in planning efficient drilling and, ultimately, completion procedures. Hottel and Johnson¹¹⁹ established a procedure for determining the first occurrence of geopressure and the precise depth vs. pressure relationship. They observed that for hydrostatic-pressure formations in a given geological province, a plot of the logarithm of compressional-wave travel time in shales, t_{sh} , vs. depth is generally a straight line. The divergence of the observed travel time t_{ob} from that obtained with the established normal trend t_n is a measure of the pore-fluid pressure in the shale and, hence, in the adjacent permeable formation (Fig. 51.82). They also established a trend of resistivity vs. depth for shales and used it similarly in conjunction with acoustic log data.

A field example showing acoustic log response in an abnormal pressure section in the North Sea is given on the right track of Fig. 51.83.¹²⁰ A remarkably accurate prediction of abnormal pressure by surface seismic measurements is shown for comparison in the left track.

A procedure for evaluation of formation pressure is summarized as follows.¹²¹

1. Plot shale velocity or transit time and establish a normal compaction trend line.
2. Locate the anomalous pressure top at the depth at which plotted data points diverge from the normal trend.
3. Take the difference between observed shale transit time and normal shale transit time.
4. Convert the difference to formation pressure gradient by means of an empirically derived curve for a given age and for a given area (Fig. 51.84 was used for the example shown in Fig. 51.83).
5. Multiply the pressure gradient obtained by depth to compute the formation fluid pressure at that depth.

Another approach for evaluating abnormal pressures is suggested by Eaton.¹²² He proposes the following empirical relationship for predicting pore fluid pressure (p_f):

$$\frac{p_f}{D} = \left[\frac{p_o}{D} - \left(\frac{p_f}{D} \right)_n \right] \left[\frac{t_n}{t_{ob}} \right]^m$$

where

D = depth, ft

p_f/D = pore fluid pressure gradient, psi/ft.

p_o/D = overburden stress gradient, psi/ft.

$(p_f/D)_n$ = normal hydrostatic pressure gradient (0.456 psi/ft for Gulf Coast, 0.434 for fresh waters),

t_n = transit time on the extrapolated normal curve at depth,

Fig. 51.82—Prediction of geopressure from shale transit time.

t_{ob} = observed transit time at depth, and
 m = empirical exponent varying regionally
 around a value of three.

Cement Bond Quality

The primary purposes of oilwell cementing are to secure casing to prevent leakage to the surface and to isolate producing zones from water zones. With the increasing cost of completing wells, accurate determination of the quality of the casing cementation has become necessary to avoid costly recompletion and squeeze cementing jobs.

The successful cementing of a well is affected by many factors: cement setting time, pressure, temperature, hole size and deviation, formation and cement characteristics, casing surface, and damage to the cement bond by perforating or squeezing operations. These and many other factors must be considered when evaluating the effectiveness of a cement job.

Early in acoustic logging, it was observed that the amplitude of an acoustic signal in a firmly cemented pipe is only a fraction of that of a free pipe.¹²³ Since then, downhole acoustic measurements have been firmly established as the primary technology for determining cement bonding not only to the casing but to the formation as well.^{124,125} Under favorable conditions even the compressive strength of cement can be determined.¹²⁶

Free Pipe. A schematic axial transmitter and receiver configuration is shown in Fig. 51.85 for cement bond logging.¹²⁷ In a free pipe, most of the energy is confined to the casing and the borehole fluid, as indicated in Fig. 51.85. The resulting acoustic waveform as recorded by the receiver is also shown in this figure. The following observations characterize waveforms observed in free, unbonded casing.

1. The first arrival of the waveform is equal to the total travel time in casing between transmitter and receiver, plus the travel time in fluid between the tool and the pipe.
2. The amplitude of the entire waveform is high.
3. The waveform exhibits a highly uniform frequency.
4. The waveform is persistent and lasts a relatively long time.

Good Bond to Casing and Formation. When the cement is perfectly bonded to both the casing and the formation, a very favorable acoustic coupling is developed. As a result, maximum energy is transferred to the formation, and very little energy is transmitted through the casing and cement sheath. As shown in Fig. 51.86, the waveform shows practically no signal at the casing arrival time and very little amplitude until the formation arrival time.

Bond to Casing and to a High-Velocity Formation. In areas of high-velocity formations, signals from the formation arrive at the same time as or earlier than the casing signal, thereby complicating the interpretation significantly (Fig. 51.87).

Cement Bond to Casing Only. A commonly occurring condition is that the periphery of the casing is totally surrounded and bonded by a hardened sheath of cement that

Fig. 51.87—Bond to casing and to a high-velocity formation.

Fig. 51.88—Cement bond to casing only.

is not bonded to the formation (Fig. 51.88). This might happen because the cement does not bond with mudcake of poorly consolidated formations, or the mudcake dries and shrinks away from cement.

Under this condition, energy traveling through the casing is attenuated drastically because of the highly attenuating cement sheath. The annulus outside the cement sheath offers very unfavorable acoustic coupling; hence, very little energy is transferred to the annular fluid and virtually none into the formation. This is indicated by the lack of later-arriving formation energy in the waveform of Fig. 51.88. The energy observed at 870 μ sec is the beginning of the fluid wave for the transmitter-to-receiver spacing of 5 ft.

Partial Bonding. A most difficult situation in evaluating cement bond quality is the condition of partial bond (Fig. 51.89). A small gap may be formed between the casing and cement in an otherwise well-bonded casing. In this situation the waveform typically contains two distinct wave energies. The first wave energy arrives at casing time, since part of the casing is free to vibrate. The second wave energy arrives at a time indicated by the velocity of the formation. Hence, both a moderately strong casing arrival and a moderate-to-strong formation arrival exists.

The typical partial-bonding waveform is characteristic of either a microannulus or a channel in the cement. A microannulus is a very small separation between casing and cement. Normally, a hydraulic seal exists with a microannulus, but not with a channel in the cement. Thus, it is important to differentiate between the two. The best way is to rerun the bond log with pressure on the casing. If a microannulus exists, the casing will expand, decreasing the separation and transferring acoustic energy to and from the formation. The casing signal will decrease and formation signals will then become more evident. However, if only channeling exists, pressuring the casing will not greatly alter the log.

Another way to differentiate between microannulus and channeling is by noting the length of section over which the condition exists.¹²⁵ Since microannulus is thought to be caused by the condition of the exterior surface of the casing, such as the presence of grease or mill

varnish, the effect tends to appear over a long section of log. Channeling ordinarily occurs over shorter sections.

Examples of various bonding conditions are illustrated by the variable-density (3D) log shown in Fig. 51.90.¹²⁸ The interval from X552 to X614 ft shows a good pipe bond but no formation bond. Only a few formation arrivals can be seen, indicating a lack of acoustical coupling between the cement sheath and the formation itself. Above and below this interval are sections of poorly bonded pipe. This probably is due to channeling. This is suggested by the strong pipe signal overriding a weak formation signal. The interval from X468 to X518 ft is well bonded, as evidenced by the strong formation signal. However, there is evidence of a microannulus between X506 and X518 ft. Here the formation signal is distorted somewhat by a casing signal.¹²⁸

A recently introduced technology, the Cement Evaluation Tool by Schlumberger, shows great promise in differentiating between microannulus and channeling.¹²⁹ This tool is based on the acoustic reflection method; however, unlike the borehole televiewer with one rotating transducer, it has eight transducers placed on a centralized sonde at 45° from each other in a helical path. These transducers, emitter and receiver, are about

Fig. 51.89—Partial bonding.

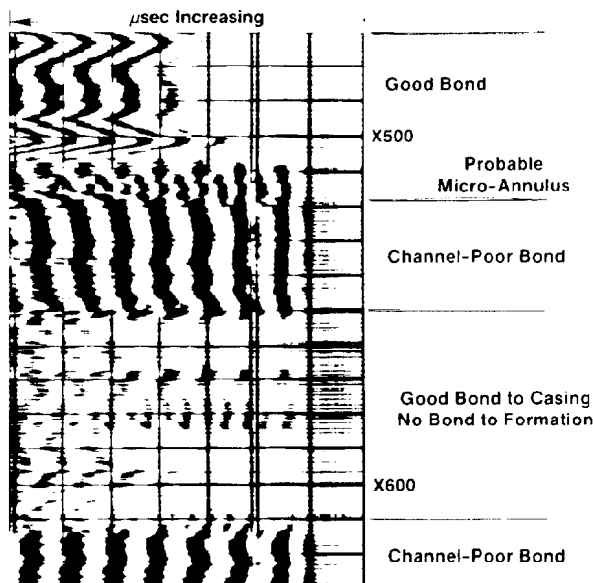

Fig. 51.90—Good bond to casing—no bond to formation.

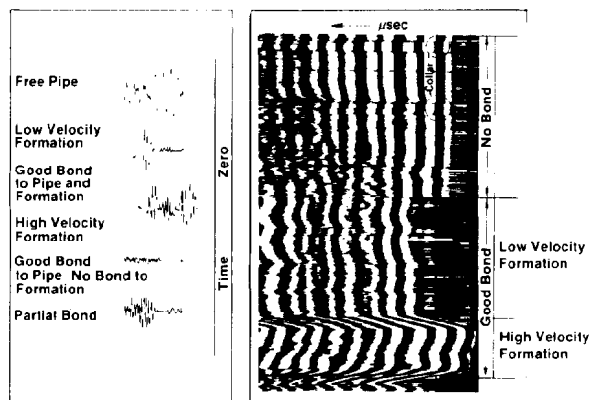

Fig. 51.92—Full waveforms and variable-density log for different bonding conditions.

Fig. 51.91—Ultrasonic cement evaluation log.

1 in. in diameter and operate at 500 kHz. They repeatedly send a short ultrasonic pulse toward the casing to make it resonate in its thickness mode. Cement behind the casing is detected as a rapid damping of this resonance, whereas a lack of cement gives a longer resonance decay.

An example of a cement evaluation log is shown in Fig. 51.91.¹³⁰ The right track can be viewed as a map of cement behind the casing. It is divided into eight channels, each one representing one transducer with a shading from white (free pipe) to black (good cement). In this example, a channel is clearly visible as a white streak.

Summary of Bonding Conditions. Typical full waveforms for various bonding conditions are summarized in Fig. 51.92.¹²⁸

When there is no cement bonded to the casing, a free casing signal is indicated on the variable-density log as straight dark lines with distortion at the collars. This distortion occurs for a vertical distance equal to the spacing between the transmitter and receiver of the logging instrument (6 ft on the example shown in Fig. 51.92).

When there is good cement bonding both to the casing and to the formation, there is no casing signal, but there is a strong formation signal. The difference in response for the low- and high-velocity arrivals for a well-bonded section is clearly illustrated in the lower section of the variable-density log of Fig. 51.92.

Cased-Hole Evaluation

Most existing wells were completed before the advent of reliable porosity logging devices; therefore, accurate porosity data for planning of enhanced recovery operations must be obtained through existing casing. Radioactivity logging measurements commonly are used for this purpose; this information, however, can be supplemented by the acoustic log measurements in wells

where a good cement bond exists between casing and the formation.¹³¹ A recent study¹³² involving laboratory modeling and computer simulations has indicated that acoustic logging can be successful in both bonded and unbonded casing.

Through-casing acoustic logs have provided reliable measurements of compressional and shear-wave velocity data for evaluating porosity and lithology. An openhole and cased-hole comparison is shown in Fig. 51.93 for the compressional and shear-wave transit times t_p and t_s . The logs were obtained by analysis of the waveforms digitally recorded with the acoustic logging system shown in Fig. 51.54. The agreement between compressional and shear transit time logs run in open and cased holes is excellent. This further enhances the role of acoustic measurements in cased-hole evaluation.

Mechanical Properties

A knowledge of the mechanical properties of rocks is important in drilling, production, and formation evaluation. Mechanical properties include the elastic properties such as Young's modulus, shear modulus, Poisson's ratio, and bulk pore compressibilities, as well as the inelastic properties such as fracture pressure gradient and formation strength. Borehole measurements of acoustic properties in combination with density log measurements are being used more and more for in-situ determination of mechanical properties of rocks.

Elastic Moduli. Elastic constants describe the mechanical properties of matter: Young's modulus, shear modulus, bulk modulus, and Poisson's ratio. Knowledge of these moduli for rocks is needed in studying the propagation of acoustic waves, as well as in practical engineering problems connected with drilling, formation fracturing, and predicting reservoir performance.

A commonly used approach to gather this information is to obtain core samples and to conduct laboratory experiments. For meaningful results, these measurements must be made at equivalent subsurface conditions. Needless to say, these are time-consuming and costly. Even then the results are suspect because the process of coring removes the overburden stress from the sample and causes other disturbances that may not be reversible.

Numerous studies have been conducted that compared elastic moduli obtained by the static (from measurements of stress and strain) and the dynamic (from acoustic velocities and density) methods. In rocks subjected to lower effective stresses, the dynamic elastic moduli are higher than the static values; as the stress increases, however, these differences decrease.^{133,134} Theoretical studies by Walsh¹³⁵ predicted that this could be caused by the presence of cracks in rocks. In fact, Simmons and Brace¹³³ found the static and dynamic moduli to be in close agreement when rocks are subjected to higher stresses (30,000 psi) so that the cracks are closed.

The relationship of the in-situ-measured elastic moduli to those determined in the laboratory was investigated by Myung and Helander.¹³⁶ They made laboratory measurements of compressional- and shear-wave velocities on core samples under simulated subsurface pressure conditions and reported a close agreement between in-situ and laboratory-determined values of dynamic elastic moduli.

Fig. 51.93—Comparison of digital-sonic logs in a well before and after casing.

Since then, many other investigators have used borehole acoustic measurements to determine elastic moduli.^{89,137,138} Compressional- and shear-wave velocities obtained from the acoustic log measurements are used with values of density from a density log to calculate Young's modulus, shear modulus, bulk modulus, and Poisson's ratio by assuming an infinite, isotropic, homogeneous, and elastic medium (see Eqs. 3 through 6).

Applications of these in-situ-determined values of moduli include predicting sand production and subsidence, and determining fracturing characteristics of formations. An application involving fracture characteristics is shown in Fig. 51.94.⁶³ The core and log data are from a section of igneous and metamorphic rocks. The fracture characteristics of the core are shown graphically as well as plotted quantitatively as rock quality designation (RQD), which is the ratio of the cumulative length of unfractured core to the unit length of core. Elastic moduli curves are quite similar to the RQD curve.

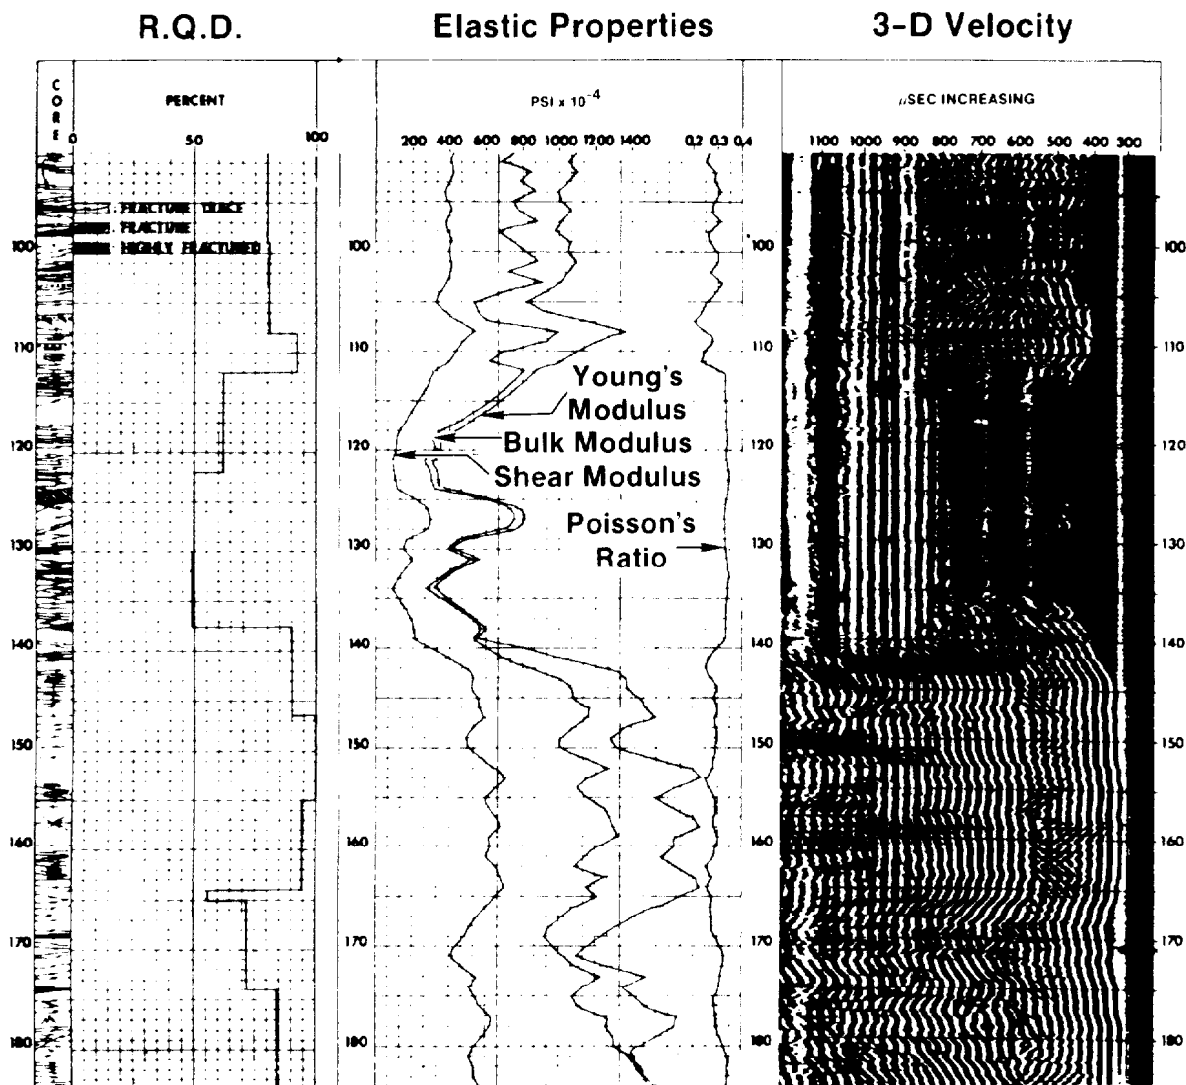

Fig. 51.94—Comparison of rock quality designation (R.Q.D.), elastic properties, and 3D velocity log.

Fracturing. Fracturing of formations is a commonly used well stimulation technique. To determine the best zones for fracturing, laboratory compressibility tests can be run on rock samples from the zones of interest. Fracture design requires a knowledge of elastic moduli, which can be obtained from borehole measurements.

An earlier use of borehole acoustic measurements was for the identification of zones favorable for fracturing. High-amplitude and high-velocity shear waves have been associated with zones that can be fractured successfully, whereas zones with low-velocity and low-amplitude S-waves were found to be quite plastic. In the example shown in Fig. 51.95, Anderson and Walker¹³⁹ indicate a well-defined shear wave in the zone from 4,600 to 4,545 ft and none above this zone.

During drilling, control of hydrostatic pressure in the borehole is necessary to not exceed fracturing pressure of the formations, thereby causing circulation loss.

However, a knowledge of fracture pressure is needed for proper design of fracturing operation to stimulate hydrocarbon production from tight formations. An estimate of fracture pressure (p_{fr}) is given by Hubbert and Willis:¹⁴⁰

$$\frac{p_{fr}}{D} = \left(\frac{p_o}{D} - \frac{p_f}{D} \right) \left(\frac{\mu}{1-\mu} \right) + \frac{p_o}{D},$$

where

p_o = overburden pressure,
 p_f = pore-fluid pressure,
 μ = Poisson's ratio, and
 D = depth.

Recent applications of this relationship are discussed by Atkinson.¹⁴¹

Fig. 51.95—Evaluation of fracturing prospects.

Sand Control. Sand-production control has been a costly problem affecting the economics of oil and gas production in many areas. To avoid unnecessary sand-control measures, various techniques have been developed that use borehole measurements of acoustic properties.^{138,142-144}

In the example shown in Fig. 51.96, the need for sand control is predicted by assuming that hydrocarbon effects on acoustic properties are predominant in poorly consolidated formations.¹⁴² In the oil zones shown, transit times are significantly higher than the value in the water zone, and the amplitudes are reduced, thereby indicating poorly consolidated rocks.

Fracture Evaluation

Many of the important reservoirs in the world produce from naturally occurring fractures, yet evaluating the

performance of these reservoirs is much less understood. Techniques for evaluating naturally fractured reservoirs are reviewed in the literature by Aguilera and van Poolen,¹⁴⁵ Suau and Gartner,¹⁴⁶ and Aguilera.¹⁴⁷ Among these, techniques based on measurements of acoustic properties are prominent. Cycle skipping observed on the transit time curve has been associated with fracturing in certain formations. Also, reduction of signal amplitude has been correlated with fractures. More successful applications, however, involve the use of variable-density or waveform logs.^{148,149} For these logs, when fractures occur, anomalies also occur in the acoustic wave banding pattern. Sometimes these are diagonal patterns, but more often they occur as sudden breaks in the banding.

Fig. 51.97 shows a variable-density log (3-D log) from a granite section in New Hampshire.¹⁴⁹ In Zone C,

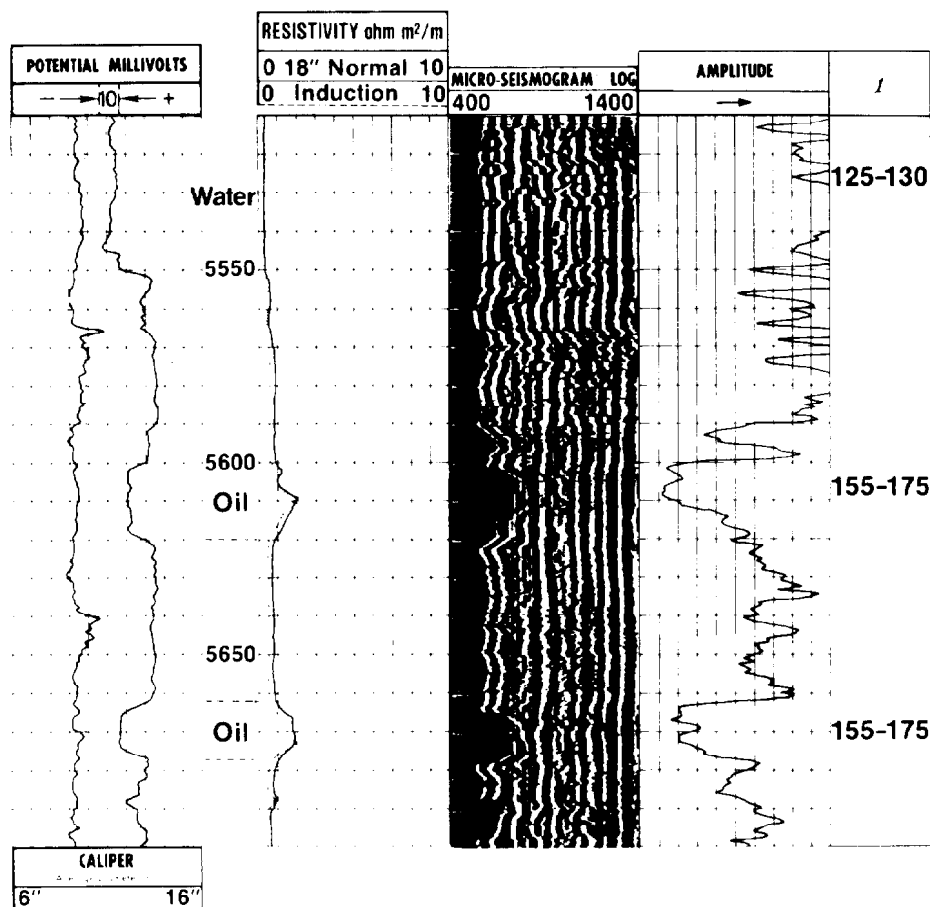

Fig. 51.96—Hydrocarbon effects indicate the need for sand control.

Fig. 51.97—Variable density (3D) log in fractured granite.

the compressional wave is not attenuated, whereas the shear-wave amplitude is reduced significantly. A theoretical study by Knopoff and McDonald¹⁵⁰ would predict this to be due to a low-angle (or horizontal) fracture. High-amplitude compressional and shear energies indicate that Zone B has no fractures. High attenuation of the compressional and shear waves in Zone A is interpreted to be caused by an oblique fracture. The diagonal energy pattern below Zone C is caused by the presence of a reflector (fracture) near the borehole.

In the foregoing analysis, fractures are considered to be thin reflectors causing distortion in wave propagation because of acoustic impedance mismatch with the surrounding rock. Since abrupt changes in lithology and porosity also can cause similar acoustic impedance mismatches, this simplified interpretation becomes much more complex.

When the hole conditions are favorable and there is no mudcake or heavy muds in the hole, the borehole reflection method provides a more straightforward technique for the evaluation of fractures. A borehole televiewer sonde operating in a circular borehole intersecting a vertical fracture is shown on the left in Fig. 51.98.¹⁰⁰ The borehole televiewer log obtained in this configuration, shown on the right, clearly depicts the vertical fracture as two dark lines.

Fig. 51.98—Vertical fracture intersecting a circular borehole and its representation on BHTV amplitude log.

The amplitude image from the BHTV, however, cannot distinguish whether the fracture is open or filled. An open fracture produces an image on the amplitude log because little or no signal returns to the sonde. A filled fracture also can produce an image if there is sufficient acoustic impedance contrast between the filling material and the host rock to produce a weaker signal. Therefore, both open and filled fractures may produce similar dark images on the amplitude log.

Transit time imaging, however, responds not to variations of signal amplitude but rather to the travel time (and, hence, the distance) from the borehole wall. On the transit time log, the distance to the borehole face is represented by a gray scale designating white for far, dark for near, and black for no signal. Therefore, an open fracture produces a black image on the transit time image, whereas a filled fracture does not. Fig. 51.99 shows a vertical fracture on the amplitude log on the left. The similar black outline on the transit time log on the right confirms that this is an open fracture.

Permeability

Theoretical studies by Biot^{45,46} have indicated that changes in acoustic attenuation may reflect the fluid mobility (the ratio of permeability to viscosity). Later studies by Wyllie *et al.*²⁴ and Gardner and Harris¹¹⁵ considered the logarithmic decrement (Eq. 6) of acoustic energy to be a result of solid friction ("jostling" decrement) in the rock matrix and viscous drag ("sloshing" decrement) within the saturant fluid.

The solid matrix losses (jostling losses) were studied experimentally by Gardner and Harris,¹¹⁵ with respect to the effects of overburden pressure and fluid saturation. The results of their investigation indicate the jostling decrement of a sandstone under overburden pressures to be almost independent of fluid saturation and signal frequency. Hence, changes in the logarithmic decrement can be attributed to sloshing loss, which, according to Biot,^{45,46} reflects changes in fluid mobility.

Later, in a theoretical study, Rosenbaum⁶⁴ applied Biot's theory to the investigation of propagation of acoustic pulses in a fluid-filled borehole surrounded by a porous medium. He predicted that permeability could be estimated from an analysis of tube wave data contained in the acoustic waveform recorded in a borehole. He suggested that, for a sealed interface between the borehole and formation, maximum sensitivity to permeability was obtained in the interval between S-wave arrival and the fluid wave. For the open interface (no mudcake), the entire signal following the S-wave arrival could be used. The P-wave arrival was least sensitive to permeability and could be used for normalization.

Results of this study were first tested by Staal and Robinson¹⁵¹ in the Groningen gas field, The Netherlands. They recorded acoustic waveforms and analyzed them to obtain a permeability profile, which compared favorably with the core analysis data.

More recently, Rosenbaum's prediction⁶⁴ of the relationship between the energy loss of the tube (Stoneley) wave and permeability was investigated more extensively by Williams *et al.*¹⁵² Using a special long-spacing acoustic logging tool, they measured the tube wave transit time and energy ratio in wells located in different geographic locations with formations of varying lithology, permeability, saturating fluid, depth, and geological age. From these wells, they also obtained whole core samples for measurements of permeability. For these widely varying conditions, they report qualitative correlations between core-measured permeabilities and the tube wave data.

An example shown in Fig. 51.100 for a Cretaceous carbonate section is highly promising as it indicates that both tube amplitude ratio, A_{R2}/A_{R1} , and transit time correlate well with a permeability increase of three orders of magnitude in the center zone.

Conclusions

Borehole measurements of acoustic properties have a wide range of applications in exploration, production,

Fig. 51.99—Vertical fracture of the BHTV amplitude log on the left, confirmed to be open by the BHTV transit time log on the right.

and formation evaluation. Theoretical and experimental studies have significantly improved our understanding of the relationships between acoustic wave propagation and formation evaluation parameters, such as porosity, fluid saturation, and lithology. This, in turn, has prompted the development of new and improved borehole acoustic measurement technology and sophisticated digital signal processing technology to analyze the large amount of data. Even then, current applications often use only a small fraction of the information available in acoustic waveforms.

Advances in the understanding of acoustic wave propagation are interactively complementing improvements in downhole recording and transmission technology, and developments in signal processing. This should result not only in a broader and more quantitative use of the present applications, but also in the development of many new applications.

Nomenclature

- A = area; or signal amplitude
- A_o = signal amplitude at the source
- b = intercept defined by Eq. 13
- c = compressibility
- d = diameter
- D_i = depth of investigation
- E = Young's modulus
- f = frequency
- $f(K_f)$ = function of incompressibility of a fluid in pore spaces
- F = force
- F_{cp} = compaction correction factor
- F_q = quality factor
- G = shear modulus
- I = intensity
- I_o = acoustic intensity at the source
- K = bulk modulus
- L = length
- m = slope
- n = number
- p = pressure
- p_d = differential pressure
- p_f = internal (pore fluid) pressure
- p_f/D = pore fluid pressure gradient, psi/ft
- $(p_f/D)_n$ = normal hydrostatic pressure gradient (0.456 psi/ft for U.S. gulf coast)
- p_{fr} = fracture pressure
- p_o = external (overburden) pressure
- p_o/D = overburden stress gradient, psi/ft
- P_d = P-wave modulus for the rock frame (or the dry rock)

- r = borehole radius
 s = arbitrary point
 S = saturation
 t = travel time
 τ = transit time
 $\tau (=1/v_p)$ = transit time for the compressional waves for a liquid-saturated porous medium
 $\tau_L (=1/v_L)$ = transit time for saturant liquid
 τ_d = damaged zone transit time
 $\tau_m (=1/v_m)$ = transit time for rock matrix that forms the solid frame of a porous medium
 τ_n = transit time on the extrapolated normal curve at depth
 τ_{ob} = observed transit time at depth
 u = particle motion at s
 v = velocity
 v_f = compressional-wave velocity of drilling mud
 v_p = compressional-wave velocity
 v_r = pseudo-Rayleigh-wave velocity
 v_s = shear-wave velocity
 v_t = tube- or Stoneley-wave velocity
 α = coefficient of absorption; or attenuation coefficient
 δ = logarithmic decrement
 ϵ = strain
 ϵ_L = longitudinal strain
 ϵ_s = shearing strain
 ϵ_T = transverse strain
 θ_s = S-wave critical angle
 λ = wave length
 μ = Poisson's ratio
 ρ = density
 ϕ = porosity

Subscripts

- a = apparent
 c = corrected
 d = dry rock
 f = pore fluid
 g = gas
 hc = hydrocarbon
 L = liquid
 m = matrix
 N = neutron
 o = overburden or oil
 p = pore volume; or P-wave modulus
 s = S-wave modulus
 sh = shale
 w = water

Acknowledgments

I wish to thank A.A. Brown, G.S. De, and K.J. Dunn of Chevron Oil Field Research Co. and M.N. Toksöz of the Massachusetts Inst. of Technology for reviewing the manuscript, Debbie Ivey for typing, and, more importantly, the participants of the Chevron Formation Evaluation seminar during the past 20 years for many helpful suggestions toward the evolution of this chapter.

APPENDIX

Theory of Elastic Wave Propagation in Rocks

The first theoretical expression of elastic behavior of a saturated porous medium was given by Gassmann.⁴⁴ Later, Biot^{45,46} developed a more comprehensive theory of elastic wave propagation in a fluid-saturated, isotropic, porous solid over a wide frequency range. The predicted velocity dispersion by this theory is, in general, less than 3%⁴⁷; therefore, the low-frequency approximation should be useful for most applications.

Velocities predicted by this theory at the lower frequencies can be expressed simply by

$$v_p^2 = \frac{P_d + f(K_f)}{\rho_b} \quad \text{..... (A-1)}$$

and

$$v_s^2 = \frac{G}{\rho_b}, \quad \text{..... (A-2)}$$

where P_d is the P-wave modulus for the rock frame (or the dry rock), and $f(K_f)$ is the function of the incompressibility of the fluid in the pore spaces. The P-wave modulus for the dry rock can be expressed, in turn, by

$$P_d = K_d + \frac{4}{3}G_d; \quad \text{..... (A-3)}$$

and the function $f(K_f)$, by

$$f(K_f) = K_f \frac{(1 - K_d/K_m)^2}{(1 - K_f/K_m)\phi + (K_m - K_d)K_f/K_m^2}, \quad \text{.. (A-4)}$$

in which K is incompressibility (or bulk modulus), G is shear modulus, and the subscripts d , f , and m refer to the rock frame (or the dry rock), fluid, and rock matrix.

For rocks containing both water and hydrocarbons, the bulk density is expressed as

$$\rho_b = \phi\rho_f + (1 - \phi)\rho_m, \quad \text{..... (A-5)}$$

where

$$\rho_f = S_w\rho_w + (1 - S_w)\rho_{hc}, \quad \text{..... (A-6)}$$

and the fluid incompressibility, K_f , which is the inverse of compressibility, c_f , is given by

$$c_f = S_w c_w + (1 - S_w)c_{hc}, \quad \text{..... (A-7)}$$

where S denotes saturation, and the subscript hc refers to hydrocarbon.

Rock frame incompressibility, K_d , in Eq. A-3, which is the inverse of compressibility of dry rock, c_d , is related to PV compressibility, c_p , by

$$c_d = \phi c_p + c_m, \quad \text{..... (A-8)}$$

on the basis of Van der Knaap's⁵⁹ definitions. Substitution of this equation into Eq. A-1, after some manipulation, results in

$$\frac{3}{\rho_b v_p^2} \frac{1-\mu}{1+\mu} = \frac{\mu}{(c_f - c_m)^{-1} + c_p^{-1}} + c_m \quad \text{A-9}$$

Further substitutions into this equation for density from Eq. A-5 and rearranging yields a quadratic equation in μ . Neglecting terms involving μ^2 (since μ is a fraction) and assuming μ to be independent of porosity yields an equation expressing $1/v_p^2$ as a linear function of porosity. For lower porosities,

$$\frac{1}{v_p} = m\phi + b \quad \text{A-10}$$

If the Poisson ratios for the saturated rock and the rock matrix are assumed to be close in value, then b becomes approximately equal to $1/v_m$. The parameter m in Eq. A-10, however, is a strong function of c_p .

As the foregoing discussion indicates, Eq. A-10 is an approximation of Eq. A-9. Therefore, the commonly used time-average equation,^{18,19} which is of the same form as Eq. A-10,

$$\frac{1}{v_p} = \left(\frac{1}{v_f} - \frac{1}{v_m} \right) \phi + \frac{1}{v_m} \quad \text{A-11}$$

(where v_f is the velocity of saturant liquid) also may be considered to be an approximation of the more general theory.

Chapter 52

Mud Logging

Alun H. Whittaker, Exploration Logging Inc.*

Introduction

Conventional mud logging has been commercially available since 1939. The service involves extraction of gases from the returning mud stream and analysis of the gas for combustible hydrocarbons. Commonly, the resulting analyses are logged at drilled depth and plotted alongside a drill-time or rate of penetration log and a cuttings sample geological log. Although the mud log data cannot be related directly to undisturbed reservoir properties, they are important indicators of potentially productive horizons in the well. The conventional mud log continues to be the most important geological data source available before wireline logs are run.

The mud logging unit offers a useful location for the operation of other wellsite analyses and services. It provides a clean, well-lighted laboratory area with a stable electrical supply and is continuously operated by geologists or geologically trained technicians. Many mud logging contractors have made use of these assets to augment conventional mud logging with an extensive range of geological and engineering services. Often unrelated to the traditional gas analysis function of the unit, these services nevertheless generally are considered aspects of mud logging now in the same manner as sonic, density, and neutron logs often are grouped with "electric logs."

The earliest expansion of mud logging services began in the 1960's with the introduction of improved methods of geopressure detection. New techniques were added to the logging unit and it became common for a separate "pressure log" to be prepared alongside the mud log. The 24-hour activity of the mud logging unit allowed continuous operation of this service in which early detection was essential.

In the 1970's, the advent of rugged microelectronics allowed the introduction of more sophisticated and automated equipment into the logging unit. Most notably, the use of drilling rig data-acquisition systems

linked to minicomputers introduced a range of drilling optimization and control services. Unlike conventional mud logging and geopressure detection, these services are essentially nongeological. Generally, engineering personnel are added to the logging crew for these services.

In the 1980's three new aspects to mud logging services have been introduced. First, direct links between a wellsite minicomputer and an office data center allow centralized surveillance and control of several wells. The logging unit provides a wellsite access point to the central computer data base and analytical software.

Second, there is the increasing use of the mud logging unit as the surface receiving and control center for downhole measurement-while-drilling (MWD) services. The mud logging unit provides both a convenient working environment and support data (e.g., total depth measurement) for this service. Additionally, the ability to integrate mud logging and MWD data in a single computer adds economy and speed to the well evaluation process.

Third, the 1980's have brought the first fundamental changes in the methods of hydrocarbon and geological analysis, which continue to be the common denominator of all mud logging services. Improved sampling techniques, pyrolysis, chromatography, and other geochemical techniques have enhanced the diagnostic and quantitative value of mud logging. Wellsite geochemical screening for reservoir and source-bed type may now be performed in the mud logging unit.

Service Types

The number and range of mud logging contractors is possibly greater than that of any other oilfield service. The logging services offered by any single contractor may range from basic hydrocarbon logging, using equipment barely more sophisticated than that introduced 40 years ago, to complex chemical and physical analyses and a complete engineering surveillance and control center.

*The chapter on this topic in the 1962 edition was written by A.J. Pearson.

Similarly, logging personnel may be graduate geologists or engineers, or technicians of various levels of expertise. In specifying the mud log service for a well, the operator's engineer, geologist, and the logging contractor should define the objectives and problems anticipated and select those aspects of the service required.

Since extra service usually implies extra cost, economics must play a part in the decision. In engineering monitoring, it is relatively easy to compute the saving in drilling time or cost required to justify some addition to logging service day rate. This is discussed in detail at the end of this chapter.

Although overlaps occur, the services provided in mud logging may be grouped in line with the traditional oilfield disciplines: (1) *formation evaluation services*¹—hydrocarbon analysis, geological analysis, and geochemical analysis; (2) *petroleum engineering services*—geopressure evaluation and petrophysical measurements; (3) *drilling engineering services*—data acquisition and data analysis. This order is convenient for the following discussion of logging services since it closely parallels the historical development of mud logging and the level of sophistication of logging units used today.

Formation Evaluation Services

Gas Extraction Methods

Although the modern mud logging unit may perform many different services, probably its most critical one is the analysis of hydrocarbon gases.² Before this analysis can be performed, a sample of gas must be extracted from the drilling mud. This is performed by the gas trap (Fig. 52.1).

The gas trap is a square or cylindrical metal box immersed in the shale shaker ditch, preferably in a location

of maximum mud flow rate. Ports in the lower part of the trap allow mud to enter and leave the trap. An electric or pneumatic agitator motor provides both pumping and degassing of mud passing through the trap.

Gas evolved from the mud is mixed with ambient air in the upper part of the trap and drawn through a vacuum line to the logging unit for analysis. This device provides a relatively cheap and reliable method of obtaining a continuous gas sample. However, the efficiency of the device is somewhat affected by drilling practice. Pump rate and ditch mud level will influence mud flow rate through the trap; mud rheology will be a factor in the degassing efficiency of the trap; and mud and ambient air temperature around the trap and vacuum line will affect the relative efficiency with which light and heavy hydrocarbons are extracted and retained in the gas phase. This latter effect is most noticeable in areas of high diurnal temperature variation, where heavier alkane gases seen in daylight may condense and be lost in the cold of night.

An alternative to the conventional gas trap is the steam, or vacuum, mud still. In this device, a small sample of drilling mud is collected at the ditch, returned to the logging unit, and distilled under vacuum. The method provides a relatively high and uniform extraction efficiency for all hydrocarbons. It is, however, a time-consuming manual process. Analyses are noncontinuous and subject to human error; for example, light hydrocarbons can evaporate while the sample stands prior to analysis.

While a useful addition to the conventional gas trap at times, the mud still does not provide a real alternative. The development of a continuous gas trap with good and consistent efficiency of extraction is a high priority in the improvement of mud logging technology.

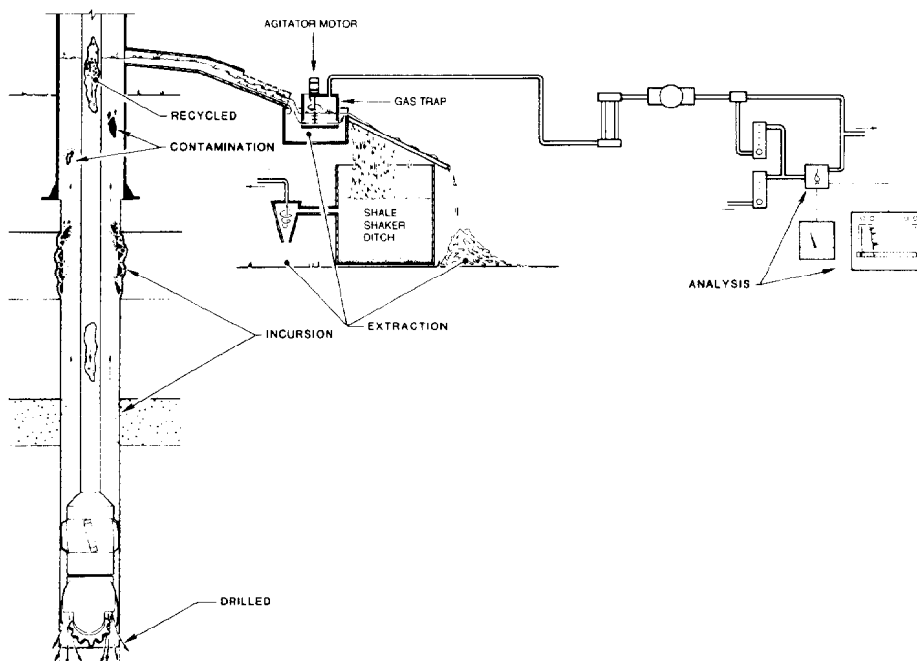

Fig. 52.1—Gas extraction at the ditch.

Hydrocarbon Analysis

The basic form of gas analysis involves the analysis by combustion of the bulk sample. Although commonly called "total gas analysis," it is, in reality, analysis for total *combustible* gases and primarily detects the low-molecular-weight alkanes (paraffins) such as methane, ethane, propane, butane, and pentane (with partial concentrations of hexane and heptane at higher ambient temperatures).

Catalytic Combustion Detector (CCD). After filtration and drying, the gas stream is injected at constant pressure and flowrate into a detector chamber (Fig. 52.2). The original type of mud logging gas detector, and probably still the most widely used, is the catalytic combustion, or "hot wire" detector (Fig. 52.3).

The hot wire detector is a Wheatstone bridge circuit consisting of four resistances: a fixed resistor, R_f ; a rheostat, R_v , used to trim or balance the bridge; and a matched pair of coiled platinum wire filaments, R_d and R_r . The two filaments are enclosed in an analysis cell with the detector filament, R_d , exposed to the flow of gas sample and the reference filament, R_r , isolated in pure air.

When a bridge voltage, V , is applied, the filaments become heated. A voltage between two and three volts is commonly selected to give a high enough filament temperature for hydrocarbon combustion at the filament surface (actual voltage used depends on the particular detector design). Combustion heat causes the temperature and hence resistance of the detector filament to rise relative to the reference filament. The bridge is unbalanced and current flows between the two sides of the bridge. Using a galvanometer of resistance R_m , this current, I_m , can be measured. Since combustion occurs at the filament surface only, the galvanometer current is quite sensitive and linear with changing gas concentration.

Obviously, detector response will depend on both the concentration and composition of the sample gas phase, since each hydrocarbon species will have its own particular heat of combustion. Table 52.1 shows these for the low-molecular-weight alkanes.

Since gas composition is unknown, the total gas detector cannot be calibrated for true compositional response. The detector is calibrated with a mixture of a single alkane, usually methane, in air. Detector response is then reported in percentage "equivalent methane in air" or EMA. Using a variable resistance, R_{vm} , in the bridge it is possible to adjust the bridge current, I_m , and graduate the galvanometer directly in percentage EMA. An older practice, which is now becoming obsolete, was to take the galvanometer reading in milliamps and relabel it as "gas units." Such units are obviously equipment specific although some company or regional standards have been enforced. Where this practice continues, confusion can be avoided by requiring the logging contractor to report calibration data on the mud log heading. For example, the contractor would report "100 total gas units = 2% EMA."

Fig. 52.4 shows the response of a typical CCD to commonly occurring combustible gases. Notice that a response of 1% EMA, or 50 total gas units, may indicate a concentration of 1% methane or a somewhat lower

Fig. 52.2—Gas analysis system.

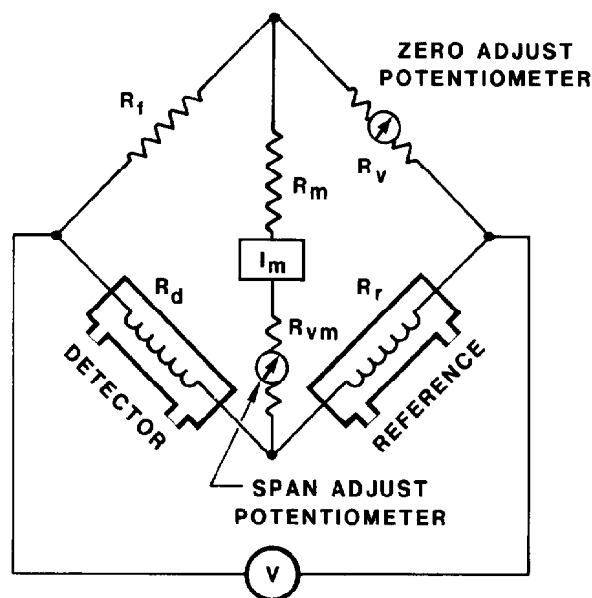

Fig. 52.3—Catalytic combustion detector.

TABLE 52.1—HEATS OF COMBUSTION OF THE SIMPLE ALKANES

	$n = 1$	Molecular Weight	E (kcal/mol)	kcal/gm	Structure
Methane	1	16	191	11.9	*
Ethane	2	30	342	11.4	**
Propane	3	44	493	11.2	***
Iso-butane	4	58	648	11.2	****
Butane	4	58	650	11.2	****

Fig. 52.4—Catalytic combustion detector response.

concentration of a mixture of methane and heavier alkanes. Total gas response may be thought of as a "gas richness indicator," increasing both with gas concentration and with addition of heavier fractions.

To assist in discriminating light alkanes from heavy ones, a second identical detector may be used. By setting a lower bridge voltage (1 to 1.4 V) and filament temperature, the detector is no longer capable of inducing combustion of methane. The resulting detector output, still reported in percentage EMA, is commonly labeled petroleum vapors, wet gas, or heavies, although only qualitative comparison of the two detector responses allows recognition of dry and oil-associated gas shows.

Response of the CCD can be maintained linearly up to the stoichiometric, or ideal, combustion composition of hydrocarbon in air. Above this composition, approximately 9.5% EMA, the detector "saturates," incomplete combustion occurs, and response becomes nonlinear. At higher concentrations, the sample must be diluted with air before it is introduced into the sample chamber to maintain a combustible gas mixture.

Theoretically, by using progressive sample dilution, a CCD can be maintained linearly up to concentrations of 100% EMA. In reality, each dilution stage requires a reduction in gas sample volume and an increasing mixing error. It is generally accepted that 40% EMA is the maximum limit of reliability of a CCD.

As an alternative to progressive dilution, where high gas concentrations are regularly expected, the detector can be reconfigured to operate as a thermal conductivity detector (TCD). Though the detector circuit remains essentially unchanged, it is operated at a lower voltage such that no gas combustion occurs. Bridge current now is reversed, responding to the cooling effect of the gas stream passing over the detector filament. Methane, which has a substantially greater thermal conductivity than air, will produce a large cooling effect, which may be linearly calibrated up to very high concentrations. The device is, however, poorly responsive to the heavier alkanes, CO_2 and hydrogen sulfide (H_2S), which have thermal conductivities close to that of air. The high conductivity gases, hydrogen and helium, will give responses even greater than that of methane.

The CCD is quite selective for hydrocarbons. Carbon dioxide (CO_2) and hydrogen sulfide (H_2S) will not burn at the detector filament. They will marginally reduce the

Fig. 52.5—Flame ionization detector.

thermal conductivity of the gas mixture and induce a small heating effect at the detector filament. This positive response is commonly so small as to be insignificant when compared with the greater hydrocarbon response. However, if the concentration of noncombustible gases becomes so high as to prevent complete combustion of hydrocarbon with air, a much larger negative response will occur.

Hydrogen will burn in the detector, even at low voltage, giving a concentration response similar to methane. Although free hydrogen does occur as an intermediate product of petroleum maturation, it is extremely reactive and diffusive. Occurrence of hydrogen in a petroleum gas show is therefore most uncommon. Significant concentrations of hydrogen have been shown to result from deep-seated structural movement, but the most common origin is from the corrosion of aluminum drillpipe or of steel drillpipe in extremely low pH drilling fluids.

A serious disadvantage of the CCD is the tendency of the catalyst surface to become poisoned by the accumulation of impurities and partial combustion products. This may result in a slow, progressive degradation of performance or a sudden, catastrophic loss, when, for example, silicon compounds are present in the mud. Regular detector calibration is essential to maintain reliable operation.

Flame Ionization Detector. The inherent limitations of the CCD resulted in a search for a more reliable detector technology. The most accepted and increasingly used is the flame ionization, or "hydrogen flame," detector (FID) (Fig. 52.5).

One important difference between the flame ionization and the catalytic combustion principles is that the flame ionization method involves complete combustion of the sample. A small quantity of sample is introduced into a hydrogen/oxygen mixture that is continuously burning in a combustion chamber. The heat generated by the hydrogen flame is sufficient to initiate complete combustion of all hydrocarbons in the sample. A large oxygen excess is maintained relative to the small sample volume and saturation never occurs. The heat output of the hydrogen flame is the sum of the heats of combustion of hydrogen and the sample hydrocarbons.

Unfortunately, most of the heat produced is from the large volume flow of pure hydrogen. The small, dilute flow of hydrocarbons produces such a small proportion of the total heat of combustion that it cannot be measured accurately. Combustion heat then cannot be used as a measure of hydrocarbon concentration. Detection of the hydrocarbons instead relies upon an unusual in-

intermediate stage in combustion that only occurs in hydrocarbons burning at high temperatures. This involves the creation of unstable electrically charged anions and cations. By placing a positive electrode, or anode, in the form of a cylindrical chimney above the hydrogen flame, the negative anions may be collected and the resultant electric current used to determine hydrocarbon concentration.

The ionization/combustion sequence is a complex one that involves many intermediate and alternate reaction steps. The number of ions created, and therefore the current flowing, is in direct proportion to the concentration of the alkanes and to the number of carbon atoms in the alkanes (Fig. 52.6). The FID response in percentage EMA is, therefore, like the CCD, a richness indicator showing increases with increasing concentration and increasing alkane molecular weight.

The FID is totally selective for compounds containing carbon-to-hydrogen (C-H) bonds. Other gases and impurities in the sample stream produce zero or negligible response and do not degrade detector performance.

Although the detector response is effectively linear throughout all concentrations, the electrometer used to monitor and amplify the detector current has performance limits of linearity. Since mud log gas shows may vary from tens of parts per million (ppm) to tens of percent, both electrical signal attenuation and sample splitting are required to ensure low-range sensitivity and high-range linearity of FID response. In most modern instruments this is handled automatically, ensuring a higher degree of accuracy than manual sample dilution.

Gas Chromatography. In addition to a total gas detector, most modern logging units will also contain a gas chromatograph. This device allows the separation of the individual alkanes and their separated detection, giving a gas analysis of composition and concentration. While this analysis is of greater value than the total gas response in EMA, the chromatograph does not provide a continuous analysis but processes batch samples separated by a number of minutes. In drilling terms, this translates into separate analyses several feet apart. The chromatograph does not replace the total gas recorder in showing the fine detail and progressive changes in a gas show.

In gas chromatography, a fixed volume gas sample is carried through a separating column by a carrier gas, usually air. The column contains liquid solvent surface or a fine molecular sieve solid. By difference in gas solubility or by differential diffusion, the gas mixture becomes separated into its components, the lightest traveling most quickly through the column and the heaviest most slowly.

Depending on the nature of the column, each component will pass through and exit the column in a characteristic time. From the column, the components pass in turn to a detector, which may be a CCD, TCD, or FID. The detector is calibrated with a gas mixture of known composition and concentrations. A separate calibration factor for each component can be used for detector response as the components occur in turn.

Since heavier components take longer to traverse the column, the time and depth interval between samples is governed by the number of components to be analyzed.

Fig. 52.6—Flame ionization detector response.

In routine logging, a chromatograph usually will be set to cycle through continuous automatic analyses for methane, ethane, propane, isobutane and n-butane. This requires approximately 3 to 5 minutes. If heavier alkanes (e.g., pentanes) need to be detected, the automatic control is disengaged and the analysis allowed to continue for a longer period of time.

Infrared Absorption Detector. The third, and least used, form of detector is the infrared absorption detector. This instrument uses the principle that any chemical bond will absorb infrared energy of a specific frequency governed by the chemical nature and geometry of that bond. For example, methane contains four identical carbon-to-hydrogen (C-H) bonds. If a gas sample is irradiated with infrared energy at a frequency characteristic of this bond, the energy absorbed by the sample will be in proportion to the number of C-H bonds and hence to the concentration of methane in the sample.

All other alkanes contain C-H and carbon-to-carbon (C-C) bonds. Although these bonds are chemically identical, they vary in geometry and hence characteristic infrared frequency, depending on their position within the alkane molecule. Theoretically it should be possible to pass the gas sample through a series of test cells, testing for infrared absorption at a series of characteristic infrared frequencies. Combination of the results would provide a continuous analysis of both alkane type and concentration—i.e., the equivalent of a continuous chromatograph.

Unfortunately, the C-H and C-C bonds show such a large number of minutely varying geometries that, instead of a series of discrete characteristic frequencies, a continuous band of overlapping absorptions occurs. At best, using a two-absorption cell system, it is possible to provide an estimate of methane concentration and total hydrocarbon concentration, in EMA. This result is comparable to the result obtainable from a dual CCD system and inferior to the results from an FID-equipped gas chromatograph.

Detection of Nonhydrocarbon Gases.¹ The most commonly occurring nonhydrocarbon gases in petroleum exploration are CO₂, H₂S, helium, nitrogen, and hydrogen. As discussed previously, the occurrence of naturally produced hydrogen is rare. Helium and nitrogen also tend to have regionally or geologically

specific occurrences. CO₂ and H₂S are common trace or significant components of natural gases and equipment for their detection should be used on any exploration well.

Chromatograph—Thermal Conductivity Detector.

The most versatile device for detection of nonhydrocarbons is a chromatograph equipped with a TCD. By selecting an appropriate column material and length, any single component or combination may be separated. The TCD will provide a response to any gas that has a thermal conductivity different from that of the carrier gas. This response will differ for each sample gas/carrier gas combination but, by using gas mixtures of known composition, calibration curves for each component can be developed.

Best response and sensitivity is achieved when the maximum difference exists between the thermal conductivities of the sample gas and the carrier gas. Thermal conductivity generally declines exponentially with increasing molecular weight. Thus the light gases (hydrogen and helium) may be readily detected by use of air as the carrier gas. For the heavier gases (nitrogen, CO₂, and H₂S) that have thermal conductivities closer to that of air, a lighter and higher thermal conductivity carrier gas must be used. Helium is a common choice but hydrogen also may be used if available.

An important consideration when assessing the reliability of analyses for nitrogen and CO₂ is their presence in the sample caused by the introduction of air into the gas trap and the aeration of drilling fluid.

Air of normal atmospheric composition, dissolved and entrained in drilling fluid, will be introduced continuously into the borehole. In the hot downhole environment, corrosion and other oxidation reactions will deplete oxygen from this air resulting in a relative increase in nitrogen and CO₂ concentration. Oxidation of carbonaceous material will further add to CO₂ enrichment. Alternatively, the presence of corrosion inhibitors in the mud may deplete both oxygen and CO₂. Regardless of the mechanism involved, oxygen depletion will increase with temperature and length of circulation time through the downhole system.

At the surface, this oxygen-depleted air and any gas recovered from the formation is mixed with ambient air at the gas trap. This air will vary in composition with the surrounding atmosphere—e.g., emissions from rig motors, vehicles, and others.

Any show of nitrogen or CO₂ from the formation must be recognized above background concentrations, which will show some random variation and a progressive increase as the hole is deepened and mud circulation becomes hotter and of longer duration. Regardless of the analytical method used, precision of the ppm level cannot be provided by the analysis. When only trace quantities of gas are expected or when a precise compositional analysis is required, mud logging analysis of CO₂ or nitrogen cannot be relied upon.

Of the nonhydrocarbon petroleum gases, H₂S and CO₂ are the most significant. They are the most commonly occurring gases in high concentrations and because of their polar nature pose serious problems of corrosion of drilling and production equipment. H₂S is

also toxic in relatively low concentrations. In many areas, detectors specific to these gases are considered standard mud logging equipment.

Infrared Absorption Detector. Continuous CO₂ detection is best handled with infrared absorption. An infrared analyzer is used that is responsive to the characteristic frequency of the carbon-to-oxygen (C-O) bond unique to CO₂. Correction of atmospheric CO₂ concentration is performed by alternately scanning two sample cells. One contains a sample from the gas trap and the other contains ambient air. Differential output provides a measure of CO₂ concentration above atmospheric.

Tube-Type Detector. Several types of H₂S detectors are used, all of which monitor a change resulting from the chemical oxidation of the gas. The simplest detector is the tube-type device in which the sample gas mixture is drawn at a controlled flow rate through a glass tube containing reactive lead acetate. The lead acetate, which is deposited on a substrate of high-surface-area silica gel granules, reacts with H₂S to produce lead sulfide and changes from white to dark brown or black in the process:

Since the amount of lead acetate in any unit length of tube is constant, the tube may be graduated in terms of concentration of H₂S in a fixed volume of sample.

The panel-mounted instrument has two tubes installed. Flow of sample from the ditch is constant through one of the tubes, and, if H₂S is present in the gas being evolved at the ditch, the lead acetate begins to discolor progressively from bottom to top (the direction of sample flow). Since the sample, and hence the discoloration, is continuous, this response is qualitative only. The discoloration indicates that H₂S is present in only trace or in enriched quantities, but no estimate of actual concentration can be made.

As soon as this discoloration is seen, a warning must be given since even trace quantities of gas can be dangerous. A quantitative analysis can be made by switching flow to the second tube and introducing a timed sample. In this case, a fixed amount of discoloration occurs and the scale allows reading of the H₂S concentration.

An alternative configuration for the tube indicator is in a small handbellows, often called a "puffer" or "sniffer," which can be used to sample the atmosphere in various locations around the rig.

Since the lead acetate reaction is not reversible, once the tube is used it must be replaced. The instrument cannot keep a continuous record of H₂S concentration but only a series of individual measurements. This is a drawback, but not a serious one since any quantity of H₂S in the atmosphere is both a health hazard and an indication that the mud system is totally saturated. Once H₂S is detected, mud treatment to remove it must begin. Gas measurement is required to ensure that it is removed and does not reappear.

The tube indicator may be used to detect CO₂ or any other gas for which a discoloring reactant is available. For CO₂, hydrazine is used in place of lead acetate.

Presence of CO_2 is indicated by a purple coloration of the chemical in the tube:

The tube method, however, is poorly suited to continuous monitoring since there will be a uniform rate of discoloration by atmospheric CO_2 .

Paper-Tape-Type Detector. A more sophisticated version of this detection principle uses continuous paper tape, impregnated with lead acetate, to allow continuous analysis and a quantitative electrical output for chart recording and activation of alarms.

The detector mechanism is similar in appearance to an open-reel tape recorder. Its operation and operating components are analogous to that of tape recording. Paper tape, a porous filter paper coated with an even concentration of lead acetate, is wound from reel to reel at a constant speed. The tape passes through a sample chamber through which gas from the ditch passes continuously. The tape will be discolored by an amount proportional to the concentration of lead acetate on the tape, the speed at which the tape is moving (both of which are constant), and the concentration of H_2S in the sample. From the sample cell the tape passes to a detector where light from a collimated source is reflected from the tape to a photoelectric cell. The output of the photoelectric cell is readily calibrated in terms of H_2S concentrations by passing through the system test paper strips with zones of different color that correspond to a range of known concentrations.

The paper-tape-type detector may be used for the detection of CO_2 or other gases if a suitably impregnated paper tape is available. Unlike the tube indicator, it is possible to discriminate between a baseline of atmospheric discoloration and a true "show" above baseline.

Although the paper-tape-type is superior to the tube indicator, both suffer the disadvantage of requiring periodic replacement of the reactive material, lead acetate, and the possible degradation of the product in storage. Indicator tubes and rolls of paper tape are supplied in sealed, dated packages and should never be used if the seal is broken or the package is beyond its expiration date.

Solid-State Electrical Detector. The most modern H_2S analyzers involve use of a solid-state electrical detector. This device depends on the reversible reduction of metallic oxides by H_2S as its means of detection. A semiconductor sensor element is exposed to a flow of gas drawn from the ditch. The surface of this element consists of a proprietary metallic oxide layer. In the presence of H_2S , this layer will be partly reduced to metallic sulfides, and its electrical resistance will change:

This is an equilibrium reaction. If H_2S ceases to be present, the reaction reverses with the reoxidation of sulfides to oxides. At all times, the sulfide-to-oxide ratio (and

hence the electrical resistance) of the layer is a direct function of the concentration of H_2S in the sample present in the vicinity of the sensor.

Alternative configurations of this device involve multiple installations with either samples being drawn from, or sensor elements located in, various locations around the rig with centralized monitoring and alarm functions. Locating the sensor in a remote location may cause problems if the sensor is exposed to potential damage or mistreatment. It does, however, remove the risk of loss of response resulting from gas dissolving in condensation in long vacuum lines.

The device has high reliability and accuracy and is widely used in the industry. There are, however, two deficiencies that should always be considered. The first and most important is that if the sensor is operated for a period of time without any H_2S present, it tends to lose reaction speed. (It is important to note here that the sensor does not lose sensitivity! It will respond, within calibration, to the presence of H_2S , but will respond somewhat sluggishly to the first appearance.)

For safety reasons, the sensor must be reactivated regularly by using a sample of H_2S to maintain its reaction speed.

Second, the sensor will respond to certain organic sulfides that may be present in oil or result from mud additive decomposition. The response to these compounds is low but may result in a false H_2S show.

Soluble Sulfide Analyzer. One disadvantage common to all H_2S gas analyzers results from the high solubility of the gas in water. H_2S will not be liberated from the drilling fluid and will not be seen by a gas analyzer until a saturated solution of the gas exists. Since serious corrosion problems may be caused by low concentrations of the gas in mud and even a few ppm of the gas in air is a health hazard, it can be seen that by the time that H_2S gas is detected at the surface, a major problem already has developed.

Early detection of H_2S requires analysis of the drilling mud. This can be accomplished by regular sampling and wet chemical analysis, but the mud logging service can provide continuous soluble sulfide analysis by using a selective ion electrode measurement system.

With this device, a sensor probe, which is immersed in the drilling fluid, contains pH (hydrogen ion) and pS (sulfide ion) specific electrodes and a temperature sensor. When H_2S dissolves in water it will in part dissociate into bisulfide (HS^-) ions and sulfide (S^{--}) ions. The solubility of H_2S and the degree of dissociation are controlled by the pH and temperature of the solution. If these two parameters and the concentration of a single dissolved sulfide species are measured it is possible to deduce the concentration of all other species. In the soluble sulfide analyzer this is done automatically by a microprocessor. By using this device it is possible to detect H_2S and begin treatment to remove it from the mud without concentrations ever becoming high enough for gas detectors to be effective or for personnel to be placed at risk.

Geological Analysis

After gas analysis, the most important function of mud logging is the sampling and evaluation of drill cuttings.

Even when the mud logging unit operator is not a professional geologist, the minimum requirement is for identification and brief description of sample lithology, estimation of reservoir properties (amount and type of porosity and permeability), and description of oil staining.

Sample Lag Time. Hydrocarbon and geological analysis depend on the representative sampling of drill cuttings and gases liberated by the cutting action of the drillbit. In interpreting the analytical results, it is necessary to account for the lag time and physical effects of the gas and cuttings travel from the bottom of the hole to the surface.¹

Lagging of samples is essential so that results may be reported or logged at the depth from which the sample originated (at the time the sample arrives at surface, the depth, of course, will be somewhat greater). Lag time may be obtained simply by calculating the time necessary to displace the total annular volume of drilling fluid as given by

$$V_{an} = V_h - V_p, \dots\dots\dots (1)$$

$$v_{an} = \frac{q_p}{V_{an}}, \dots\dots\dots (2)$$

and

$$t_l = \frac{D}{v_{an}}, \dots\dots\dots (3)$$

where

- V_{an} = annular volume, m³/m,
- V_h = hole capacity, m³/m,
- V_p = pipe capacity and displacement, m³/m,
- v_{an} = annular velocity, m/s,
- q_p = pump output, m³/s,
- t_l = lag time, s, and
- D = depth, m.

Separate calculations must be performed for each annular section (drillpipe in casing, drillpipe in open hole, drill collars in open hole, etc.).

Calculated lag times are used when first drilling out of casing or in hard rock areas where an in-gauge hole is expected. However, a calculated lag time cannot take into account capacity variation in out-of-gauge holes or variation in pump rate or efficiency (for example, when the pump is stopped to make a connection).

Determining and using lag in terms of pump strokes has distinct advantages over lag determined on a time basis. The counters tracking the cuttings up the hole stop automatically when the pump is stopped. Clocks would continue to run, and some subtractive factor would have to be introduced. The most important advantage, however, lies in accuracy. A lag determined in terms of an interval of time is correct for only one speed of the circulating pump (that speed at which the lag determination was run), whereas the lag in pump cycles is accurate for any pump rate.

The lag can be determined by placing a tracer in the drillpipe at the surface when the kelly bushing is "broken off," allowing the tracer to be pumped through the hole and back to the surface, and counting the number of strokes required of the circulating pump to make this circulation. From this total pump stroke count, the number of strokes required to pump the tracer down through the pipe to the bottom of the hole is subtracted. This figure is calculated on the basis of the capacity of the drillpipe and the displacement of the circulating pump. The result is the "lag stroke."

Various materials (such as whole oats, barley, or strips of colored cellophane) may be used as tracers and picked up on the shaker screen for approximating the lag. Under ordinary circumstances, however, calcium carbide placed in the drillpipe will react with the mud to form acetylene. This gas will be picked up by the mud gas detector and is the most convenient and reliable method for determining the lag. Acetylene gas appears as wet gas on the gas detector and is easily distinguished from methane produced from the formation.

Representative Cuttings Samples. There is no substitute for representative cuttings samples accurately correlated to the depth from which they came. They are the required supportive data for the evaluation of any mud logging, geological, geophysical, or engineering data. Every rig has a shaker screen for separating the cuttings from the mud as they reach the surface. The shaker screen may or may not be a good place from which to take cuttings samples.³⁻⁵ If the shaker screen is used, a board or catching box should be placed at the foot of the screen for collecting composite samples. This becomes especially important where drill rate is low, to ensure that the sample collected is representative of the whole interval drilled and not just the final few inches.

Where a traditional "rhumba" shaker is used, differences in flow through the possum belly (ditch at the rear of the shale shaker) will result in density and size sortings of cuttings across the various screens. This sorting can be of assistance to the logging geologist in partially separating large cavings from the smaller bottomhole cuttings. However, great care must be taken to ensure that a representative sample is caught. Where a modern "doubledeck" shaker is used, cuttings on both the upper and lower screens should be sampled.

A sampling depth interval should be set that the mud logger can be expected to maintain while keeping up with other responsibilities. Sample intervals can be shortened as the hole is deepened and drill rate falls. The mud logger should never allow more than 15 minutes to pass between catching samples. For example, if the sample interval is 10 ft and the drill rate is 10 ft/hr, the mud logger should take four scoops of samples over the hour to fill the sample bag for the interval. Special samples should always be taken whenever background gas changes are seen or the lag time after drilling breaks occur. If a board or catcher box is used, it must be cleaned off after each sample is taken.

Samples should be taken from the desilter or desander outlets whenever these are running. In this way, the logging geologist can establish the quantity and appearance of sand and fine solids commonly contaminating the mud system. If an unconsolidated formation is penetrated,

sample from the desander will contain both formation sand and mud solids. The logging geologist must be able to discriminate between these.

Washing and preparing the cuttings to be examined are probably as important as the examination itself. In hard rock areas, the cuttings are usually quite easily cleaned, in which case washing is a matter of merely hosing the sample in a container of water to remove the mud film. Washing the cuttings in many areas, however, particularly areas and zones of tertiary sands and shales, is more difficult and requires several precautions. The clays and shales present are often soft and of a consistency which goes into solution and makes mud. Care must be taken to wash away as little of the shale as possible, and, in determining the sample composition, to take into account that which is washed away.

After washing the cuttings to remove the mud, they are washed through a 5-mm sieve unless doing so will further cause excessive loss of shale or clay. It is generally considered that the cuttings will pass through the 5-mm sieve, and that the material that does not is cavings and may be discarded. However, the material that does not pass through should be examined for sand cuttings. If they should be present, these afford an excellent opportunity for study of larger-than-normal cuttings chips.

Cuttings from wells drilled with oil-based or oil-emulsion muds are usually more representative of the drilled formation than cuttings drilled with water-based mud because the oil emulsion prevents sloughing and dispersion of clays and shales into the mud. At the same time, washing and handling cuttings drilled with this type mud poses somewhat of a problem; they cannot be cleaned by washing in water alone. It is usually necessary to wash the cuttings first in a detergent solution to remove the mud. Some of the liquid commercial detergents available may be used. In extreme cases, it may be necessary to wash the cuttings first with a nonfluorescent solvent such as naphtha, and then wash them in a detergent solution to remove the solvent. Use of a solvent is not advisable unless absolutely necessary because of the risk of removing any oil staining present.

An oven mounted on the wall of the logging unit can be used to dry a portion of the cuttings sample after it has been washed, but some of the washed cuttings are examined wet under the microscope. A sample of unwashed cuttings also is required for cuttings analysis in the blender. Although these cuttings should not be rigorously washed, a light rinsing to remove surface drilling mud film is advisable.

The logging geologist should extract a small amount of sample from each stage of the sample preparation process. From examination of all samples, an accurate estimate of sample composition can be produced.³ Once the percentages of the various constituents have been estimated, the sample description in logical order should contain (1) rock type, (2) color, (3) hardness (induration), (4) grain size, (5) grain shape, (6) sorting, (7) luster, (8) cementation or matrix, (9) structure, (10) porosity, (11) accessories, and (12) inclusions.

Only a visual sample examination usually is required at the wellsite in clastic (sand/shale) formations. In carbonates, other tests may be required to determine the chemical and physical nature of the rock. The simplest of these is to test cuttings with dilute hydrochloric acid; the

rate of reaction, which is rapid for calcite and slow for dolomite, provides a guide to relative composition.

This test can be made more quantitative by use of a calcimeter. In this device a weighed sample is treated with acid in a sealed reaction chamber. Reaction is monitored by measuring either the volume or pressure of evolved CO₂ over time until reaction is complete. Output is percentage of calcite and dolomite in the rock sample.

In more complex mixed carbonates and sulfates (e.g., anhydrite and gypsum), a chemical stain kit may be used. Small samples of washed drill cuttings are spot-tested with a series of chemical test solutions. Characteristic coloration of a test solution is indicative of the presence of a particular mineral in the sample.

Many excellent texts are available that discuss the geological aspects of mud logging. These include Low,⁶ Maher,⁷ and McNeal.⁸ Since this chapter deals primarily with the technology of mud logging, they are not discussed further here.

Hydrocarbon Content of Samples

In addition to a geological evaluation, cuttings samples must be tested for hydrocarbon content. A blender or cuttings gas analysis must be performed on every sample caught. This involves disintegration of a sample of cuttings in a blender, extraction of a sample of liberated gas, and injection into a total gas analyzer. This can be performed by manual extraction with syringe and injection into the unit's online gas analyzer. However, for speed and continuity of operation, modern logging units use automatic extraction and injection into an independent catalytic combustion cuttings gas analyzer.

As soon as a representative cuttings sample has been taken, a measured amount (100 cm³ in a measuring cup) of unwashed sample is placed in the blender jar and covered by 600 cm³ of water, then blended for 30 seconds and left to stand for another 30 seconds before taking a gas sample. If the hole is caving badly, the amount of cuttings may be increased but should be consistent—especially before and through a show. With hard carbonates, low-porosity sandstones, or similar reservoir rocks that cannot be efficiently pulverized by the cutter blades (40 to 60 seconds' blending is recommended), the blender jar should be allowed to stand for 2 or 3 minutes before taking any gas readings. After the gas analysis is performed, the water should be inspected for oil signs or petroleum odor. Any droplets can be skimmed off for examination. The crushed rock material also may be of value in clarifying lithological evaluation.

The blender is a good evaluation tool because it gives some indication of the quality of the reservoir with respect to the porosity and the GOR. A good porosity sandstone generally will be well-flushed by the time it reaches the surface, so the amount of cuttings gas obtained will increase proportionately to the decreasing porosity. This is also true with a sucrosic dolomite or high-porosity limestone such as chalk. However, if the reservoir is a fractured carbonate, etc., with all the oil and/or gas in the fractures, little or no cuttings gas will be recorded and the use of the blender as a porosity indicator is of limited value, because future production is

going to be more dependent on the complexity of the reservoir fracturing than the inherent porosity and permeability of the rock itself.

In oil reservoirs, gas is normally in solution with the oil, and the agitation of a covered sample provides an excellent index of the amount of gas with the oil, which is significant in view of the gas already recorded from the ditch. A high cuttings gas with an oil show should be treated as a very significant show and should be one of the more important factors to consider in the overall evaluation.

When large intervals of reservoir rock are cored, the blender readings obtained are not likely to be as informative as those obtained if the section had been drilled normally. Generally, the amount of sample is reduced because the center is still in the core barrel. With the often slower drill rate, the percentage of cavings may be increased. Also, if a diamond head is being used, the rock will be coming back in a very ground-up and often badly altered state. Thus, if the geologist is agreeable, representative 100-cm³ samples from the more broken-up parts of the recovered cores may be blended with water, and any readings can be used to supplement the readings obtained during the actual coring.

Inspection for liquid hydrocarbons should be made at the microscope (oil-stained cuttings), the blender jar (petroleum sheen and odor after blending), and in an ultraviolet light inspection box (fluorescent oil droplets on cuttings and diluted mud samples).

Visible oil stain and color is an important indication of oil presence and type as are ultraviolet fluorescence intensity and color, grading from dull brown for the heaviest (residual or wet) oil to bright blue-white for light oils and condensate. However, crosschecking of observations is essential to confirm the presence of oil. Many mud additives, contaminants, minerals, or rig floor debris will have an oily appearance or odor and may fluoresce under ultraviolet light. Only if visible stain and ultraviolet fluorescence yield the same conclusion is oil confirmed. For example, samples contaminated with pipe-dope will have a dark oily ap-

pearance suggesting heavy oil. However, the same cuttings examined under ultraviolet light will show a bright blue-white fluorescence characteristic of the highest gravity. This incompatibility allows the identification of a contaminant and avoids the logging of a false show. A good mud logger should examine all mud additives stocked at the wellsite and determine, before their use, their characteristic properties and appearance when mixed with drilling mud or cuttings.

If a true oil stain is identified, a single, representative cutting should be tested with an organic solvent. This is the "cut test." Solvent cut is valuable in assessing fluorescence and allows deductions to be made of oil mobility and permeability of the reservoir. By removing the oil from the colored background of the cutting, the solvent allows a better estimate of fluorescence. The way in which the solvent cut occurs (e.g., instantly for high-gravity oils, more slowly for more viscous lower-gravity oils, or irregularly streaming from limited permeability) also yields useful information. If no cut can be obtained from a washed cutting, the test should be repeated on a dried cutting, a crushed cutting, or after application of dilute hydrochloric acid. This will produce the required cut and yield further evidence on permeability or effective porosity. After the cut solvent has evaporated, a residue of oil remains in the cut dish, displaying the oil's natural color.

Finally, if sufficient oil is present, it may be possible to determine its refractive index. Just as oil stain color and fluorescence progressively change with oil type, refractive index correlates well with oil gravity. Portable refractometers that require only a small droplet of sample are available for use in the mud logging unit. By using a small quantity of oil (skimmed from the surface of the blender jar or a diluted mud sample), a very reliable estimate of oil gravity can be obtained.

Geochemical Analysis

More sophisticated analyses of hydrocarbon and hydrocarbon source material involve the principle of pyrolysis—thermal decomposition of a sample in an inert atmosphere. Three such devices are presently available: the Rock-Eval II™ (RE), the Oil Show Analyzer™ (OSA), and the Thermalytic Hydrocarbon Analyzer™ (THA). All these devices use variations of the Institut Français du Pétrole—Centre de Recherches du Groupe Petrofina (IFP-FINA) temperature-programmed pyroanalysis method developed by Espitalie.^{3,9} The process involves the heating of a weighed rock sample through an increasing temperature program in an inert helium stream. Since combustion cannot occur, the helium carries away from the sample hydrocarbons and CO₂ resulting from the thermal volatilization of petroleum and organic source material in the rock. These evolved gases may be analyzed by flame ionization and thermal conductivity detectors. The amount of gas expressed as milligrams per gram of rock, the evolved gas, and the time and temperature of evolution may be used to characterize the richness and type of a reservoir or source rock.

The differences between the three devices are shown in Fig. 52.7. The RE II uses a uniform temperature ramp of 25°C/min up to 550°C. The helium stream carrying evolved gases passes to a CO₂ trap and then to an FID.

Fig. 52.7—Comparative results of REII, OSA, and THA.

On completion of the pyrolysis the trapped CO_2 is passed to a TCD. The output showing temperature, FID and TCD response is called a "pyrogram."

The RE II pyrogram characteristically shows two distinct peaks in FID response. The first, S1, represents true hydrocarbons, oil and gas, volatilized from the sample. The second, S2, represents hydrocarbons generated by the thermal cracking of hydrogen-rich organic source material, kerogen, in the sample. The temperature, T_{max} , at which the peak of S2 occurs is indicative of the maturity of the kerogen. Mature kerogen, capable of generating oil or gas, will have a T_{max} in the range of 435 to 470°C. A lower T_{max} indicates immature kerogen and a T_{max} above 470°C indicates postmature material that has already yielded the majority of its hydrocarbon product.

The TCD response, S3, represents the yield of CO_2 from the thermal cracking of oxygen-rich kerogen in the sample. A comparison of S2 and S3 provides the relative hydrogen/oxygen richness of the kerogen. This is useful in estimating source type. Hydrogen-rich kerogen is prone to rich oil yields, whereas oxygen richness gives more gas-prone and lower-yield kerogen.

The oil show analyzer (OSA) differs from the RE II in that it uses a nonuniform temperature consisting of two temperature steps followed by a temperature ramp. Following completion of pyrolysis the sample is further heated in an oxygen atmosphere causing the complete combustion of all remaining organic carbon in the sample.

The OSA pyrogram generally shows three characteristic peaks in FID response with S0 and S1 corresponding to the two temperature steps and representing the splitting of the RE II S1 peak into a lower-temperature (gas-indicating) peak and a higher-temperature (oil-indicating) peak. The S2 peak and T_{max} are the same as those seen in RE II. S4 represents CO_2 produced by pyrolysis (S3 equivalent) and by combustion. Combination of the pyrolysis and combustion gas products provides a measure of the total organic carbon content or the gross organic richness of the rock.

RE II has become widely used as a laboratory instrument and both it and the OSA have seen use in the mud logging unit in frontier exploration. The restriction on their wider implementation in mud logging has been the high complexity (and price) of these instruments, which has limited their use to the most advanced logging units and demanding exploration environments.

The THA, a much simpler device, is better suited to routine mud logging services. It uses only an FID and a temperature program similar to the OSA pyrolysis phase (without the final combustion phase). The THA pyrogram provides S0, S1, S2 and T_{max} . Neither CO_2 analysis, S3, nor S4 is available from the THA.

The Modern Mud Logging Unit

There are six basic requirements for a modern mud logging unit² based on the previous discussions.

1. A total combustible gas analyzer using catalytic combustion or flame ionization detector.
2. A gas sample dilution system, allowing maintenance of linear detector response at high gas concentrations or a backup thermal conductivity detector.
3. An automatic cycling chromatograph capable of

isolating and detecting methane, ethane, propane, butane, and isobutane or a second, low-voltage catalytic combustion detector, allowing discrimination of "total gas" from "petroleum vapors."

4. A separate cuttings gas analyzer, allowing gas analysis from blended cuttings samples.

5. A microscope and ultraviolet light inspection chamber for the identification and description of lithology and liquid hydrocarbons.

6. A pumpstroke counter, which, in conjunction with calcium carbide lag tests, allows gas readings and cuttings samples to be lagged back to correct drilled depth.

In addition, the unit requires a drilling depth and time recorder for the determination of sample depth and the calculation of rate of penetration, an important rock strength/porosity indicator. Ideally, this should be independent of the driller's depth recorder.

Since mud logging samples (gas, oil, and cuttings) are extracted from the mudstream, changes in mud chemistry and rheology must be considered when evaluating mud log results. The logging unit should be equipped to perform basic mud tests—e.g., mud balance, Marsh funnel, sand test kit, and filter press. Laboratory glassware and chemicals are required to perform chemical tests and titrations on cuttings and mud filtrate samples.

Although pressure control is not a *standard* function of mud logging (see Petroleum Engineering Services), the mud logger, by continuously monitoring mud gas content, should be aware of situations of potential drilling hazard. It is therefore usual for the mud logging unit to be equipped with a level monitor for the active mud pit. This allows the mud logger to be a second line of defense, after the driller, in detecting a well kick or loss of circulation.

The Mud Log

Format¹

Fig. 52.8 shows a typical modern mud log. There are currently no industry standards for mud logs, and presentation varies among operators. However, the track order commonly follows that shown in the example.

Track 1 is used for rate of penetration (ROP). Also included in this column are items of drilling data that may affect interpretation of the log (bit types, changes in drilling parameters, circulation breaks, etc.).

Track 2 is for depth notation and for symbolic representation of special evaluations (for example, cored or tested intervals).

Track 3 is a graphical representation of formations penetrated. Usually the column is subdivided into 10 equal columns and graphic symbols are used to represent 10% increments of lithology types seen in cuttings. Unlike other tracks on the log, the lithology track is not a calibrated physical measurement but a subjective assessment. Care should be taken to establish rules of drafting acceptable to the preparer and user of the log.

Even after removal of cavings and contaminants, a cuttings sample is not truly representative of a single depth interval. Variation in particle size and density cause differences in annular recovery rate and mixing of cuttings in the annulus. A true cuttings percentage will never show sharp formation boundaries as a result of this mixing. For example, a thin sandstone within a massive

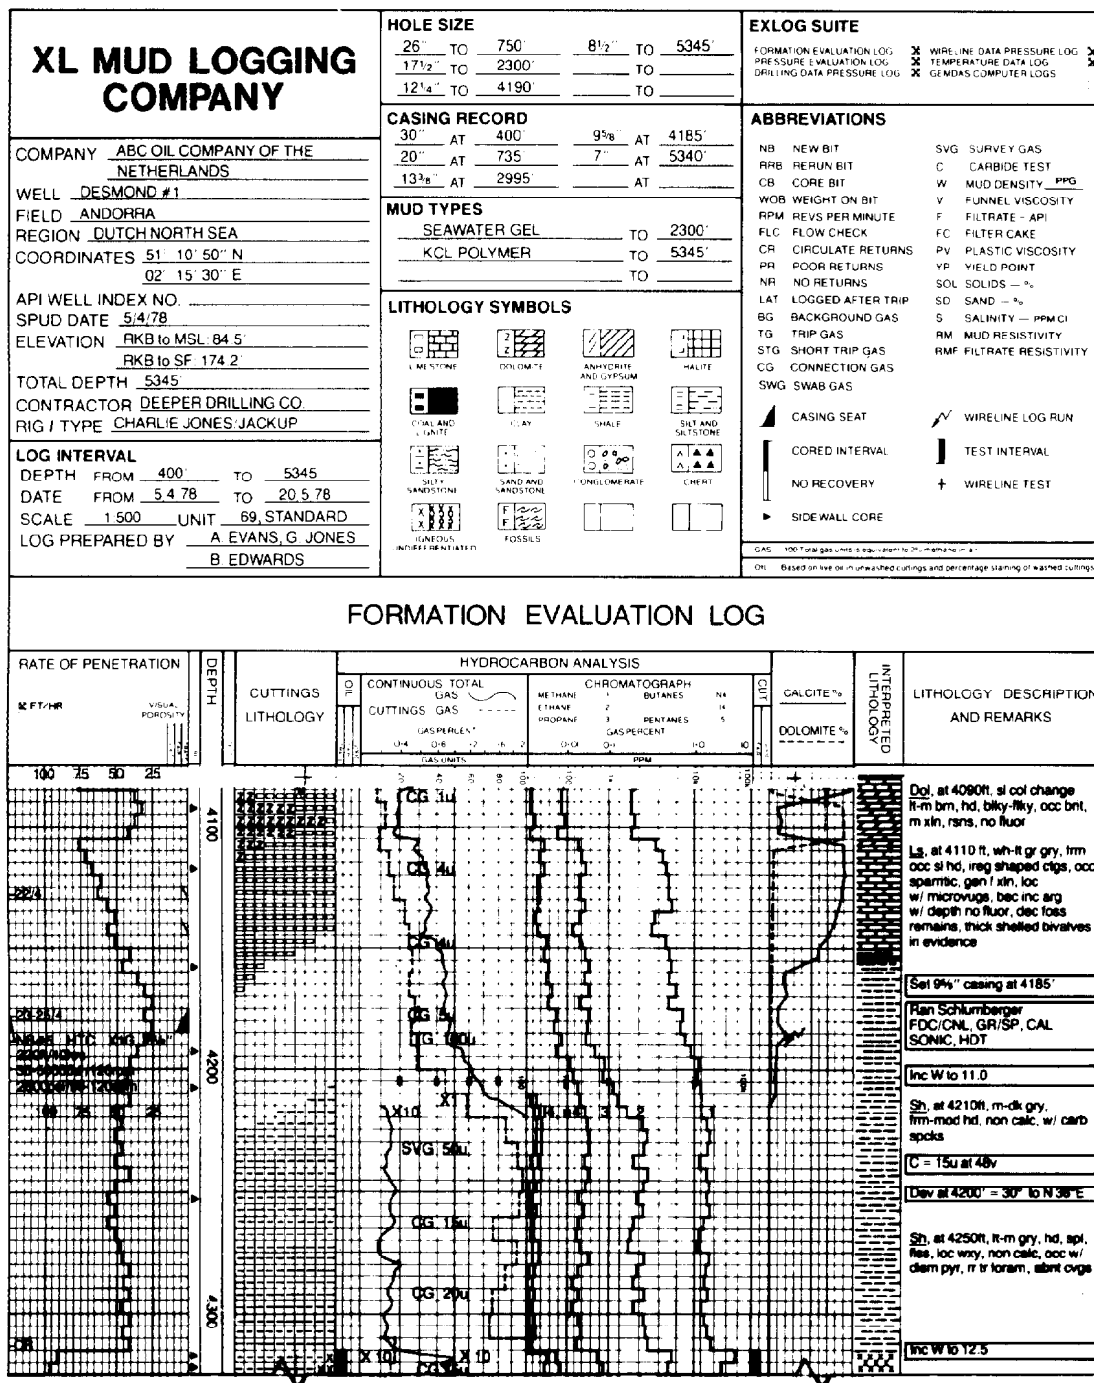

Fig. 52.8—Mud log format.

shale with sharp boundaries shown clearly by ROP and total gas analysis may appear from cuttings to be a sandy shale horizon of much greater vertical extent.

A geologist may use all available data to prepare an interpretive lithological log. That is, in the previous example, to sharply show the sandstone boundaries as indicated by ROP. Sometimes a mud logger will attempt to add some degree of interpretation to a cuttings log. Again, in the example the mud logger would show the presence of sand in all the cuttings samples but exaggerate the percent sand in the sample coinciding with the higher ROP.

This "semi-interpretation" may result in confusion when later sample examinations are compared with the mud log and, in my opinion, mud loggers should be instructed to prepare a true cuttings log representing the percentages of lithologies actually seen in the sample. If the mud logger is geologically qualified and the operator's geologist requires geological interpretation, then an interpretive lithological log should be prepared as an *additional* track on the mud log.

Track 4 presents the results of hydrocarbon analyses. It may consist of one single width track but most often is subdivided into two or more separate tracks, as in the example. Track 4 will include the results of total gas, cuttings gas, and chromatographic analyses and when oil shows occur, an estimate of oil show quality and oil cut will be added. Supplementary gas analyses (helium, hydrogen, CO₂, or H₂S) also may be added to this track or plotted on a supplementary log.

Track 5 primarily is used for brief sample descriptions. Also included in this track are mud test results, casing and cementation records, hole deviations, carbide test results, and many other operating data used in interpretation of the mud log. On wider format logs, Track 5 also may be subdivided to add an interpretive lithology and an extra data track to be used for the results of special analyses or calculations.

Interpretation

The object of logging drilling-mud gas shows is to identify potentially productive oil and gas horizons. While such zones often may be indicated by major events—e.g., large gas and fluorescence shows—more critical interpretation is required to avoid false alarms or missed opportunities.

Total Gas shows

The magnitude of a total gas show is not in itself a conclusive indication of show quality. Gas detected at the surface originates in three ways: (1) from the disintegration of a cylinder of rock by the drill bit as the hole is deepened, (2) from the influx of gas from previously drilled formations exposed in the borehole wall, and (3) from the drilling mud itself in the form of recycled oil and gas and decomposition of mud additives.

In extreme cases (for example, in long, geopressured shale sections or when using oil-based drilling fluids) influx or contamination may constitute the majority of gas seen at the surface. In such circumstances the magnitude of a gas show from a potential reservoir must be evaluated against the established background gas level from overlying sediments. Gas shows from relatively

thin horizons may be submerged in a high background and not identified from total gas alone (Fig. 52.9).

Even gas reliably identified as resulting from a drilled interval may be misleading as a show-quality indicator. Factors that affect the magnitude of a gas show include the volume of the rock cylinder crushed in the drilling process, controlled by bit diameter and ROP and dilution of liberated gas in mud (i.e., the flow rate of drilling mud passing bottom as the hole is cut). Thus, gas show magnitude will be expected to increase in larger diameter holes, at higher ROP's, or at reduced mud flow rate (Fig. 52.10).

A simple technique is available to remove these factors from evaluation by normalizing gas show magnitude to a standard or "normal" set of drilling conditions:

$$G_{pn} = G_{poB} \left(\frac{q_{oB}}{q_n} \right) \left[\frac{\pi \left(\frac{d_n}{2} \right)^2}{\pi \left(\frac{d_{oB}}{2} \right)^2} \right] \frac{R_n}{R_{oB}}, \dots (4)$$

where

- G_{poB} = observed total gas, %,
- G_{pn} = normalized total gas, %,
- q_{oB} = observed mud flow rate, m³/s,
- q_n = "normal" mud flow rate, m³/s,
- d_{oB} = observed bit diameter, m,
- d_n = "normal" bit diameter, m,
- R_{oB} = observed ROP, m/s, and
- R_n = "normal" ROP, m/s.

Once a "normal" set of conditions are selected, the equation can be readily simplified giving

$$G_{pn} = G_{poB} \left(\frac{q_{oB}}{0.050} \right) \left[\frac{\pi \left(\frac{0.251}{2} \right)^2}{\pi \left(\frac{d_{oB}}{2} \right)^2} \right] \frac{0.010}{R_{oB}}$$

and

$$G_{pn} = \frac{0.0126 G_{poB} q_{oB}}{(d_{oB})^2 R_{oB}}, \dots (5)$$

where

- $q_n = 0.050 \text{ m}^3/\text{s}$ (793 gal/min),
- $d_n = 0.251 \text{ m}$ (9.875 in.), and
- $R_n = 0.010 \text{ m/s}$ (118 ft/hr).

Normalization can be very useful in correlation of gas shows between wells drilled with very different programs. However, it should be remembered that normalization cannot remove the effect of influx and contamination; nor does it account for varying gas trap efficiency with ambient conditions.

Finally, remember that the gas produced by drilling is liberated by the crushing of material at the bottom of the hole and is representative of the fluid composition within the rock pore space at the time of impact. Remember that oil and gas flow from a producing well; they are *not* mined. The presence of a fluid within a rock is not

Fig. 52.9—Mud log total gas shows.

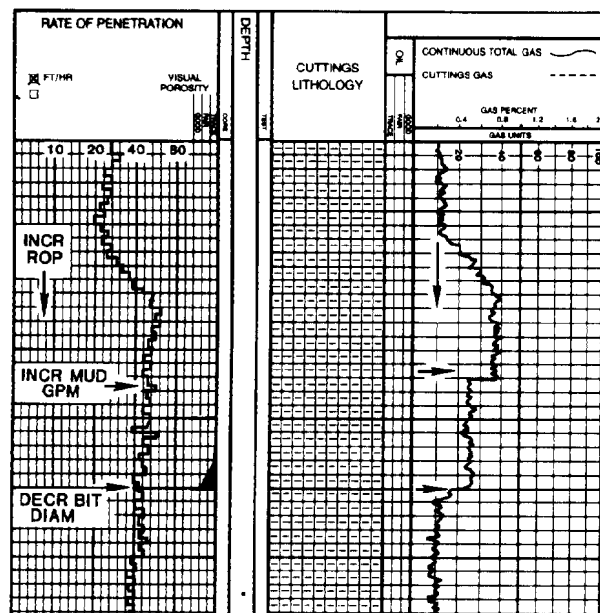

Fig. 52.10—Variation of total gas with drilling parameters.

necessarily indicative of productivity of that fluid *from that rock*. Comparison of total gas analyses from mud and cuttings and chromatography can yield useful clues as to the productivity of a hydrocarbon-containing formation.

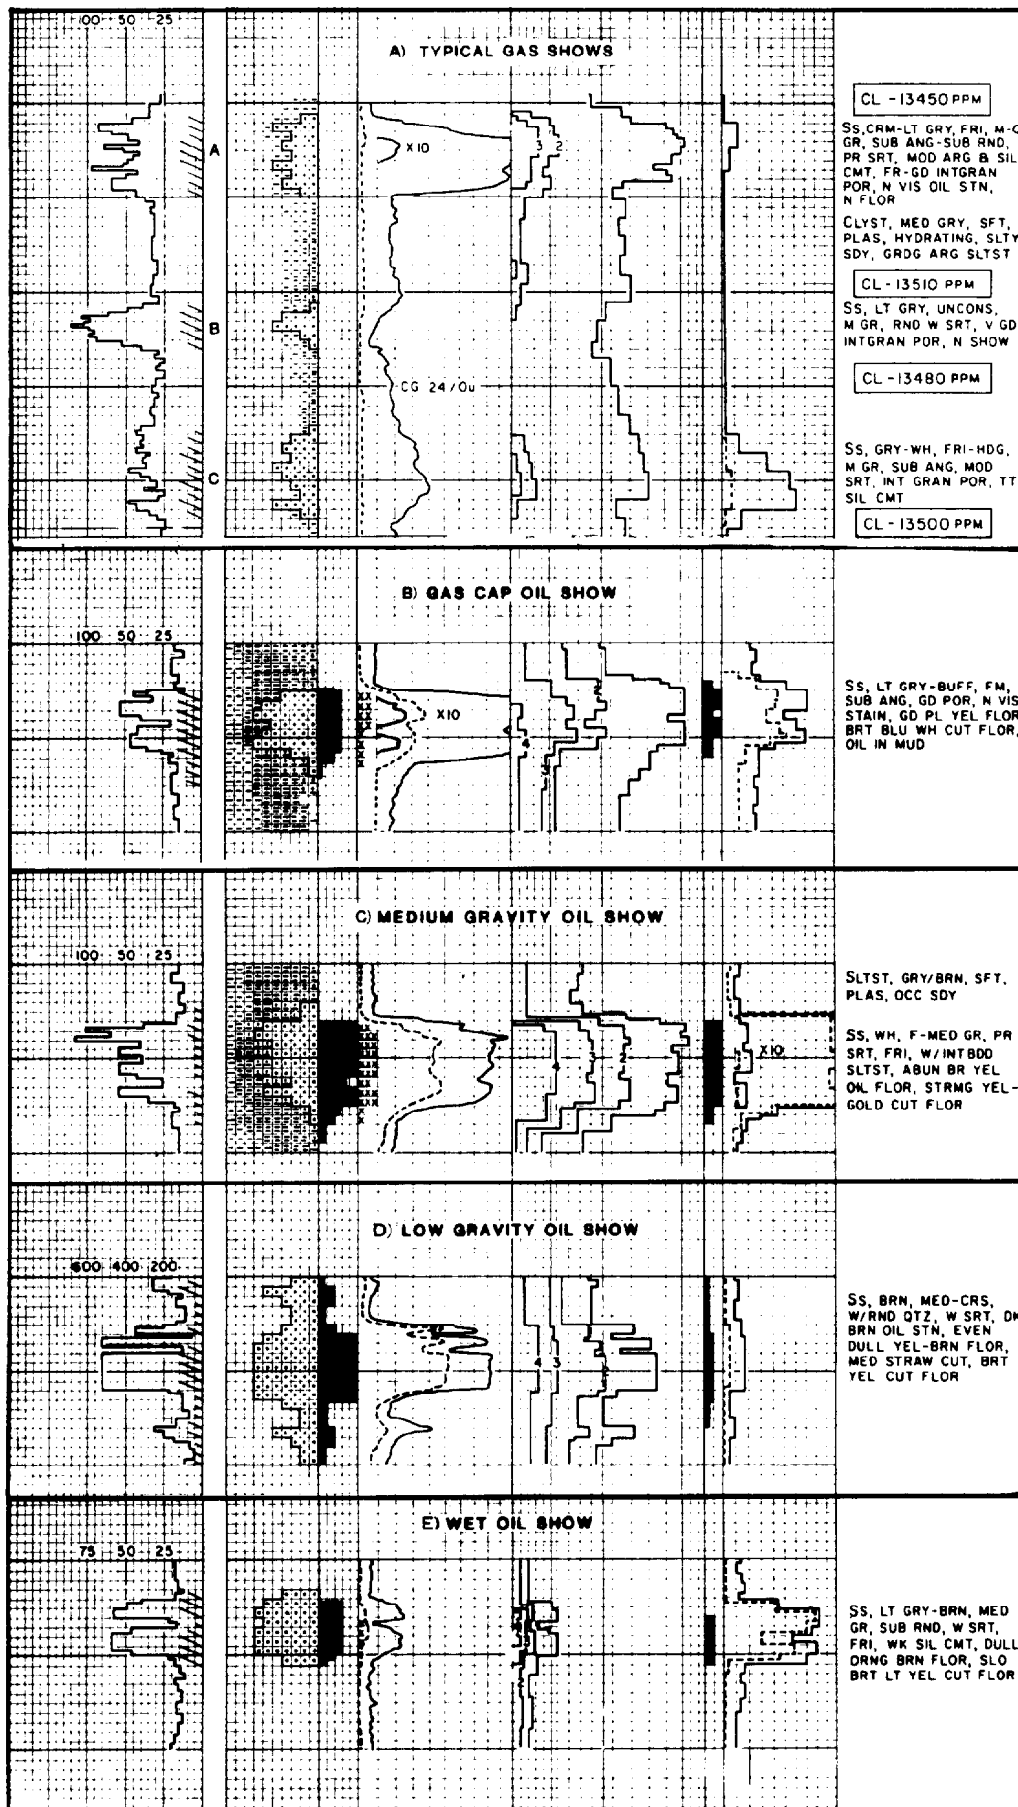

Total gas from the cuttings blender test is a good indicator of fluid mobility. As the crushed rock cuttings are carried to surface and relieved of formation

hydrostatic pressure, exsolution and expansion of gas should effectively flush the cuttings, leaving only a small volume of residual fluid at the surface. When higher cuttings total gas, relative to ditch total gas, is observed, this is an indication that this flushing has been impeded. An obvious explanation is that the rock lacks sufficient permeability to allow gas expansion and flushing. However, residual low-gravity oil or tar will have a similar effect in impeding gas exsolution and escape. Inspection of cuttings lithology, fluorescence, and the cut test should provide confirming evidence (Fig. 52.11). For example, strong cementation or shaliness in the cuttings would be indicative of low permeability, whereas dark or dull oil stain and fluorescence with a slow cut or absence of cut is more indicative of heavy oil.

At the opposite extreme of mobility, a formation may be so permeable that it is flushed effectively with mud filtrate even before being drilled. On recovery to surface neither mud nor cuttings will contain hydrocarbons. Indeed, no cuttings may be seen since such formations are commonly unconsolidated and disintegrate on recovery.

In this circumstance the first observations will be a sharp increase in rate of penetration followed, after the lag time, by a "negative" gas show; total gas declines below the original background. Testing the desander effluent or a mud sampling probably will show an increase in loose sand grains. The negative gas shows confirms only the excellent permeability, and for this reason alone the zone deserves closer inspection when a resistivity log is available. No evidence is available of the formation's fluid content from the mud log.

Most potential reservoirs fall between these two extremes: producing (1) a positive gas show and (2) cuttings blender gas, depending on permeability and oil

gravity. Color and fluorescence of the oil stain and results of the cut test are indicative of oil type. However, note again that presence of hydrocarbons in the rock and even presence of porosity and permeability are not conclusive evidence of hydrocarbon productivity.

Chromatogram Interpretation

The hydrocarbon chromatogram is often a useful guide to reservoir productivity. It is not the actual amount of any one alkane that is significant but the relative amounts of light and heavy components characteristic of the overall reservoir fluid. Such characteristics normally can be recognized on the mud log itself. An aid to this can be the calculation and plotting of the numerical ratios of the values of the various hydrocarbons (e.g., C_2/C_1 , C_3/C_1 , etc.). Such gas-ratio plots will often yield distinctive "character" or "events" not always immediately evident from the chromatogram itself. However, interpretation of the plots depends on the same logical procedures.

Most petroleum hydrocarbons originate from a similar organic source and proceed in their maturation by a similar temperature- and pressure-controlled physico-chemical process. For this reason, petroleum accumulations, although markedly different in composition, tend to show a spectral relationship to each other in terms of the type and amount of hydrocarbon species present. Therefore, although two crude oils of 30°API gravity may be extremely different in total composition, they will contain some similar components in similar compositional relationships to each other. Since petroleum maturation continues by the continuous "cracking" of complex branch molecules into simpler straight chain molecules, these significant relationships are readily seen in the petroleum gases methane through butane. Thus, study of chromatographic analysis of these gases often may lead to a gross estimate of the type and quality of the reservoir.

At low temperatures and shallow burial, biological and catalytic decomposition of organic debris results in a low-yield production of methane and CO_2 . Though the CO_2 will dissolve in and migrate with pore waters, the methane will accumulate in porous zones either as free gas or in solution in water. Such zones will yield impressive gas shows when drilled, but with few exceptions will produce only gas-cut water.

It is a reasonable general rule that a gas show containing methane as the only significant component is not commercially productive and is unworthy of further evaluation. However, it also should be remembered that exceptional cases do occur, including the southern North Sea nonassociated gas reservoirs that produce +94% methane.

At higher temperatures, organic material first polymerizes to form kerogen, which is then hydrogenated and cracked with increasing temperature to form bitumens, tars, and progressively higher-gravity oil and gas. Associated petroleum gases are fragments of this cracking process and as cracking continues, the proportion of light to heavy gases increases in a manner similar to the lightening of the liquid hydrocarbon. This fractionation of gases and liquids continues during the migration of the hydrocarbons from source to reservoir.

The end result of this process is reflected in a gas show chromatogram. A gas-productive interval will show predominantly methane and ethane with only traces of the heavier alkanes. Oil productivity is signaled by the enrichment of the heavier alkanes, especially propane. Decreasing oil gravity is reflected by progressively greater proportions of propane and the butanes. In lower-gravity oils, the concentration of these gases may exceed that of ethane. But all productive horizons will contain methane as the dominant alkane. Zones in which methane represents at least half of the total gas usually contain heavy residual oil from which the lighter gas and liquid fractions have migrated, leaving an immovable, nonproductive fluid.

These general rules of chromatograph evaluation can prove useful in reservoir evaluation but of course should not be used in isolation. Conclusions regarding oil gravity and mobility should be compared with the results of blender tests, cuttings examination, fluorescence, and cut tests. Furthermore, evaluation should proceed from the prior-show baseline values and throughout the show interval. Considering the variables inherent in the drilling, transportation, and extractions of samples, no conclusion may be drawn from a single sample or analysis.

Conventional Mud Log

The conventional mud log offers more drilling and formation evaluation data in a single form than any other data source. Many of these data are subject to uncontrolled variables in the measurement technology and by the very nature of borehole environment. As a result, no simple conclusive rules of quantitative log evaluation are available. However, integration of all the data on the log with geological and regional experience can make the conventional mud log a most powerful exploration tool.

Petroleum Engineering Services

Geopressure Evaluation

The petroleum engineering functions of mud logging developed from the introduction of a number of pressure evaluation techniques during the 1960's. These techniques are practiced conveniently in the logging unit and in some cases use data or equipment already available in the unit. Also, interpretation of the resultant data requires the same integrative approach, using drilling data and geological evaluation, as required in mud log interpretation. Unlike mud log evaluation, however, pressure evaluation techniques are able to provide reliable quantitative estimates of formation parameters, such as pressures and porosity.¹⁰

Drilling into a geopressured zone causes a change in a number of basic formation/drilling relationships. This change is usually a reversal of a gradual depth-related trend in a lithologically uniform formation.¹¹ Compaction increases uniformly with depth in a normal pressured clay rock. A geopressured zone may be poorly compacted relative to those zones overlying it. Porosity and water content decrease uniformly with depth in a normal pressured clay rock. A geopressured zone in which dewatering has been slowed will show a reversal in the trend, with increased water content and increased porosity. Other factors relating to fluid movement, such as ionic concentrations, hydrocarbon saturations, etc.,

may be different in geopressed zones. Differential pressure across bottom is the difference between the drilling mud hydrostatic pressure and the fluid pressure in pores of the undrilled formation at the bottom of the hole. Since drilling mud usually is denser than formation fluids, this difference will be positive and will increase with depth. In a geopressed zone, the formation pore pressure is abnormally high and the differential pressure across bottom will decline or even become negative.

Thus, any measureable parameter that reflects any or all of these factors may be used as a means of interpreting changes in formation pressure and eventually as a means of evaluating and obtaining quantitative estimates of formation pore pressures.

Gas Analysis. The incursion of formation fluids into the borehole may result from a number of causes, some but not all of which result from an underbalanced condition—either temporary or permanent.¹² If an underbalanced condition exists, there will be a natural tendency for fluid to flow from the formation into the borehole. With a formation having good porosity and permeability, this flow will be massive and a kick will occur. Such a kick will be indicated by the incursion of formation fluid downhole, causing the expulsion of mud from the borehole at surface. Were this to continue, a blowout would result. It is the logging geologist's responsibility (other duties permitting) to monitor the mud pit level and to report any unpredicted or unexplained level changes. A massive incursion of fluid resulting in a well kick is unlikely to be misinterpreted as a gas show. In fact, if the hole is full, the kick should be recognized by a rise in pit level long before the fluid causing it has time to appear at surface.

However, minor incursions caused by slight or temporary underbalance, or where insufficient permeability to provide a sustained kick exists, do occur and must be interpreted correctly.

When an underbalance sufficient to cause a kick exists but there is insufficient permeability to sustain a massive fluid influx, a steady fluid "feed-in" may result. If this minor flow is from a discrete formation already cut, it will be noticeable — producing a sustained minimum gas background even when circulating but not drilling. If this is the case, the logging geologist should make a note of this sustained circulating gas on the mud log.

If the feed-in is from the formation currently being drilled, then as a greater and greater area of formation in the borehole wall is exposed by drilling, increasing flow will take place. If this is the case, the mud gas will exhibit a sustained minimum when circulating but will consistently rise as drilling proceeds. Cuttings gas will inevitably be high relative to mud gas since it is only the lack of permeability that is preventing the feed-in from becoming a kick. Where permeability is effectively absent (e.g., in clays or shales) even a minor feed-in cannot take place. Fluid pressure in the rock will gain access to the borehole by the opening of pre-existent microfractures and partings in the rock. The result will be the caving or sloughing of rock fragments into the borehole, accompanied by a small amount of gas. A minimum gas background and, in this case,avings recovery exist when circulating without drilling.

Fig. 52.12—Connection gas indicating underbalance.

Circulating bottomhole pressure is higher than when the mud is static. This is caused by annular pressure losses when circulating. It is therefore possible for a feed-in, caving, or even a kick to result because of a resultant underbalance when circulation is stopped. Furthermore, pressure is further reduced because of the swabbing effect when pipe is moved upward—e.g., when making a connection. The literal meaning of "swabbing" is the pulling of a full-gauge tool from the hole, acting like the plunger in a syringe and initiating fluid flow into the borehole. Swabbing by moving the drillstring does not work in this way. When pipe is pulled upward, the high-viscosity gelled mud will attempt to move with the pipe, thus reducing the effective hydrostatic pressure acting on the borehole wall. Pressure reduction is a function of pulling speed, mud rheology, and annular diameter. The important consideration is that pressure reduction takes place not just below the bit but at all points in the open hole.

Downtime gas or connection gas is a gas show resulting from the momentary underbalance caused by pump shutdown and/or pipe movement. It can be recognized by the occurrence of discrete gas show appearance at, or slightly less than, the lag time after circulation recommences. This is gas actually being produced by the formation and, while not being plotted on the mud log, the value should be reported on the log because it is indicative of formation permeability and fluid content. When a connection gas occurs, the logging geologist also should check a flowline mud sample for evidence of produced oil or salt water with the gas. The incidence of connection gas should be reported to the

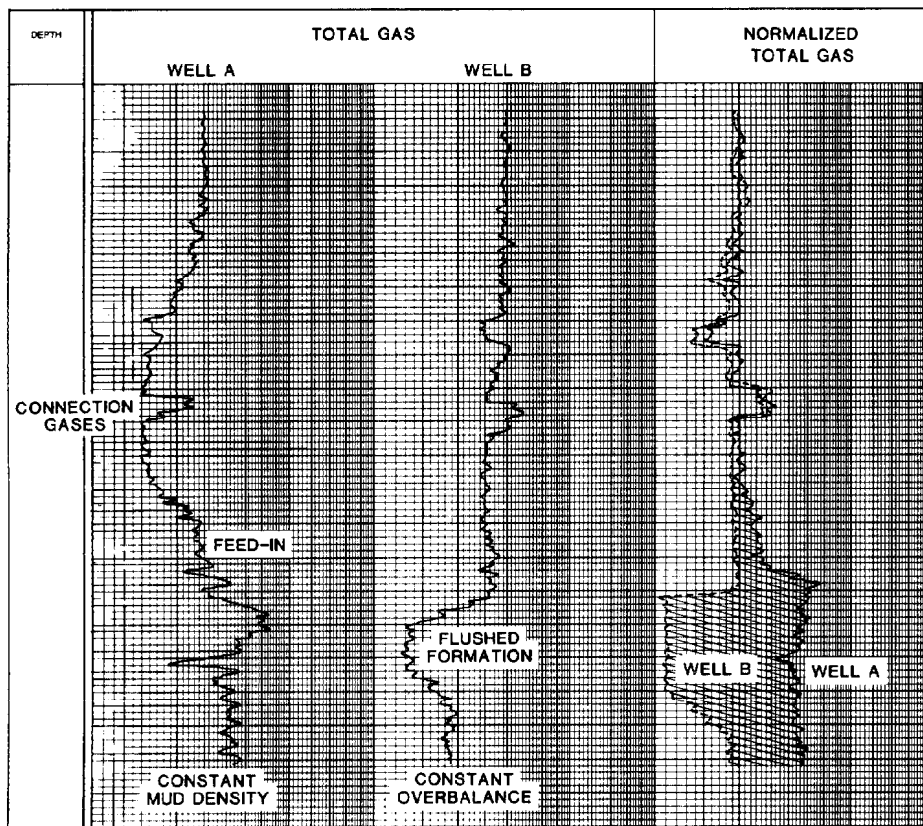

Fig. 52.13—Normalized total gas.

drilling supervisor, who may choose to increase mud density in response to the indicated underbalance.

It is important to remember that the entire openhole section will be underbalanced by swabbing. The connection gas may not come from the bottom of the hole but from some horizon above. In fact, two or even more connection gases may result from a connection. For this reason it is important that lag time and annular velocities should be identified accurately by the logging geologist so that connection gases can be identified with the producing formation and the mud log annotated accordingly.

Drilling into a permeable reservoir with an underbalance is potentially dangerous because a kick may result. Even if a kick does not occur immediately, the hazardous situation will be marked by an increasing feed-in as more formation is drilled, accompanied by progressively larger connection gases (Fig. 52.12). The condition should be reported by the logging geologist and noted on the mud log. If increases in mud density alleviate or remove the effect, this should also be noted on the mud log in explanation of the consequent reduction in gas.

Fig. 52.13 demonstrates the effect of varying differential pressure on gas show magnitude. The total gas curves for two wells drilled through a similar section are shown. The data for both wells have been normalized to reduce the effects of hole diameter, ROP, mud pump output, and surface extraction efficiency. Well A was

drilled with a constant mud density, whereas in Well B mud density was controlled to maintain a constant positive differential pressure (overbalance).

In the upper portion of the section, the two gas curves are similar and the normalized gas curves coincide almost exactly. In the lower portion a progressive deviation between the two wells is seen that is somewhat reduced but remains evident even in the normalized curves. We can interpret this as being caused by the penetration of a transition zone into a geopressured zone.

In Well A, maintaining a constant mud density results in a decreasing overbalance and eventually an underbalance or increasing negative differential pressure. Connection gases occur and become larger with deeper penetration. Additionally, feed-in of gas from the underbalanced borehole wall causes an increase in background gas that, since it is not a product of freshly cut formation, cannot be accounted for in the normalization calculation.

Well B, on which a constant overbalance was maintained by increases in mud density, did not show increases in gas background or connection gases. Indeed, if any zone showed good permeability, the overbalance may have resulted in flushing gas away from the borehole and a reduction in observed total gas.

By careful observation of these phenomena, a fairly accurate log of differential pressure (and hence pore pressure) may be obtained. This information should be used in conjunction with the other techniques described in the following paragraphs.

Cuttings Evaluation. During the normal mud-logging process, cuttings are sieved and graded to a size assumed to be representative of drilled cuttings. The larger fragments are cavings from the walls of the borehole and play no part in the compilation of a lithological log.

In geopressure evaluation, these cavings play a major role. The presence of cavings in the sample indicates that the borehole wall is unstable. The most noticeable and usually most predominant cavings are those of clay, shale, or calcareous lithologies. Coal, however, will cave as a matter of course, hence interpretations should not include coal cavings. The amount of cavings in the bulk sample is an indication of the degree of instability of the borehole walls. Simply watching the cuttings traverse the shaker screens will give a reasonable indication of the amount and size of the cavings in relation to the bulk sample.

Cavings are produced by underbalanced drilling and stress relief. Abrasion of the walls by the drillpipe will also cause cavings, but generally these will not be discernible from cuttings because of their small size.

If the pore pressure is higher than the hydrostatic pressure in the borehole, the hydrostatic pressure differential will cause the pore fluids to move toward the borehole. In an impermeable formation, the resultant pressure gradient adjacent to the borehole wall may become great enough to overcome the tensile strength of the rock. When this occurs, the rock fails in tension and cavings are formed.

All parts of the earth's crust contain stresses that change with depth, area, lithology, history, etc. Drilling a hole in the ground relieves some stresses other than those in the vertical plane, and the hole geometry in relation to some stresses acts to concentrate them. If the borehole wall is not supported sufficiently by the mud column, it may fail either (1) in compression from the vertical stress or (2) in tension from the horizontal stress, or both.

The drilling process causes the formation of microcracks and fractures, and these act as areas of stress concentration and potential initial failure points. Thus it is sometimes noticed that part of a borehole may cave copiously for a short time and then become stable. This is because of the removal of the damaged zone (i.e., cavings) adjacent to the bore/formation interface. Formation is exposed that is more coherent and lacks concentrations of stress, thus it absorbs the extra energy without failing.

Cavings produced by underbalanced drilling are typically long, splintery, concave, and delicate (Fig. 52.14a). Cavings produced by stress relief tend to be more blocky and can vary in size tremendously, depending on the formation characteristics. Examples are shown in Fig. 52.14b.

Remember that if the cavings are clays, they may react with the mud and lose their distinctive morphology. Interpretations based on reactive clays should be pursued with caution. The quantity and nature of cavings should be regularly reported on the mud log or on a supplementary data log if pressure evaluation services are being performed.

Shale Bulk Density. Shale density determination can be of great value since it provides information on the compaction of the shale. Under normal conditions, shale

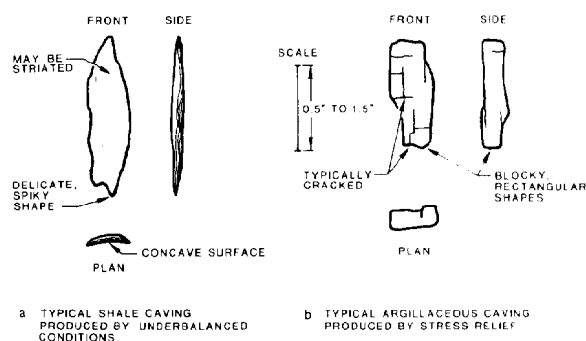

Fig. 52.14—Cavings resulting from underbalance and stress relief.

density should increase with depth. Any deviation from this consistent trend may indicate that geopressures exist. The magnitude of the bulk density change will vary with the type and magnitude of the geopressure. Often, the bulk density will decrease, but in other cases it may remain constant or continue to increase but at a lower rate than the previously established trend. Several methods are used for measurement of shale bulk density.

Pycnometer Method. By using a container with repeatable volume, this method involves measuring change of weight resulting from displacement of fluid by the sample. The most practical application of this method at the wellsite is to use a mud balance.

Place enough cuttings in the cup so that the balance indicates 8.34 lbm/gal (i.e., density of fresh water) with the cap on. Fill the cup with water and weigh again. The new reading is W_2 in the following equation.

$$\gamma_s = \frac{8.34}{16.68 - W_2}, \quad \dots \dots \dots (6)$$

where γ_s is the specific gravity of sample and W_2 is the "mud weight" of sample and water, lbm/gal.

Mercury Pump Method. The bulk volume of a known weight of sample is measured. The bulk weight of a prepared sample is first established using an accurate chemical balance. The bulk volume of selected cuttings is then determined using a high-pressure mercury pump by the Kobe system (Boyle's law principle) at a pressure of about 24 psi, which is recorded on the attached pressure gauge. Mercury is used to compress the air around the cuttings but does not contact the sample material.

The high accuracy of the instrument and large amount of sample used (approximately 25 g = 2,000 individual shale cuttings) give good consistency of results. Because of the accuracy and convenience in operation, this method should be used whenever possible; however, very careful and consistent sample handling is necessary for best results.

Buoyancy Method. The sample is weighed in air and in a liquid of known density. This is an alternative version of the pycnometer method. Theoretically, it should be a more accurate method if an accurate laboratory balance

is used. In practice, it is most inaccurate since the density of the liquid will vary with ambient temperature.

Density Comparison Methods. The simplest of these is the "float-and-sink" method. Shale cuttings are immersed in fluid mixtures of different densities in which they will either float or sink, depending on relative densities. This method is inexpensive and quick but is limited in sensitivity because of large difference in the densities of available fluids (approximately 0.1 to 0.05 g/cm³ and easy contamination of calibrated fluids.

Density Gradient Method. This consists of a fluid column in which density varies uniformly with depth. This is prepared by the partial mixing of a light fluid (neothene) and a heavy fluid (tetrabromoethane) in which beads of known density are suspended. A calibration curve of density vs. depth is prepared. Shale cuttings immersed in the column will sink to the level at which their density is the same as the fluid. Depth is recorded and density read off from the calibration curve.

Both of the heavy liquid methods (density comparison and density gradients), while being quick and simple, have the disadvantage of determining the density of individual cuttings. Special care must be taken to ensure that cuttings are true bottomhole cuttings, and several determinations should be made for each interval to avoid anomalous results. Six or eight cuttings should be chosen that are representative and free of dust or cracks that may

trap air and water and result in low apparent densities. In addition, the fluids used have unpleasant odors and some of them may be hazardous to health. Toxicity labels should be checked for specific mixtures but it is a good general rule to use these fluids in a fume hood or with a vapor extraction system.

It is commonly observed that shale density may decrease as much as 0.5 g/cm³ or more. If this reduction occurs over a significant depth interval, the calculated overburden gradient may reverse. The low-density zone also may change in lithologic character. Fissility, plasticity, carbonate content, color change, and other differences may not be apparent. Measurements from cuttings from water-based muds usually are too low, simply because of the adsorption characteristics of clays. Likewise, measurements taken from wireline logs can also give false indications. Specifically, the formation density log can be affected by a rugose hole and the shallow depth of investigation may not read beyond the hydrated zone. The result is erroneously low readings, causing excessive calculated porosities. The sonic log will be affected greatly by hydrated clays, resulting in very high transit times, high porosities, and too low densities.

Values may be successfully obtained from these logs when water-based muds are used, but caution should be exercised as errors may exist, as explained earlier.

Fig. 52.15—Shale data log.

The best densities are those obtained from wells drilled with less reactive muds, such as oil- or potash-based fluids. Both actual cutting densities and log densities should be accurate because the clay remains in its virgin state.

Increases in density beyond the normal trend because of decreased porosity or calcification should be noted carefully since these may constitute caprocks above geopressures. Precipitation of pyrite or high iron concentration results in abnormally high bulk densities in clays and shales. It has been proposed that in some wells the occurrence of pyrite in shales masked the density reduction caused by porosity increase. Careful microscopic examination of clays may indicate the occurrence of very fine pyrite, and high iron concentration is indicated by a red/brown color cast. Pore pressure interpretations cannot be accomplished by using shale density if heavy minerals are present; however, since shale density is mainly used for qualitative purposes in geopressure evaluation, the role of the other geopressure indicators remains unchanged.

Any decrease in density (without change in clay character) may be recognized as a pressure transition zone.

Recognition of a normal bulk density trend line may be difficult because of degree of scatter in the rectangular coordinate plot. A semilog plot considerably reduces this scatter, but the normal bulk density range (approximately 1.6 to 2.7 g/cm³) results in a more distorted trend line and difficulty in recognizing deviations (Fig. 52.15).

Shale Factor. Ion-exchange reactions take place between an adsorbent solid and a solution. Ions bound to the solid surface are released into the solution and other ions from the solution become fixed at the surface. Ion exchange can proceed by the exchange of positive ions (cations) or negative ions (anions) but not both. The reactivity of a solid compound in ion exchange reactions is governed by its specific surface (surface area per unit volume) and by the surface density of ion exchange sites (points on the surface where ions may be bound). Reactivity is expressed as cation or anion exchange capacity (CEC or AEC) using units of milliequivalents (of a suitable ion) per hundred grams (of the compound).

Various clay types have different CEC's and consequently different adsorption capacities. A smectite-rich clay will undergo diagenesis to illite with increasing temperature and ionic exchange. For diagenesis to proceed, water must be flushed from the clays. If potassium exchange cations are not available, a montmorillonite clay will lose its water but will not convert to illite. Thus, if this type of clay is drilled with a water-based mud, the clay will immediately rehydrate and cause severe drilling problems.

Shale factor is a measure of clay CEC. CEC will decrease as clays convert from montmorillonite-rich to illite-rich with temperature (and thus with depth). Pure montmorillonite clays have a CEC of approximately 100 meq/100 g. Pure illites show no swelling characteristics, but their CEC is generally between 10 and 40 meq/100 g. Kaolinites have a CEC of approximately 10 meq/100 g. Of the most common clay types, it is only the smectite group (including montmorillonite) that has an affinity for water. Thus, any clay zone that contains montmorillonite

Fig. 52.16—Shale factor response.

will have an affinity for water in an amount proportional to the montmorillonite content, and this will be shown by a proportional value of shale factor. Note that the shale factor as measured at the wellsite will not give values corresponding to actual chemical CEC. This is because of impurities in the sample, methodology, experimental error, and the fact that the methylene blue dye (used in the titration) is a very large molecule and thus cannot be adsorbed in interlayer sites.

If the clay is calcareous, and calcimetry is also being performed, then the shale factor may be corrected for carbonate content as given by

$$F_{sht} = \frac{100}{100 - C_{carb}} \times F_{sha}, \dots\dots\dots (7)$$

where

F_{sht} = true shale factor, meq/100 g,

F_{sha} = apparent shale factor, meq/100 g, and

C_{carb} = carbonate content, %.

For example, a calcareous clay has a carbonate content of 37%, and an apparent shale factor of 16:

$$F_{sht} = \frac{100}{100 - 37} (16) = 25 \text{ meq/100 g.}$$

Theoretically, shale factor should indicate whether montmorillonite dehydration or compaction disequilibrium was the major mechanism in generating an apparent geopressure. Geopressures caused by compaction disequilibrium indicate that the pressured zone is immature with respect to shallower, normally pressured sediments. This implies that diagenesis has been restricted by the inefficiency of the dewatering mechanism, resulting in clays containing a larger proportion of montmorillonite within the geopressed zone. Shale factor would thus decrease to the top of the geopressed zone, increase within the zone, and then decrease as the pore pressure gradients decline (Fig. 52.16). Any overall increase in shale factor within a geopressed zone indicates that compaction disequilibrium has played a part in its formation.

Fig. 52.17—Distortion of heat flow around an insulating geopressed zone.

If, however, a geopressed zone was caused by montmorillonite dehydration, then upon entering the interval a sharp decrease in montmorillonite content will be observed. Hence the geopressed zone will contain less montmorillonite, because it has been converted to illite, which releases to the pore spaces water that has been unable to escape fast enough and results in a pore pressure increase. Shale factor thus will decrease in the pressured zone (Fig. 52.16).

Shale factor cannot be a geopressure indicator. The differing responses described are not definitive, and geopressure has to be indicated from other sources before an interpretation by use of shale factor can be achieved. Geopressures caused by montmorillonite dehydration and compaction disequilibrium may cause no change in shale factor; also, if geopressures were caused by another process (e.g., aquathermal pressuring that results when trapped pore fluids are heated but are unable to expand and is therefore independent of matrix composition), a change may not be reflected in shale factor with depth.

In the past, the consensus was that shale factor should increase in geopressed zones and could thus act as an indicator. Re-evaluation of the various geopressure mechanisms show that this is not necessarily the case. However, shale factor should be capable of delineating between compaction disequilibrium and montmorillonite dehydration as the major geopressure mechanism.

Flowline Temperature. The geothermal gradient, the rate at which subsurface temperature increases with depth, can be calculated from

$$g_G = \frac{T_2 - T_1}{D_2 - D_1} (100), \dots \dots \dots (8)$$

where

g_G = geothermal gradient, °C/100 m,
 T_1 = temperature, °C (at depth D_1 , m), and
 T_2 = temperature, °C (at depth D_2 , m).

For any given area, the geothermal gradient is usually assumed constant. While the average gradient across

normally pressured formations may be constant, geopressed formations exhibit abnormally high geothermal gradients.¹³

Since a constant flow of heat occurs radially from the earth's core to the surface, the total flow of heat across any depth increment will be constant. However, the temperature differential across an increment depends on the thermal conductivity of the material. Since overall heat flow from the earth's surface is generally constant within any particular area, the heat flux through the various formations with depth is in equilibrium. The rate of change of temperature across a formation with a low thermal conductivity (caused mainly by high porosity) will be high; conversely, a low geothermal gradient is indicative of high thermal conductivity formations—i.e., lower porosity. Water and hydrocarbon migration to shallower depths may also affect the geothermal gradient. Pore fluids, as insulators, retain heat so that on migration these hot fluids modify the temperatures of the formations that they pass through and ultimately become trapped. Fowler¹⁴ cited examples from the Middle East, Canada, and U.S. oil fields of geothermal gradient bulges that indicated possible entrapment of hot fluids from greater depths. The mechanism also may be related to montmorillonite dehydration, because the huge volume of water squeezed from the clay provides the impetus for migration. "Dead" basins (i.e., no source rocks) have been shown to exhibit normal geothermal gradients, hence on initial exploration wells the geothermal gradient may indicate the potential of the whole area.

An insulating zone produces a distortion in the isothermal lines that normally run perpendicular to the lines of heat flow (Fig. 52.17; Ref. 15).

Because of the high geothermal gradient, these are more closely spaced in the insulating zone. In the zones above and below, the isothermal lines are more widely spaced in compensation and the zones exhibit a reduced geothermal gradient. The converse occurs in beds of high thermal conductivity (i.e., sands and some limestones).

Since water has a thermal conductivity of about one-third to one-sixth that of most rock matrix materials, it can be seen that thermal conductivity is directly related to the degree of compaction of a formation. The higher-than-normal water content of geopressed shales reduces the thermal conductivity. Therefore, the top of a geopressed zone is marked by a sharp increase in geothermal gradient. The temperature of the mud at the flowline may reflect the geotemperature, and recording of flowline temperature is a practical method to determine temperature gradient, provided variable factors such as pump rate, lag time, ambient temperature, lithology, and temperature changes at the surface that are caused by mud mixing and chemical treatments can be accounted for. In areas where large annual temperature variations occur, considerable differences may be noted in flowline temperatures; even diurnal temperature fluctuations may cause a 10°C variation in flowline temperature while drilling.

Prior to reaching a geopressed zone, a temperature transition zone will be encountered in which, because of distortion of the isothermal lines, there will be a reduction in geothermal gradient. In practice, this effect is

Fig. 52.18—Flowline temperature log.

reflected in the flowline temperature gradient, even to the extent of a fall in flowline temperature (i.e., a negative gradient), followed by an extremely large increase in flowline temperature as the geopressured zone is penetrated (Fig. 52.18).

A dual temperature probe system with sensors at the flowline and suction pit is effective in removing surface effect, if lagged differential temperature is plotted. It is normally sufficient for the points to be plotted at 30-ft intervals unless more frequent temperature variation is noticed, but points plotted at 10-ft intervals allow more accurate data and better resolution for improved interpretation. Circulations, mud additions, water additions, and other significant events should be noted.

It is found that the resultant temperature curve is broken when the bit is changed, or during short trips or other downtime, and a certain time is necessary for the mud system to re-establish a temperature equilibrium upon circulation. The rate at which this thermal equilibrium is re-established may be significant, as a more rapid re-establishment may indicate an increased geothermal gradient. Drilling variables that affect the

rate of re-establishment of equilibrium include total mud volume. The practice of reducing active pit volume to a minimum, dictated by hole size, aids in reducing the time required to attain equilibrium after tripping and reduces the circulation time needed to stabilize flowline temperature. A discontinuity in the plot also occurs at each casing depth and corresponds to a change in hole size. A higher annular velocity in open hole reduces the amount of heat gained from exposed formations, and a lower annular velocity in the marine riser increases the amount of heat lost to the sea. However, these factors only lead to a change in measured temperature; the rate of change of temperature should remain unchanged. Since pressure predictions can be based on temperature gradient rather than on temperature magnitude, each depth segment between discontinuities can be analyzed separately for gradient trends. It is also helpful to replot a smoothed curve of segments end to end without regard for absolute temperature values. In certain cases it has been found that, instead of plotting the individual segments as an end-to-end smoothed curve, end-to-end plotting of the individual segment trend lines may be of

Fig. 52.19—Response of drilling rate to geopressure.

value. This trend-to-trend smoothed curve is merely a graphical method of removing irrelevant scatter from the plot.

The reduction in temperature gradient caused by distortion of isothermal lines may be noticed before the geopressured zone is encountered; that is, an advance warning of geopressure may be given. Thus a fall in flowline temperature gradient followed by a sharp rise when the geopressure transition zone is drilled provides a warning that even closer attention must be paid to other drilling parameters to achieve confirmation of possible geopressures. However, like other methods of pressure evaluation, flowline temperature reflects a varying physical parameter in an assumed constant rock type; therefore, changes in lithology must be closely monitored to avoid false indications.

Drilling Models. Bingham¹⁶ proposed that the relationship between ROP, weight on bit (WOB), rotary speed, and bit diameter may be expressed in the general form

$$\frac{R}{N} = K_D \left(\frac{W}{d_b} \right)^d, \quad \dots \dots \dots (9)$$

where

- R = ROP, ft/min,
- N = rotary speed, rev/min,
- d_b = bit diameter, ft,
- W = WOB, lbm,
- K_D = matrix strength constant (dimensionless),
- and
- d = formation "drillability" exponent (dimensionless).

Jorden and Shirley¹⁷ solved Eq. 9 for d , inserted constants to allow common oilfield units to be used and to produce values of d -exponent in a convenient workable range. Most important, however, they let K_D be unity,

removing the need to derive empirical matrix strength constants, but making d -exponent lithology-specific as in

$$d = \frac{\log \left(\frac{R}{60N} \right)}{\log \left(\frac{12W}{10^6 d_b} \right)}, \quad \dots \dots \dots (10)$$

where

- d = drilling exponent (dimensionless),
- R = ROP, ft/hr,
- N = rotary speed, rev/min,
- W = WOB, lbm, and
- d_b = bit diameter, in.

In a constant lithology, d -exponent will increase as the depth, compaction, and differential pressure across bottom increase. Upon penetration of a geopressured zone, compaction and differential pressure will decrease and be reflected by a decrease in d -exponent (Fig. 52.19).

Differential pressure is dependent on mud density as well as formation pore pressure. Therefore, any change in the mud density used promotes an unwanted change in d -exponent.

Rehm and McClendon¹⁸ proposed a "mud weight corrected" drilling exponent of the form

$$d_{xc} = \frac{\log \left(\frac{R}{60N} \right)}{\log \left(\frac{12W}{10^3 d_b} \right)} \left(\frac{g_{nfb}}{\rho_{ec}} \right), \quad \dots \dots \dots (11)$$

where

- d_{xc} = corrected d -exponent (dimensionless),
- R = ROP, ft/hr,
- N = rotary speed, rev/min,
- d_b = bit diameter, in.,
- g_{nfb} = normal formation balance gradient, lbm/gal,
- ρ_{ec} = effective circulating density, lbm/gal, and
- W = WOB, 1,000 lbm,

or in the metric form

$$d_{xc} = \frac{\log \left(\frac{R}{18.29N} \right)}{\log \left(\frac{W}{14.88 d_b} \right)} \left(\frac{g_{nfb}}{\rho_{ec}} \right), \quad \dots \dots \dots (12)$$

with R in m/hr, N in rpm, W in tonnes (1,000 kg), d_b in cm, and g_{nfb} and ρ_{ec} in g/cm³.

This correction was empirically derived but has been applied worldwide with much success. The use of actual mud density in place of effective circulating density (ECD) has been found to be acceptable within normal limits of accuracy. ECD should, however, be used when available.

Factors not considered by d -exponent in its basic form are drilling hydraulics, tooth efficiency, and matrix strength.

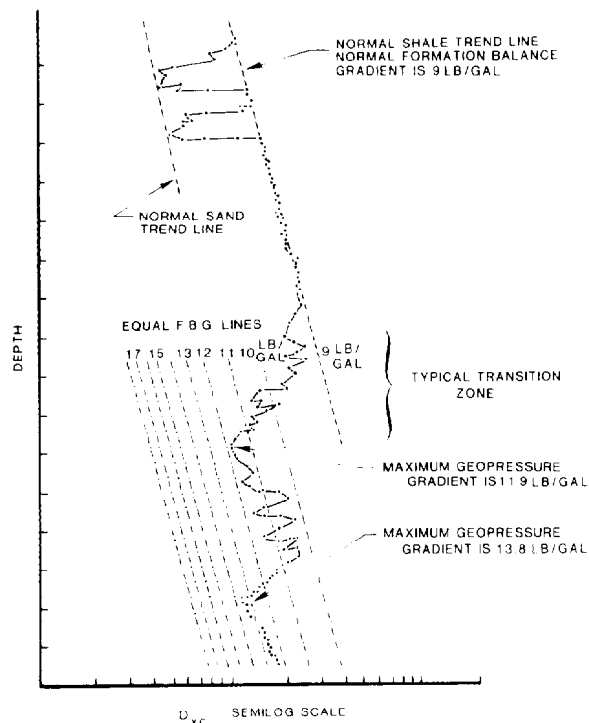

Fig. 52.20—Example of formation pore pressure gradients for d_{xc} plot.

Drilling hydraulics become important in large holes where efficient hole cleaning is impossible and in soft formation where jetting will make a large contribution to drilling.

Matrix strength controls both magnitude and rate of change of d -exponent with depth.

Tooth efficiency can affect d -exponent in two ways: (1) tooth wear will cause a gradual increase in d -exponent (i.e., decrease in ROP), and (2) a change of bit type may produce a change in d -exponent, especially if the change is a radical one (e.g., from milled-tooth bit to an insert or diamond bit).

If differential pressure becomes large, the simple ratio correction to the d -exponent will not eradicate the effect on ROP.

Furthermore, the relationships among force applied, W/d_b , rotary speed, N , differential pressure, g_{nh}/ρ_{ec} , and ROP, R , are more complex than the d -exponent formulation would imply. While working well within certain normal working ranges, radical changes in any of these parameters (for example, change in hole size after setting casing) may result in a shift in d -exponent trend.

When plotted on a logarithmic scale against depth, the d -exponent will exhibit an approximately linear increasing trend through "normal," hydrostatically pressured formations. Where geopressure, abnormally high formation fluid pressure is encountered, d -exponent values will fall consistently below the extrapolation of this normal trend. It has been shown empirically that d -exponent deviation may be related to formation pore pressure anomaly by the simple ratio

$$\frac{p_{pa}}{p_{pn}} = \frac{d_{xcn}}{d_{xco}}, \dots (13)$$

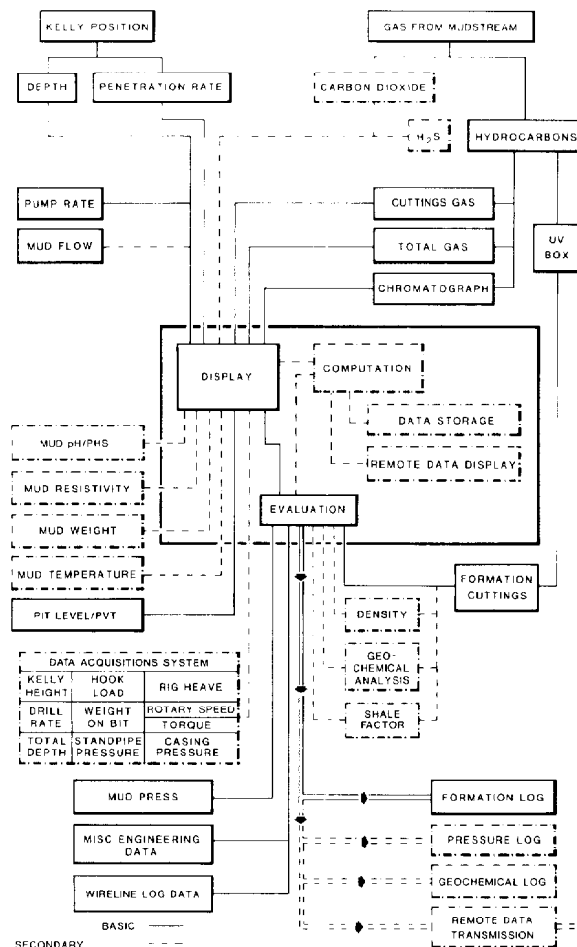

Fig. 52.21—Logging unit systems.

where

p_{pa} = actual pore pressure at depth of interest, psi, or formation balance gradient, lbm/gal equivalent mud density (EMD),

p_{pn} = normal pore pressure, psi, or formation balance gradient, lbm/gal (EMD),

d_{xco} = observed corrected d -exponent at depth of interest, and

d_{xcn} = expected corrected d -exponent on normal trend line at depth of interest.

Using this relationship, it is possible to calculate pore pressure or formation balance gradient (equivalent mud density to balance pore pressure) from d -exponent. Alternatively, the relationship may be used to prepare an overlay allowing direct reading of formation balance gradient from the d -exponent plot (Fig. 52.20).

Drilling exponents may be calculated from driller's data using a simple calculator and manual plotting and trend recognition. However, quality of the data is greatly improved when a data-acquisition system provides WOB, rotary speed, and mud density directly to the logging unit and a minicomputer is used to read these sensors automatically, to perform the calculations, and to print or plot the results. Computer-equipped mud log-

Fig. 52.22—Formation pressure log.

ging units were introduced to provide pressure evaluation services in areas of known geopressed problems (e.g., offshore U.S. gulf coast) and high-risk, hazardous exploration areas (e.g., the North Sea). Fig. 52.21 shows the available equipment configurations of a computerized logging unit. In addition to pore pressure, this type of unit commonly provides a pressure log including supplementary calculations of fracture pressure, overburden pressure, and kick tolerance (Fig. 52.22).

Petrophysical Measurements

Mud Log Data. As discussed previously, mud log data are qualitative in nature. It is not possible with conventional mud log measurements to obtain quantitative values of such parameters as porosity, permeability, hydrocarbon saturations, etc. However, the mud logging unit may provide special equipment or services, allowing more quantitative evaluations.

For example, while a mud log gas analysis cannot be truly representative of gas production composition, gas analysis of recovered fluids from a well test can be. Using conventional gas analyzers and chromatograph, a quantitative analysis of recovered natural gas may be obtained. For more complex fluids, special chromatographs, pyrolyzers, or analyzers can give complete analysis of oils or sour gas. The logging unit also may provide ionic analysis of recovered waters and, by use of tritium (^3H) or nitrate (NO_3^-) tracers, provide discrimination between recovery of mud filtrate and true formation water. These types of service can be of special

value in remote locations where logistics or distance prevent rapid transport of samples to an analytical laboratory.

Core Analysis. In addition to gas and fluid analysis, conventional core analyses¹⁹ (porosity, bulk density, permeability, and saturations) also may be performed in the logging unit when the drilling operation is remote from the laboratory. Wellsite core analysis offers the advantages of rapid evaluation and high-quality samples from fresh core but is rarely of the high quality to be expected from the specialized equipment and personnel in a core laboratory. A new technique, which is suitable to the logging unit, uses a pulsed nuclear magnetic resonance analyzer to determine fluid content, total and free-fluid porosity, and permeability. This device, working on a principle analogous to the nuclear magnetic logging tool (NML), provides accurate, repeatable data from minimal quantities of sample and without complex sample preparation. Samples may be obtained without causing core or sidewall core destruction and the test may be performed on cuttings.

Drilling Porosity

The d -exponent (Fig. 52.20) develops a consistent trend with depth controlled by increasing overburden loading and compaction. Changes in formation pore pressure gradient will result in major, consistent deviations from this trend. The d -exponent data also will exhibit minor,

Fig. 52.23—Drilling porosity log.

inconsistent scatter about the prevailing trend, reflecting continuous variation in rock mineralogy, cohesion, and porosity.

More sophisticated, second-generation drilling exponents are able to isolate the major pore pressure and minor rock character variations. With this type of analysis it is possible to provide a continuous log of pore pressure and "drilling porosity." It is important to remember that drilling porosity, although scaled in percentage units, is not a true porosity measurement. It is primarily a rock strength indicator, reflecting both porosity and intergrain cohesion. As such, its response is very similar to that of the sonic log, and the two logs correlate extremely well (Fig. 52.23).

Unlike the *d*-exponent, the second generation drilling exponents require complex manipulations and iterations, limiting their use to logging units equipped with a computer. Also, unlike the *d*-exponent, they do not involve a widely published and used single method. Although based on similar drilling response models, all mud logging contractors offer drilling porosity logs involving their own unique mathematical methods that are commonly held as proprietary secrets. While understandable from a commercial view, this policy places the user in the position of being able to judge the value and reliability of a particular log only on the bases of his or her own experience and limited published results. It is hoped that, with the maturation of this type of service, wider publication and discussion of methods will begin.

Drilling Engineering Services

The mud logging unit can provide two levels of service of value to the drilling engineer—data acquisition and data analysis.

Data Acquisition

An automatic data acquisition system located in the logging unit will monitor sensors installed on equipment, flowline, mud pits, pumps, etc. Simple calculations are performed on the data (e.g., calculation of total depth and ROP, summation of pit volumes, comparison of current values with high- and low-alarm setpoints). Results then are displayed on TV monitors at various locations around the rig and may be recorded on a printer or magnetic tape. By use of a dedicated land line or satellite link, data can be transmitted to a remote location, allowing several rigs to be monitored from a single central control room.

This type of equipment was introduced by mud logging service companies as a means of obtaining drilling and mud data more reliably and rapidly than could be expected from standard rig instrumentation. While these data were required initially for pressure evaluation analyses, the data acquisition system provided an important secondary function as a rig monitoring service by supplying the drilling engineer accurate, up-to-date drilling information while away from the rig floor and a complete foot-by-foot record of drilling progress and performance on paper or magnetic tape.

Since that time, several conventional rig instrumentation manufacturers have upgraded their product lines to include similar data acquisition systems that operate in an unmanned, or "stand-alone," mode. While this offers the operator the advantage of flexibility in selecting services (i.e., the mud logging service best suited to the geologist and the data acquisition service best suited to the engineer), it does have drawbacks.

Reliability of a data acquisition system is primarily controlled by the operation of its sensors. In the rigorous environment of the rig this requires regular attention. The success of a stand-alone data acquisition system is related entirely to the training and motivation of the rig crew or the availability of manufacturer's service personnel.

The mud logging unit is manned at all times. Trained personnel are available at all times to calibrate, maintain, and service the data acquisition system and its sensors. Since these personnel are already at the wellsite as part of the mud logging service, this extra margin of reliability is achieved without extra cost beyond the similar cost of the data acquisition hardware.

Data Analysis

Beyond simple data acquisition, the mud logging service also may supply computers, software, and specialized wellsite personnel for drilling data analysis. The desirability of such services depends on the difficulty and cost of the drilling operation, availability of oil company expertise at the wellsite, and quality of communication with the exploration headquarters.

For example, infill drilling in an established domestic field using a well-developed drilling program, experienced wellsite supervisors, and close communication with home office requires data acquisition only as a means of monitoring optimal and safe adherence to the drilling program. On the other hand, on an offshore wildcat, the availability of data analysis and expertise at the wellsite can be very cost effective.²⁰ An increase in drilling efficiency or a decrease in downtime sufficient to save a single day of rig time can, in these circumstances, produce sufficient savings to pay for data analysis services for the whole well.

Data analysis services offered include: (1) bit optimization—selection of bit type and operating parameters to optimize bit ROP and bit life; (2) bit economics—cost per unit depth and breakeven calculation between bit types; (3) drilling hydraulics²¹—optimization of drillstring, nozzle, and annulus hydraulics; (4) directional analysis—determination of well path, bottomhole position, and intersection points for deviated wells; (5) trip monitoring—calculation of string weights, swab pressures and fillup requirements for tripping, monitoring of pit level deviations, and overpull (frictional drag in the borehole); (6) casing calculations—assembly of casing tally, calculation of cement volumes and mixing requirements, and monitoring of displacement; (7) pressure control—calculation of mud weight, volume and pressure requirements for safe well control¹⁰; and (8) logistics—usage and inventory control of well expandables, equipment maintenance scheduling, well progress data base, and report generation.

Selecting a Mud Logging Service

Mud logging contractors commonly offer three levels of standard service: (1) standard mud logging; (2) mud logging and data acquisition, and (3) mud logging and data analysis (including pressure evaluation). For the most basic level of mud logging, a single operator may be responsible for 24-hour operation. More sophisticated services and data acquisition usually require two geologists working 12-hour tours. Data analysis services require two people, a geologist and an engineer, on each tour.

Each of these services may be augmented with extra equipment such as sensors, special gas detectors, pyroanalyzers, more powerful computers or peripherals and specialist personnel at extra day rate as the drilling program demands.^{2,10}

At least two mud logging contractors now offer an additional, fourth level of service in which mud logging and data analysis are combined with an MWD service.

Very little of the information gathered by a mud logging unit is not obtainable from some other source. For example, stand-alone instrumentation can monitor gas, mud, and drilling parameters; rig crews can catch samples; porosity is available from wireline logs; and oil company geologists and engineers may perform geological evaluation and drilling data analysis. Why then is mud logging such a widely used service?

The advantage of mud logging service is that all these data may be derived from a single source, the mud logging unit, located at the wellsite and continuously manned with dedicated, specially trained personnel. Therefore the data are obtained more reliably, more quickly, and usually more economically than from any other combination of sources.

Reliability and speed therefore are the tests required in selecting a mud logging contractor. The equipment must be designed and maintained adequately to provide reliable and safe operation in the rigorous wellsite environment. The wellsite crew must be trained to operate, maintain, and troubleshoot the equipment and to understand its output. The contractor must maintain adequate service personnel and inventory to allow rapid repair or changeout in the event of major malfunctions. The logging crew must be trained in geological and engineering theory, be experienced in practical drilling operations, and have a thorough knowledge of the geological section, drilling program, and operational procedures of the particular well and operator.

Once a contractor is selected, economy becomes the prime consideration in choosing a level of service. In day-rate drilling, time and money may be directly equated. Any service that speeds well progress, reduces downtime, or promotes decision-making is potentially a cost saver. Even on footage drilling, personnel, communications, etc., are cost-generating factors which may be reduced by improved drilling efficiency. On rank wildcat exploration wells, the "bird in the hand" philosophy may be desirable to obtain data at the earliest possible time as a hedge against the risk of it being unavailable later. For example, to obtain porosity measurements from the mud logging unit while drilling is an investment against later borehole loss or damage that may prevent later wireline logging.

Quantification of cost saving is possible by using the same methods used to calculate drilling cost per foot. In its simplest form this is

$$C_d = \frac{C_{be} + C_r t_l}{D_t}, \dots\dots\dots (14)$$

where

C_d = drilling cost, \$/m,
 C_r = rig cost, \$/D,
 C_{be} = cost of bits and expendables, \$,
 t_l = time on location, days,
 D_t = total well depth, m.

For optimization of services and products this can be expanded to the form

$$C_d = [(C_{F1} + C_{F2} + \dots C_{Fn}) + (C_{dr1} + C_{dr2} \dots C_{drn}) \times (t_r + t_t + t_o + t_e + t_d)] \div D_t \dots\dots\dots (15)$$

and

$$C_d \times D_t = \Sigma(C_F)_n + \Sigma(C_{dr})_n \times \Sigma(t)_n, \dots\dots\dots (16)$$

where

C_F = individual fixed cost items or footage charges services, \$,
 C_{dr} = individual day rate services, rentals, salaries, etc., \$,
 t_r = rotating time, days,
 t_t = tripping time, days,
 t_o = off-bottom time (reaming, conditioning, well control, etc.), days,
 t_e = evaluation time (logging, testing, coring, etc.), days, and
 t_d = downtime (breakdowns, weather, decision making, etc.), days.

Using this formulation, it is possible to calculate the decrease in one cost category required to offset an increase in any other.

For example, consider the use of drilling optimization. Let us assume, conservatively, that regional statistics indicate that by upgrading a mud logging unit to include data acquisition equipment no overall ROP improvement is obtained but that a well can be completed using one less bit. Well cost as a result of this is given by

$$(C_d \times D_t)' = [\Sigma(C_F)_n - \Delta C_{Fb1}] + [\Sigma(C_{dr})_n + \Delta C_{xr}] [\Sigma(t_l)_n - \Delta t_{tl}], \dots (17)$$

where

ΔC_{Fb1} = cost of one bit saved, dollars,
 ΔC_{xr} = extra cost of mud logging, dollars/D,
 $(t_l)_n$ = total time on location, days
 Δt_{tl} = time for one trip saved, day, and
 $(C_d \times D_t)'$ = well cost, dollars.

For cost effectiveness (i.e., for the additional service to save its own cost or more), overall well cost must be unchanged or reduced. Thus,

$$\Delta(C_d \times D_t) = (C_d \times D_t)' - (C_d \times D_t) \leq 0, \dots\dots\dots (18)$$

$$\Delta(C_d \times D_t) = -\Delta C_{Fb1} - [\Sigma(C_{dr})_n \times \Delta t_{tl}] + \Delta C_{xr} \times [\Sigma(t_l)_n - \Delta t_{tl}], \dots\dots\dots (19)$$

and

$$\Delta C_{xr} \leq \frac{\Delta C_{Fb1} + [\Sigma(C_{dr})_n \times \Delta t_{tl}]}{[\Sigma(t_l)_n - \Delta t_{tl}]} \dots\dots\dots (20)$$

If this is evaluated as true, that the day rate for the extra equipment is in fact less than the evaluated expression, then the service is cost effective on the particular well. In this case, substituting some reasonable figures such as:

Onshore	Offshore
$\Delta C_{Fb1} = \$1,000$	$\Delta C_{Fb1} = \$1,000$
$\Sigma(C_{dr})_n = \$6,000/D$	$\Sigma(C_{dr})_n = \$19,000/D$
$\Delta t_{tl} = 12 \text{ hours} = 0.5 \text{ day}$	$\Delta t_{tl} = 12 \text{ hours} = 0.5 \text{ day}$
$\Sigma(t_l)_n = 30 \text{ days}$	$\Sigma(t_l)_n = 35 \text{ days}$

we obtain for onshore:

$$\Delta C_{xr} \leq \frac{1,000 + (6,000)(0.5)}{(30 - 0.5)} = \$135.59/D.$$

The extra equipment will result in an overall cost saving on the well so long as it does not increase the mud logging daily rate by more than \$135/D.

We obtain for offshore:

$$\Delta C_{xr} \leq \frac{1,000 + (19,000)(0.5)}{(35 - 0.5)} = \$304.35/D.$$

Using these same figures, let us now assume that, in addition to saving one bit, an overall decrease of 5% in drilling time is also achieved. If $t_r = 21$ days, saving in rotating time = $21 \times 5\% = 1.05$ days, then for onshore:

$$\Delta C_{xr} \leq \frac{1,000 + [6,000 (0.5 + 1.05)]}{(30 - 0.5 - 1.05)} = \$362.04/D.$$

For offshore:

$$\Delta C_{xr} \leq \frac{1,000 + [19,000 (0.5 + 1.05)]}{(35 - 0.5 - 1.05)} = \$910.31/D.$$

These cost justifications, or cost savings, refer only to the *extra* cost of data acquisition above that of standard mud logging and include only those benefits resulting from drilling optimization. Other cost savings resulting from better rig and mud monitoring and well control may also be quantifiable from a study of regional drilling statistics.

A cost benefit analysis of this type is a worthwhile approach to all aspects of drilling cost reduction. Cost saving resulting from advanced evaluation and monitoring commonly is appreciated in expensive offshore exploration. As the above examples show, such techniques may be equally successful in comparatively cheaper onshore development drilling, especially where problems such as geopressure or crooked holes occur.

Standards For and Status of Services

The terms "mud logging" covers a diverse range of services and qualities of service. It is regrettable that, in the U.S. especially, the whole industry is accorded a status reflecting its lowest level. Field employees of the higher quality and more reputable contractors commonly eschew the term "mud logger," preferring the title "logging geologist" or "logging engineer," depending on their educational background. The wide range of equipment and techniques used by such companies commonly results in their personnel being the best educated and trained service personnel present on any wellsite.

In 1980, the Soc. of Professional Well Log Analysts (SPWLA) established a Hydrocarbon Well Log Standards Committee comprising members of both the service company and exploration company sides of the field. The efforts of the committee have done much toward establishing standards and status representative of the best of the industry.^{22,23} I express my gratitude to this committee and its members for these efforts and for assistance in the development of this chapter.

Nomenclature

C_{be}	= cost of bits and expendables, dollars
C_{carb}	= carbonate content, %
C_d	= drilling cost, dollars/m
C_{dr}	= individual day rate services, rentals, salaries, etc., dollars
C_F	= individual fixed cost items or footage charges services, dollars
C_r	= rig cost, dollars/D
d	= formation "drillability" exponent (dimensionless)
d_b	= bit diameter, ft or in.
d_n	= "normal" bit diameter (m)
d_{oB}	= observed bit diameter (m)
d_{xc}	= corrected d -exponent (dimensionless)
d_{xcn}	= expected corrected d -exponent on normal trend line at depth of interest
d_{xco}	= observed corrected d -exponent at depth of interest
F_{sha}	= apparent shale factor, meq/100 g
F_{shf}	= true shale factor, meq/100 g
G_{pn}	= normalized total gas (%)
G_{poB}	= observed total gas (%)

g_G	= geothermal gradient, °C/100 m
g_{nfb}	= normal formation balance gradient, lbm/gal
K_D	= matrix strength constant (dimensionless)
N	= rotary-speed, rev/min
p_{pa}	= actual pore pressure at depth of interest, psi, or formation balance gradient, lbm/gal equivalent mud density (EMD)
p_{pn}	= normal pore pressure, psi, or formation balance gradient, lbm/gal (EMD)
q_n	= "normal" mud flow rate (m ³ /s)
q_{oB}	= observed mud flow rate (m ³ /s)
q_p	= pump output, m ³ /s)
R	= ROP, ft/min
R_n	= "normal" ROP (m/s)
R_{oB}	= observed ROP (m/s)
t_d	= downtime (breakdowns, weather, decision making, etc.), days
t_e	= evaluation time (logging, testing, coring, etc.), days
t_l	= lag time, seconds
$(t_l)_n$	= total time on location, days
t_o	= off-bottom time (reaming, conditioning, well control, etc.), days
t_r	= rotating time, days
t_t	= tripping time, days
V_{an}	= annular volume, m ³ /m
V_h	= hole capacity, m ³ /m
V_p	= pipe capacity and displacement, m ³ /m
v_{an}	= annular velocity, m/s
W	= WOB, lbm
$(C_d \times D_t)'$	= well cost, dollars
ΔC_{Fb1}	= cost of one bit saved, dollars
ΔC_{xr}	= extra cost of mud logging, dollars/D
Δt_{tl}	= time for one trip saved, day
ρ_{ec}	= effective circulating density, lbm/gal

Chapter 53

Other Well Logs

Richard M. Bateman, Vizilog Inc.*

Introduction

Many well logs generally are not classified as electrical, nuclear, or acoustic logs. The most important of these are discussed in this chapter. Included as miscellaneous well logs are: (1) measurements taken while drilling (MWD), (2) directional surveys, (3) dipmeter logs, (4) caliper logs, and (5) casing inspection logs. All of these are used by the petroleum engineer on occasions. The logs are discussed in the order listed, which was selected for convenience only and is unrelated to the importance of the logs.

MWD

MWD plays an increasingly important role in modern drilling practices. It allows an operator almost immediate feedback on both the geometry of the hole being drilled and the characteristics of the formations penetrated. Without MWD this kind of information is available only from conventional sources such as deviation surveys and logs that, a priori, must be run after the drilling has taken place. Of particular benefit, MWD can be applied when drilling directional wells and/or when overpressured formations are of concern.

By having the kind of information MWD can supply more or less in real time, the driller may take appropriate action, such as changing the weight on bit (WOB), increasing the mud weight, or pulling out of the hole for a conventional logging run once the desired formation has been reached.

Many different MWD measuring systems are in commercial use today. However, they all have common characteristics: (1) a downhole sensor sub, (2) a power source, (3) a telemetry system, and (4) surface equipment. The downhole sensor subs may contain instrumentation capable of measuring parameters such as torque,

WOB, borehole pressure, borehole temperature, tool face angle, natural formation gamma ray activity, formation acoustic travel time, formation resistivity, hole deviation from vertical, and hole azimuth with respect to geographic coordinates. The sensors and the telemetry system can be activated by a surface power source, a downhole turbine, or downhole batteries. In the case of a surface power source it is necessary to make electrical connections between the surface and the downhole sensors, which, in turn, requires either special drillpipe or an electric cable. With a downhole turbine the circulating mud itself drives an electric generator located in the MWD drill collar. This, in turn, leads to an increase in the hydraulic horsepower required of the mud pumps to maintain circulation. In the case of batteries no special cabling or additional mud pumping is required, but the MWD system is limited by the life of the batteries used. Once they are discharged no further measurements can be made and the MWD sub must be retrieved and redressed with fresh batteries.

The telemetry system most commonly used is that of coded mud pressure pulses. The output from a specific sensor is converted from analog to a digital form and encoded as a series of pressure pulses, which are detected and decoded at the surface. The pressure pulses may be in the form of overpressure or underpressure anomalies introduced, respectively, by either a relief valve "shorting" the mud circulation or a check valve "choking" it.

However, coded mud pressure pulses are not the only means available for telemetry. Other methods, either in use or under experimentation, include: (1) electromagnetic e-mode (electric current) or h-mode (magnetic field); (2) acoustic telemetry through drillpipe and/or tubing in straight hole, or through the earth by seismic waves; (3) hardwire systems; (4) systems with self-energizing repeaters; and (5) hybrid systems that combine various transmission methods.¹

* Author of the original chapter on this topic, entitled "Miscellaneous Well Logs," in the 1962 edition was A.J. Pearson.

Fig. 53.1—Typical MWD downhole assembly.

The surface equipment consists of a decoder of the mud pulses (or other parameter, depending on the telemetry system in use) together with signal processing hardware and software that together produce the data that the drilling engineer needs. Output may be in the form of a visual display, either on the rig floor or at a remote site, or as a hard copy listing, or log, of the parameters recorded. Data also may be recorded on magnetic tape for future use.

In most systems, the transmission of data to the surface is selective. For example, a measurement of hole deviation and azimuth may require that the drilling process be suspended temporarily and the drillstring held motionless for a short period. Readings then are accumulated in a "buffer" and only transmitted to the surface when mud circulation recommences.

Fig. 53.1 illustrates an MWD downhole assembly with its mud pulse transmitter, turbine generator, and sensor sub.

Fig. 53.2 shows a data transmission schematic for MWD. Typically, each measurement or "word" is transmitted as part of a data frame, which in turn consists of a synchronization word and 15 measurement words. Some measurements are transmitted more than once in each frame. Current telemetry systems are capable of transmitting a complete frame in a matter of 1 or 2 minutes. The actual sampling rate in terms of measurements per unit of depth is inversely proportional to the rate of penetration (unit of depth/ unit of time).²

Fig. 53.3 shows a complete MWD logging system schematic and integrates surface and downhole sensors, the telemetry system, the surface hardware and software (for computer processing of the data), and the final product in the form of a log.³

Fig. 53.4 shows an MWD log on which is displayed gamma-ray, short normal resistivity, annular temperature, downhole WOB, surface WOB, and computed directional data (drift and azimuth).

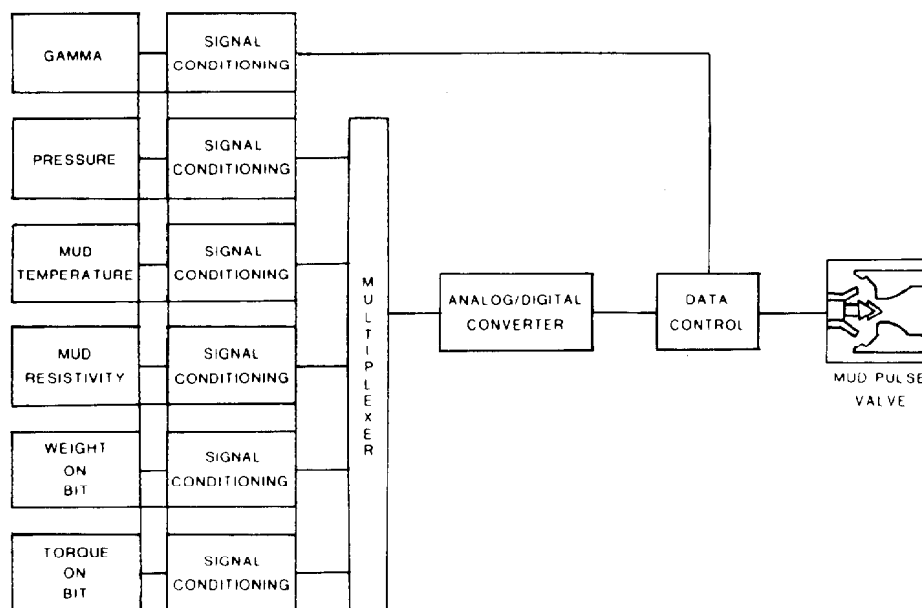

Fig. 53.2—MWD data transmission schematic.

Fig. 53.3—MWD logging system schematic.

Fig. 53.5 shows a comparison between an MWD-generated computed directional survey and a multishot run in the same well. Table 53.1 illustrates a directional survey listing corresponding to the plan view shown in Fig. 53.5.

Directional Surveys

Directional surveys^{4,5} are used to determine the location of the hole path with respect to the surface location. This information is used (1) to prove legally that the bottomhole location is under the correct surface property, (2) to ascertain the bottomhole location in purposely deviated wells, (3) to determine the radius of curvature of the hole as it affects the ability to run casing or tools, and (4) to differentiate between measured depth and true vertical depth (TVD) when using formation elevations for structural mapping.

Available Tools

The two basic types of directional surveys are continuous surveys and station surveys. The station surveys can be either single shot or multishot. Single or multi refers to the number of stations recorded. Single shot surveys normally are recorded during the drilling operation and are

recorded at given depth or time intervals. These single-shot records are accumulated and used to plot the hole path. Multishot surveys are the result of several shots run at given depth intervals after the hole has been drilled. Continuous surveys are run after a portion of the hole has been drilled. These are recorded continuously over the selected interval. Although continuous, multishot, and single-shot instruments are all different, there is another classification of instruments that must be considered when choosing a survey.

Surveys run inside metal casing cannot use the magnetic compass for hole direction. Gyroscopes normally are used whenever a survey is needed inside casing. These gyroscopes must be aligned on the surface before proceeding with the survey. They also should have their alignment verified as part of the after-survey checks.

The openhole directional surveys normally use magnetic compass orientation to fix the hole direction. This requires the input of the deviation between magnetic and true north. All devices use a pendulum system for determining the angle of hole deviation.

All continuous dipmeter surveys measure data that can yield a directional survey. This directional survey is available either as part of the dipmeter or as a separate

Fig. 53.4—An MWD rotary drilling log.

survey over portions of the hole where formation dips are not desired. At present, this instrument does not work in a cased hole, so the survey must be tied in to known coordinates at the bottom of the casing.

Any device that uses a magnetic compass to fix direction will be affected by metal in or near the borehole. This effect must be considered when a survey is run in an open hole that has been whipstocked past abandoned drillpipe or may be near a cased wellbore.

Fig. 53.6 illustrates a gyroscopic survey tool incorporating an accelerometer.

Legal Requirements

Each state has a separate definition of what constitutes a "legal" directional survey. These definitions may include specifications such as (1) length of downhole sensor, (2) whether or not such assembly is centered, (3)

method of calculating station-type surveys, (4) professional qualifications of person supervising or certifying the results, and (5) documentation, presentation, and distribution of results. These criteria must be considered when choosing a service company and a type of survey.

Computation of Results

Directional surveys are available in any area where directional drilling is done or where dipmeters are available. The field log may be a series of station readings or a continuous curve showing hole direction and deviation. The computed results will include a well plat that shows the vertical projection of the wellbore. Additional plots may show wellbore projections on a vertical plane passing through the surface location. A tabulated listing will show the wellbore coordinates and deviation angle.

Fig. 53.5—Comparison of MWD directional with multishot directional.

Methods of Calculation. There are many methods of calculating directional surveys.⁶ Most companies use one of the following five basic methods.

1. Tangential Method. This method uses the inclination and azimuth angles at the bottom of each course length (distance between readings or stations). This is usually the most common and least accurate method. The error introduced increases with the inclination angle and the course length. This method is not recommended.

2. Balanced Tangential Method. This method uses the inclination and azimuth angles at both the top and bottom of each course length to tangentially balance the two sets of measurements over the course length. This method is more accurate than the tangential method but is still sensitive to the course length.

3. Angle Averaging Method. This method uses a simple mathematical average of the inclination and azimuth angles at the top and bottom of the course length to compute the survey using the tangential method. This is more accurate than the tangential method but still simple enough for hand calculations in the field. Course length should be kept as short as feasible.

4. Radius of Curvature Method. This method uses the inclination and azimuth angles at the top and bottom of the course length to generate a space curve representing the curve path. This space curve passes through the measured angles at the top and the bottom of the course length. This method usually is considered the most accurate but is still sensitive to course length.

5. Mercury Methods. This method is used by the U.S. Government at the Mercury Test Site in Nevada. This is a combination of the tangential and balanced tangential methods. The portion of the course length defined by the length of the surveying instrument is treated by the tangential method. The remainder of the course length is treated by the balanced tangential method.

All these methods are critical to the course length or separation between stations. As the course length increases, their inaccuracies and deviations from each other increase. As the course length decreases, they all become more accurate. On very short course lengths (10 ft or less) there is very little to choose between the methods. For this reason, directionals computed from

continuously measuring devices, such as dipmeter tools, may be more accurate than station reading devices. Dipmeter devices normally compute every 1 or 2 ft although data listings may be accumulated and listed only every 50 ft.

Presentations. Directional data are normally presented both in well sketches and tabulated data. Well sketches include two elements.

1. Planar View. This is a vertical projection of the wellbore path on a horizontal plane. Such a projection shows the separation between the wellbore and the surface location. The wellbore path is marked with measured depths.

2. Vertical Sections. These are of two types. The first is a projection of the wellbore on a vertical plane through the surface location and aligned at various azimuths. The second is plot of depth against closure where closure is the horizontal distance of the wellbore from the surface location. The tabulated data listing will show the measured depth, vertical depth, hole azimuth, deviation angle, x and y distances, and closure distance.

Field Examples. Fig. 53.7 shows a number of presentations of deviation survey computations including: (A) plan view, (B) vertical section, and (C) depth vs. closure. The deviation survey listing is also shown in Table 53.2.

Dipmeter Logging

Introduction

The dipmeter tools are run to determine the direction and angle of formation dip from the survey of one borehole. This information is of obvious importance in the study of structural and stratigraphic problems.⁷

As illustrated in Fig. 53.8, the angle of formation dip is the angle between a horizontal plane and the bedding plane of the formation. The strike of a formation is the direction of the horizontal line formed by the intersection of these two planes. Although strike is a common geologic term (particularly in surface geology), it is more convenient to use "dip azimuth" in discussing the dipmeter. The direction of dip is perpendicular to the strike. In the remainder of this section dip azimuth will be used instead of strike.

Dipmeter tools are in a class by themselves. The technique, the purpose, and the interpretation of dipmeter logs are entirely different from those of other logging tools. The dipmeter's purpose is to measure the dips of formations. To do this, the tool must simultaneously and continuously do two separate jobs: first, it must orient itself in space, normally with respect to magnetic north and vertical, and second, it must react to formation bedding planes.

All present dipmeter tools go about this job in the same way. An inclinometer section supplies continuous measurements of deviation, both the amount and the direction, and of the orientations of the tool's electrode array, either with respect to the borehole direction or magnetic north (a few specialized tools for far north operations use gyroscopic orientation, nominally with true north). At the same time, an electrode array is maintained in contact with the borehole wall by pressured linkages. The electrodes respond to resistivity variations, while the expanding linkages activate a caliper recording.

These pads, normally numbering four, are identical, and so mounted as to remain in a plane normal to the tool axis. When an anomaly is detected by at least three pads, these deflections plus the caliper reading identify three points in what is assumed to be a plane, the plane of deposition of the formation. This identification is then referred to vertical and true north, giving the true dip of the formation.

Recording correct data with a dipmeter tool is a straightforward, more or less mechanical process, though the tools used to do it are some of the most sophisticated in the industry. Interpreting the data draws heavily on computer technology.

Fig. 53.7A—Deviation survey plan view.

Fig. 53.7C—Deviation survey depth vs. closure.

Fig. 53.7B—Deviation survey vertical section.

Tools Available. All major service companies use four-arm dipmeter tools. Fig. 53.9 shows a typical dipmeter tool's mechanical section with the four pads, the electrodes, and the caliper assembly visible. Most of these tools will operate to 20,000 psi and 350°F in holes between 6 and 16 in. in diameter. Different varieties of tools handle low- and high-deviation holes by using different methods of measuring hole deviation and hole azimuth angles. Fig. 53.10 illustrates a monitor log and a computer-answer log.

Calibration. The dipmeter is essentially a physical tool, and its calibration is physical. The inclinometer section is adjusted to read correctly in a special test jig. Special care is given to ensure that the deviation sensor registers zero with the tool held vertical. The operation of the inclinometer is checked before and after each log run, first by allowing the tool to hang vertical in the derrick, then by rotating the tool manually through at least one full revolution.

The calipers are checked as usual, by calibration jigs of known diameter. Four-arm dipmeters record a separate caliper with each opposing pair of pads, which can thus flex independently of each other while remaining in the same plane. Finally, the sensitivity of the electrodes is checked by shorting them out in sequence; this also verifies the correct wiring of the electrode array.

Oil-Base Muds. Dipmeters run in oil-base muds present a special problem. Because the oil-base mud will not connect the resistivity electrodes to the formation electrically it is necessary to use special knife-edge blade

Fig. 53.8—Illustration of dip, strike, and dip azimuth.

electrodes. These blades mechanically cut into the formation and make contact with the water in the formation. This method does not give the quality of data that is obtained with the conventional system in water-base mud. The reason for this is the considerable amount of noise introduced into the resistivity recording caused by the knife blade sliding along the borehole wall. The better the contact made between the knife edge and the formation, the better the quality of the resistivity measurements. Two important things can be done to improve this contact.

1. Make sure that the knife-edge blade is sharp. Demanding new blades is the best way to ensure sharp edges. New blades are also less likely to have electrical insulation problems.

2. Have the logging company dress and adjust their dipmeter tool to apply the maximum arm pressure. This will force the knife edge electrodes into the formation mechanically. This adjustment may be made with different spring mechanisms or by applying greater pad pressure through a hydraulic linkage. Either way this is very important to obtain good resistivity data.

Because the oil-base mud dipmeter is a low-usage tool, the service company should be given maximum notice so they can prepare for the job. All special instructions and stipulations should be given at the same time.

When recording the log, it should be remembered that the final data can be expected to be only 10 to 20% as good as an ordinary dipmeter. Therefore, it is advisable to consider multiple repeats over critical zones. The data usually will be valid only for general structural use so particular attention should be paid to shale zones. All resistivity curves should have good character, although their similarity will not extend down to small details. A slow or dead curve usually indicates a faulty knife-edge electrode. The orientation curves are unchanged from an ordinary dipmeter so the same comments apply to both.

The Computed Dipmeter Log

The computation of dipmeter surveys⁸ requires sophisticated software and a substantial computer. The task requires that the anomalies recorded on the resistivity traces at bed boundaries be correlated and the displacement of each with respect to the others along the borehole be determined. Once this step has been taken then any two pairs of displacements are sufficient to define a plane. Where more than three resistivity curves are recorded, as with most modern dipmeter tools (4-, 6-, and 8-pad tools are in use), then multiple pairs of

Fig. 53.9—Four-arm dipmeter tool.

displacements may be chosen and multiple apparent bedding planes defined. The correct choice of the most probable bedding plane is determined by the interpretation logic in the dipmeter program. The correlation of one resistivity curve to another is a more mechanical task and is controlled by the interpreter's choice of three parameters—the correlation length, the search angle, and the step length—as illustrated in Fig. 53.11. A short interval of one curve is correlated to a second curve at discrete steps throughout a depth range defined by the search angle. At each step a correlation function is evaluated.

When the value of the correlation function is determined at each step, then a correlogram can be built and a search made for a maximum value. This maximum indicates the displacement of the curve sector defined on the first curve by the correlation interval from a similar section on the second curve. Successive correlations are continued in the same correlation interval with other curves and then in the next correlation interval and so forth.

Once a plane at any point in the well has been defined its orientation relative to vertical and geographic north also must be computed. This requires that the position of the tool in the hole and the deviation and azimuth of the hole itself be known. These data are supplied from the orientation section of the tool.

The dipmeter log, as recorded, is not evaluated easily for quality, so an appraisal of the computed log should be included in dipmeter quality control. A computed dipmeter log may be available on location, if a computer logging unit is available, but it is normal to wait for days or even weeks for the results if processing is done at a central computer office.

Working with the computed log, look for two distinct defects: undetected problems with the recorded data and problems with the computation. A computed dipmeter should model real-life geology; if it seems not to do that, an investigation is in order. If the problem is in the computation, it normally can be solved by repeating the computation job. Even if the problem is with log measurements, the logging company's computer experts often can solve it by special handling.

Application of Dipmeter and Directional Data

Dipmeter Patterns. Once a dipmeter log has been run and computed then the results have to be interpreted in the light of known geological and geophysical facts. In general dipmeter results are used to find gross structural features, fine stratigraphic features, and true vertical and true stratigraphic thicknesses.

The most common method of representing computed dipmeter results is by an "arrow" or "tadpole" plot. A series of special characters is plotted as a function of depth with their origin indicating the dip magnitude and a short line indicating the dip azimuth, as illustrated in Fig. 53.12A. For the purpose of reference the uphole direction on the plot is considered north and the clockwise direction the short line points from its base is the dip azimuth angle. When viewed together as patterns, these dip vectors or "tadpoles" can be interpreted in terms of gross geological structure or sedimentary detail as illustrated in Fig. 53.12B.

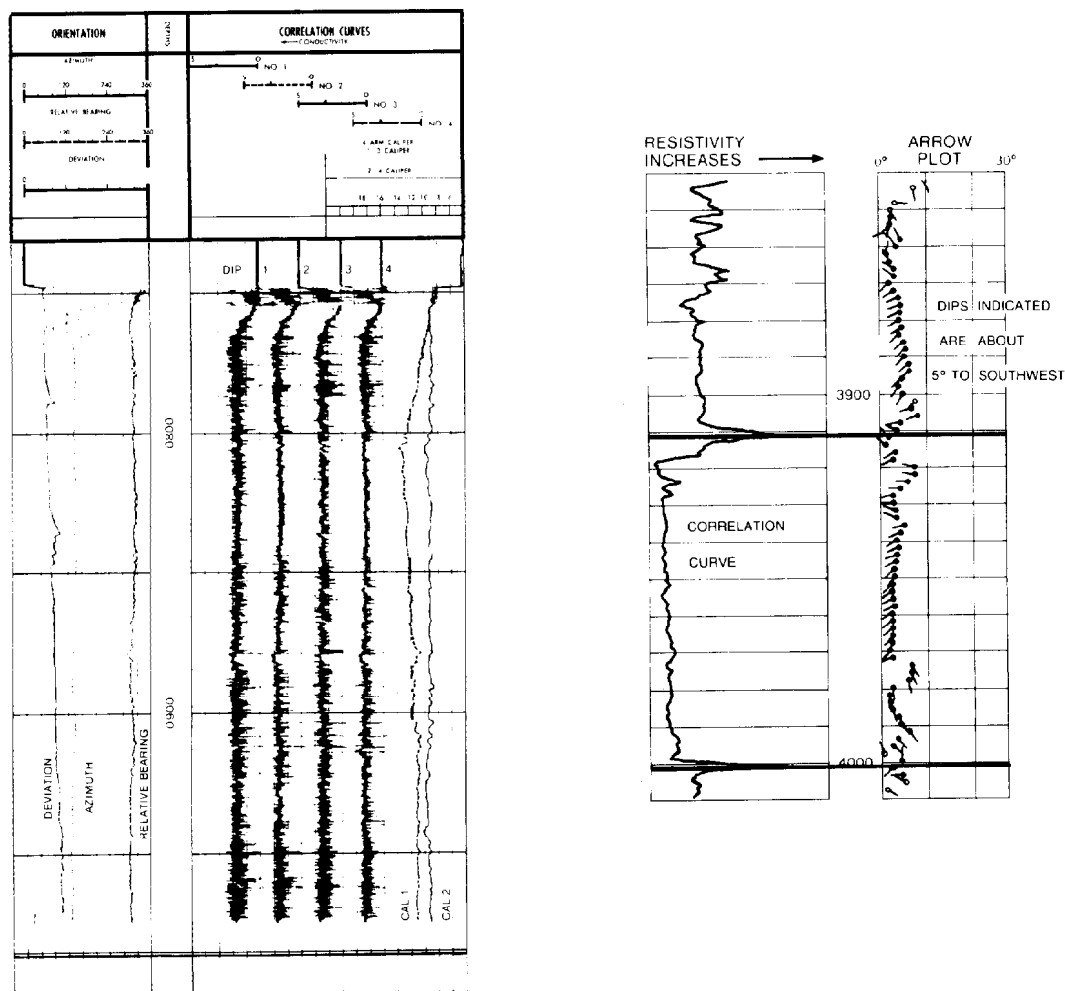

Fig. 53.10—Dipmeter monitor log and computed dipmeter log.

Fig. 53.11—Dipmeter computation terms "correlation interval," "step," and "search."

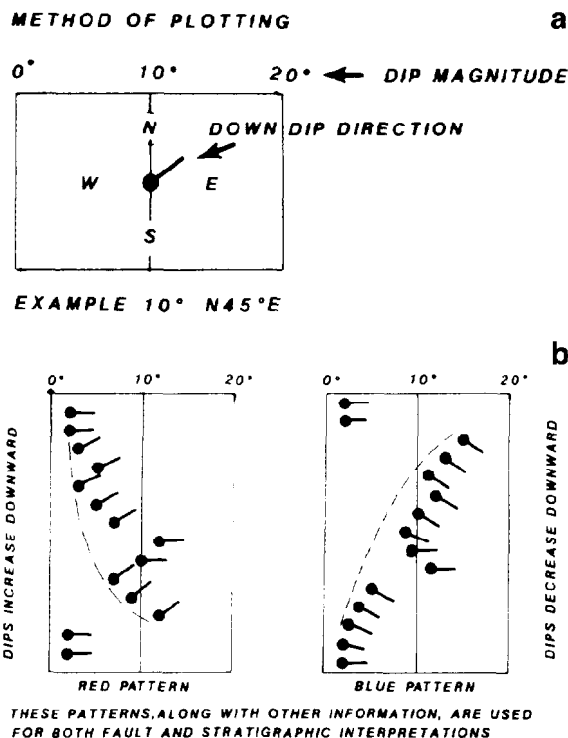

Fig. 53.12—Dipmeter interpretation rules showing (a) method of plotting dips and (b) patterns of dips.

Fig. 53.13 shows three common structures: a folded structure (anticline), an unconformity, and a normal fault. Fig. 53.14 shows three common sedimentary features: a channel cut and fill, a buried bar with shale drape, and current bedding.

Other complex patterns may develop, such as those related to: (1) missing and repeat sections (Fig. 53.15A), (2) stratigraphy of continental deposits (Fig. 53.15B), (3) stratigraphy of continental shelf deltas (Fig. 53.15C), (4) stratigraphy of continental shelf tide/wave-dominated deposits (Figs. 53.15D and E), and (5) continental slope and abyssal environments (Fig. 53.15F). Other forms of representing dip data are also used to good effect, such as polar and stereographic plots and azimuth frequency diagrams.

One of the main uses for dip data as far as the reservoir engineer is concerned is in computation of reservoir volumes, which require true vertical thickness measurements (TVT). For the geologist a related measure, the true stratigraphic thickness (TST) is of immediate concern.⁹⁻¹³

In the simple case where the wells are vertical and the bedding is horizontal, correlations can be made directly between logs of neighboring wells. Reservoir volume is calculated by multiplying reservoir thickness (directly derived from the logs) by reservoir area (delimited by other means).

However, this simple case is exceptional because (1) most reservoirs exist as the result of some structural event or accident, implying some formation dip at least at the reservoir periphery, and (2) most wells deviate to some extent from vertical, intentionally or not. As long

as dips and deviations do not exceed a few degrees, the simple vertical-horizontal case is approximated closely enough not to need corrections. But when deviations and dips exceed about 10 degrees, corrections are needed because apparent formation thicknesses measured on logs are greater than true stratigraphic thicknesses by different amounts in different wells. This adds to the difficulty of well-to-well log correlation. Also, if wells are deviated from vertical, and if formations have substantial dip, apparent thicknesses differ from the vertical thicknesses needed for reservoir volume calculation, and must be corrected.

To achieve these corrections in a convenient manner, modern data processing affords three different computed log products: the true vertical depth (TVD), TST, and TVT plots. Proper interpretation of these plots requires considerable caution and may be quite difficult.

Common Principles of TVD, TST, and TVT Plots.

Figs. 53.16 through 53.18 illustrate the principles of thickness transformations. Formation parameters recorded by logging tools are reproduced without alteration, but their depths are altered to suit respective purposes. Depths should be thought of as summations of overlying formation thicknesses.

Two methods exist for computation of altered depths: (1) *common surface point*, which assumes a hole drilled from the same surface point or formation top with a different course, and (2) *common subsurface point*, which assumes a hole drilled either vertically, or normal to the bed dip, from some point in the actual well course, such as a formation top, or a point of formation dip change. Depths may be reset arbitrarily at the common point. In this approach it is set to zero, thus representing only thickness as counted down from the common point.

TVD Plot. This plot ignores formation dip and corrects for well deviation only. Thus, it represents formations as they would look in a vertically drilled well, provided the formations had zero dip. It is useful in areas of directional drilling where dip is low, for well-to-well correlations, and for reservoir volume calculations. It usually is run only in the common surface point mode.

TST Plot. This plot accounts for formation dip, and requires knowledge of true well course, whether vertical or not. It displays formations as though the well had been drilled perpendicular to them. If a change of dip occurs, an equal and opposite change of deviation is assumed.

If only one dip is present, the plot represents the logs that would have been obtained if the well had been drilled at the same location perpendicular to that dip. If more than one dip is present, the interpretation becomes more complicated. At each dip change, some stratigraphic column must either disappear, or thin, or thicken, or even repeat itself.

TVT Plot. This plot is closely related to the TST, and as such accounts for both well deviation and formation dip. It shows formation thickness as though the well had been drilled vertically through the dipping beds. Evidently, a TVT in a vertical hole would be identical to the original log. The TVT is meant to be used for reservoir volume calculations from deviated hole logs.

Reductions in Special Cases. If the well is vertical and the formations are horizontal, all three transformed logs would be identical to the original log, and the processing

Fig. 53.16—Principle of true vertical depth (TVD).

Fig. 53.17—Principle of true stratigraphic thickness (TST).

Fig. 53.18—Principle of true vertical thickness (TVT).

would be a waste of computer time. If the well is deviated and the formations are horizontal, the TST and the TVT are identical to the TVD, and running the latter is sufficient. If the well is vertical and the formations dip, the TVD and TVT plots would be wasted computer time, but the TST may be useful in well-to-well correlations. If the well is drilled perpendicular to the formation dip (as it often tends to be in hard rocks in particular) the TST would be a waste of computer time, but the TVT is needed for reservoir calculations, and the TVD may be of use if deviation is pronounced.

Algorithms. The algorithms used for computing the TVD, TST, and TVT have been covered well in the literature.¹⁴ Any implementation of these algorithms for computer applications should be approached with caution. Many programming languages differ in their treatment of trigonometric functions for angles exceeding 90°. Another area requiring care is in the matter of precision. When depth data are processed, a repetitive accumulation of depth increments is made. As many as 10⁴ or more additions must be made in a normal well. Thus the precision of each increment must be at least one part in 10⁶ or better. Depending on the computer used (16 bit, 32 bit, etc.) the programming of these algorithms should demand appropriate precision.

By way of summary, all three plots perform valuable functions, but all three may be misleading if not used with the proper caution, in particular with respect to absolute depths.

1. The TVD is incorrect in both formation thicknesses and in absolute depths if formations have appreciable dip.

2. The TST is always correct in formation thicknesses. It should be run in the common subsurface point mode. If changes of dips are present, it should reset the subsurface point at each change of dip and make independent plots through each dip zone. This resetting may be made automatically if the program allows it, and manually otherwise.

3. The TVT may produce apparent thicknesses greater than measured thicknesses. Such thicknesses may be fictitious when beds are truncated in their vertical extension by unconformities or faults. It should be run in independent sections for each change of dip, in the common subsurface point mode, as for the TST.

Fig. 53.19—A typical borehole.

Caliper Logs

Introduction

The caliper log measures the diameter of the borehole. The first caliper logs were developed to determine borehole size in holes shot with nitroglycerin. These early logs showed large variations in hole size even in the portions of the hole that had not been shot. This illustrated the need for the caliper log over the entire hole.

Methods of Recording

Several types of caliper are currently in use. One type consists of three or four spring-driven arms, which contact the wall of the borehole. The instrument is lowered to the total depth (TD), and the arms are released either mechanically or electrically. The spring tension against the arms centers the tool in the well. The arms move in and out with the change in wellbore diameter. The arm motion is transmitted to a rheostat so that change in the resistance of an electric circuit is proportional to the hole diameter. The borehole diameter is recorded at the surface by measuring the potential across this resistance.

Another instrument uses three flexible springs, which contact the wall of the borehole. These springs are connected to a plunger that moves up or down as the springs expand or contract with changes in borehole diameter. The plunger passes through two coils. When an alternating current is passed through one coil, an electromotive force (EMF) is induced in the other coil. The amount of this induced EMF is a function of the plunger position and is proportional to borehole diameter. Either of the preceding instruments may be adjusted so that they will record borehole area rather than hole diameter. If the caliper log is used to determine hole volume, area should be recorded on a linear scale. If the caliper log is used to determine hole configuration, the hole diameter is recorded on a linear scale.

A third type of caliper log is the microcaliper, which is discussed in connection with the electrical-log microdevices. This instrument uses two pads rather than arms or flexible springs. Hole diameter is determined by the movement of these pads, which are held against the borehole wall by springs.

Typical Borehole Configuration

A schematic of a typical borehole is shown in Fig. 53.19. As illustrated in this figure, some formations cave considerably, causing enlarged holes. Other formations do not cave, and because of the presence of mudcake, the hole size actually may be reduced to less than bit size. Although not illustrated in Fig. 53.19, some formations may swell, causing reduction in hole size.

The primary cause of formation caving is the action of the drilling fluid. Action of the bit and the drillpipe also have an effect. Most drilling muds are composed primarily of water. The chemical action of this water on shales (hydration of the shales) causes many shales to disintegrate and slough into the hole. The amount and rate of this sloughing depend on the nature of the mud and shale. Other shales (heaving shales) swell rather than disintegrate.

If a freshwater mud is used to drill a salt section, it will dissolve salt until the mud becomes salt-saturated. The drilling fluid does not react with formations such as

limestone, dolomite, and sandstone. However, if those formations are permeable, a mudcake will be formed, as illustrated in Fig. 53.19. This mudcake forms rapidly. The character (density and thickness) of the mudcake varies with the mud used to drill the well. Of course, thickness of the mudcake is limited by erosion of the drilling fluid while circulating.

In some areas the shallow portion of the hole is drilled with water. If loosely cemented sands are encountered, they may cave under this condition.

The action of the bit is probably not too important. But if a thin sand is surrounded by shales that have caved, the bit probably knocks off part of the sand ledge with each round trip.

Action of the drillpipe against the side of the hole causes some enlargement even in sandstones and limestone. Usually this enlargement is not great enough to affect hole volume appreciably, but it may cause the drillpipe to become differentially pressure stuck, necessitating a fishing job. Formation wear by the drillpipe will cause the hole to be noncylindrical, in which case a four-arm caliper will display the long and short axes of the hole.

Interpretation and Application of Caliper Logs

Caliper logs usually are recorded on vertical scales from 1 in.=100 ft to 5 in.=100 ft. The horizontal scale is selected to show a detail picture of hole diameter and is usually on the order of 1 in.=4 in. Because of the difference in scales, it is easy to get the impression from caliper logs that tremendous cavities are created. When plotted on the same horizontal and vertical scales, it is evident that the normal borehole is quite regular. This should be remembered when using the caliper log.

The primary uses of the caliper log are: (1) to compute hole volume to determine the amount of cement needed to fill up to a certain depth, (2) to determine hole diameter accurately for use in interpreting other logs, and (3) to locate permeable zones as evidenced by the presence of a filter cake. Other applications of the caliper log include proper location of casing centralizers, and packer seats for openhole drillstem tests.

Caliper logs are also available in conjunction with hole deviation and hole azimuth measurements, in which case the log is referred to as a borehole geometry log.

Fig. 53.20 is an example of a borehole geometry log using a standard three-track presentation. The borehole orientation is displayed in Track 1, while the two independent orthogonal caliper readings are recorded in Track 2 with a standard scaling. The caliper data are also available in Track 3 but with a reduced sensitivity. Together with the bit size and future casing size, this visual display, enhanced by the shading between the calipers and the bit size, quickly gives a clear impression of the borehole shape. Within the depth track the total hole volume integration is recorded along the edge of Track 1, and the cement volume (the difference between the total hole volume and the future casing volume) is presented along the edge of Track 2.

Fig. 53.20—Borehole geometry log.

Casing Inspection Logs

Introduction

Inspection of the mechanical state of the completion string is an important aspect of production logging. Many production (or injection) problems can be traced back to mechanical damage to, or corrosion of, the completion string. A number of casing inspection methods are available including: (1) multifingered caliper logs, (2) electrical potential logs, (3) electromagnetic inspection devices, and (4) borehole televewers or borehole TV. Of these the majority measure the extent to which corrosion has taken place. Only the electrical potential log may indicate where corrosion is currently occurring. With the exception of the caliper logs, all the devices require that the tubing be pulled before running the survey, since most are designed to inspect casing rather than tubing, and all are large-diameter tools.

Caliper Logs for Tubing and Casing Inspection

Various arrangements of caliper mechanisms are available to gauge the internal shape of a casing or tubing string. Fig. 53.21 illustrates three such tools. Table 53.3 lists the various sizes available, their respective number of feelers, and the appropriate casing size.

Tubing Profile Calipers. Tubing profile calipers will determine the extent of wear and corrosion, and will detect holes in the tubing string—all in a single run into the well. The large number of feelers on each size of caliper ensures detection of even very small irregularities in the tubing wall.

In pumping wells, the tubing caliper log may be run by one person and there is no need for a pulling unit crew to be present. A "pull sheet" showing the maximum percentage of wall loss of every joint of tubing in the well may be prepared. Before the well is pulled, a program of rearranging the tubing string can be provided. Moving partially worn joints nearer the surface and discarding thin-wall joints substantially prolongs the effective life of tubing strings and reduces pulling costs in pumping wells. In flowing or gas lift wells, the tubing profile caliper provides an economical method to check

Fig. 53.21—Casing and tubing profile caliper tools.

TABLE 53.3—TUBING AND CASING PROFILE CALIPERS

Sizes of Tubing Profile Calipers

Tool Diameter (in.)	Number of Feelers	OD (in.)
1½	20	2
1½	20	2¼
1¾	26	2¾
2⅞	32	2⅞
2⅞	44	3½
3⅞	44	4

Sizes of Casing Profile Calipers

3⅞	40	4½ to 6
5⅞	64	6⅞ to 7⅞
7¼	64	8⅞ to 9
7¾	64	9⅞
8¼	64	10¾
9⅞	64	11¾
11⅞	64	13¾
13⅞	64	16
17⅞	64	20

periodically for corrosion damage, to monitor the effectiveness of a corrosion inhibitor program, or to detect and remove damaged tubing joints when working over a well.

Split Detector. This is an accessory tool that may be run in combination with the tubing profile caliper. This tool, functioning much like a magnetic collar locator, is designed to detect and log vertical splits or hairline cracks in the tubing that might be difficult to locate with the profile caliper. In practice, the split detector is used to log down the tubing, and the profile caliper to log up the tubing. This gives a complete inspection for wall thickness and splits in one run of the cable in the well.

Casing Profile Calipers. Casing profile calipers are available to log 4½-in.- through 20-in.-OD casing. The tool is especially valuable where drilling operations have been carried on for an extended period of time through a string of casing. The determination of casing wear is of great importance when deciding if a liner can be hung safely, or if a full production string is required. In producing wells, the casing profile caliper will locate holes or areas of corrosion that may require remedial work. The tool is also valuable when abandoning wells because it permits grading of casing to be salvaged before it is pulled.

Casing Minimum-ID Calipers. The minimum-ID caliper can pass through and accurately measure restrictions as small as 3⅞ in. in casing with a nominal ID up to 13¾ in. This log is of particular value in determining areas of collapsed or deformed casing, identifying casing-weight change intervals, or detecting parted casing.

Examples of these logs are given in Fig. 53.22.

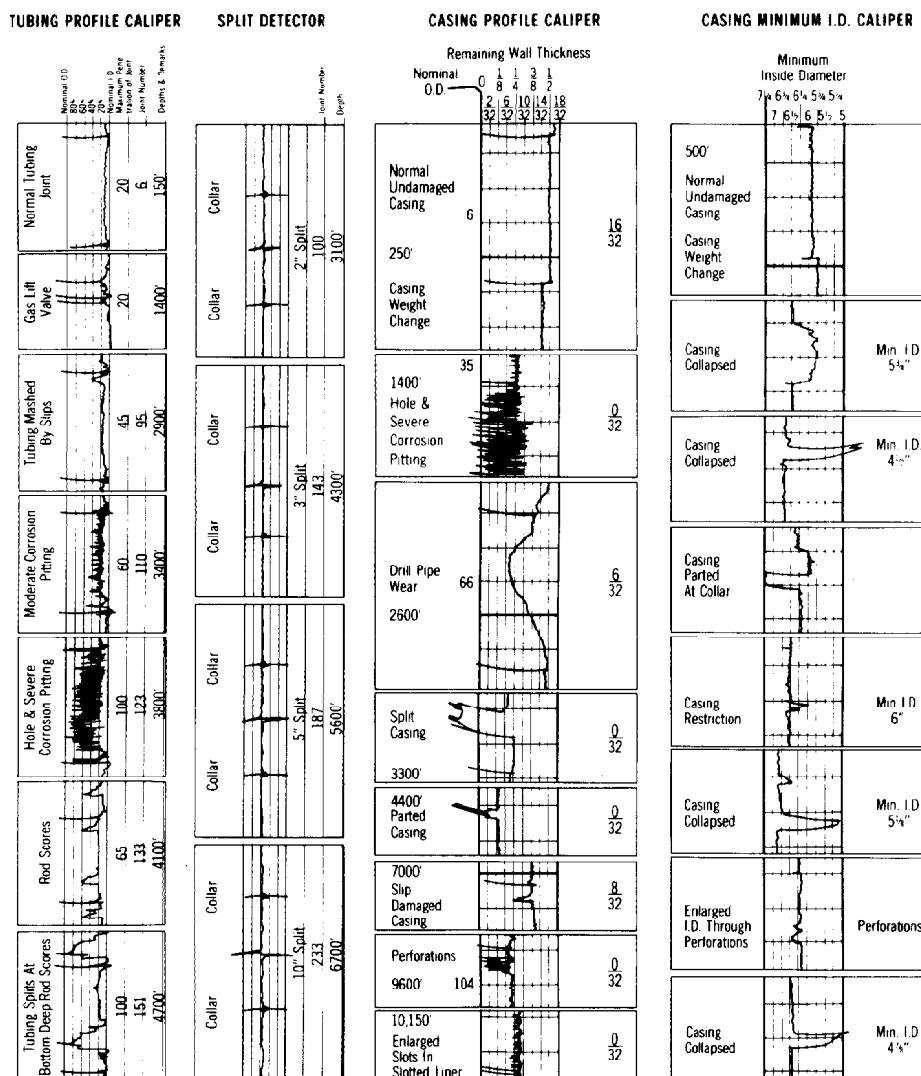

Fig. 53.22—Tubing and casing profile logs.

Electrical Potential Logs

An electrical potential log determines the galvanic current flow entering or leaving the casing. This will indicate not only where corrosion is taking place and the amount of iron being lost, but also where cathodic protection will be effective. The magnitude and direction of the current within and external to the casing is derived mathematically from electrical potential measurements made at fixed intervals throughout the casing string. To achieve reliable results from this kind of survey, the borehole fluid must be an electrical insulator (i.e., the hole must be either empty or filled with oil or gas). Mud or other aqueous solutions will provide a "short" that invalidates the measurements. The log itself is a recording vs. depth of the small galvanic voltages detected. Fig. 53.23 illustrates such a log with three different runs recorded, each with a differing level of cathodic protection applied to the casing.

Figs. 53.24 and 53.25 show an interpretation of casing potential profile logs run both with and without cathodic

protection. Note that in Fig. 53.25 the metal loss has been reduced to practically zero by the application of an appropriate cathodic protection.

Electromagnetic Devices

The most commonly used casing corrosion inspection tools are of the electromagnetic type. They come in two versions, those that attempt to measure the remaining metal thickness in a casing string¹⁵ and those that try to detect defects in the inner or outer wall of the casing.¹⁶ Although frequently run together, these tools will be discussed separately.

Electromagnetic Thickness Tools. The electromagnetic thickness tools are available under a variety of trade names such as ETT (Schlumberger), Magnelog (Dresser), and Electronic Casing Caliper Log (McCullough). They operate in a manner similar to openhole induction tools. Each consists of a transmitter coil and a receiver coil. An AC is sent through the transmitter coil.

Fig. 53.23—Casing potential profile.

This sets up an alternating magnetic field, which interacts both with the casing and the receiver coil (see Fig. 53.26). The coils are spaced about three casing diameters apart to ensure that the flux lines sensed by the receiver coil are those that have passed through the casing.

The signal induced in the receiver coil will be out of phase with the transmitted signal. In general the phase difference is controlled by the thickness of the casing wall. Thus the raw log measurement is one of phase lag in degrees and the log is scaled in degrees. Fig. 53.27 illustrates an ETT log in severely corroded casing. Note that an increasing thickness corresponds to an increase in the phase shift angle and vice-versa. Some presentations of this log show a rescaling in terms of actual pipe thickness. This requires that the operator make some calibration readings in the type of casing present in the well. It is quite common to see quite large differences in thickness between adjacent stands resulting from a number of variables, such as the drift diameter of the pipe, the weight per foot, the magnetic relative permeability of the steel used, etc.

The ETT-type tool is good at finding vertical splits in pipe, since the magnetic flux lines pass perpendicular to the casing wall. A horizontal circumferential anomaly is less well defined.

Eddy Current and Flux leakage Tools (Pipe Analysis Log). Another closely related measurement uses a slightly different technique and forms the basis of the Pipe Analysis Log (PAL).¹⁶ Two electromagnetic measurements are of interest in the context of the pipe analysis tool—magnetic flux leakage and eddy current distortion.¹⁷

Fig. 53.24—Casing potential profile analysis—without cathodic protection.

Fig. 53.25—Casing potential profile—with cathodic protection.

Flux leakage. If the poles of a magnet are positioned near a sheet of steel, magnetic flux will flow through the sheet (Fig. 53.28). So long as the metal has no flaws the flux lines will be parallel to the surface. However, at the location of a cavity either on the surface of the sheet or inside it, the uniform flux pattern will be distorted. The flux lines will move away from the surface of the steel at the location of the anomaly, an effect known as flux leakage. The amount of flux distortion will depend on the size of the defect. If a coil is moved at a constant speed along the direction of magnetic flux parallel to the metal sheet, a voltage will be induced in the coil as it passes through the area of flux leakage. The larger the anomaly, the greater the flux leakage and, therefore, the greater the voltage. The magnetic flux is distorted on both faces of the sheet, regardless of the location of the

Fig. 53.26— Electromagnetic thickness tool.

Fig. 53.27— Electromagnetic thickness log.

Fig. 53.28—Magnetic flux leakage principle.

defect, and therefore the coil needs to be moved along only one surface to survey the sheet completely. Since the coil must be moved through a changing magnetic flux to produce a voltage, no signal is generated when it is moved parallel to the surface of an undamaged sheet of steel.

Eddy Currents. When relatively high frequency AC is applied to a coil close to a sheet of steel, the resulting magnetic field induces eddy currents in the steel (Fig. 53.29). These eddy currents, in turn, produce a magnetic field that tends to cancel the original field, and the total magnetic field is the vector sum of the two fields. A measure voltage would be induced in a sensor (receiver) coil situated in the magnetic field. The generation of eddy currents is, at relatively high frequencies, a near-surface effect. Therefore, if the surface of the steel adjacent to the coil is damaged then the magnitude of the eddy currents will be reduced, and, consequently, the total magnetic field will be increased. This will result in a variation in the sensor coil voltage. A flaw in the sheet of metal on the surface away from the coils will not be detected and, depending on its distance from the surface, a cavity within the sheet will not influence the eddy currents either.

Tool Principle. The measuring sonde consists of an iron core with the pole pieces of an electromagnet at each end, and 12 sensor pads in two arrays between the pole pieces (Fig. 53.30). The two arrays are offset radially to ensure complete coverage of the inner surface of the casing. Each of the pads contains a transmitting coil (for the eddy current measurement) and two sensor coils wound in opposite directions (for both the flux leakage and eddy current measurements). The two sensor coils are wound in opposite directions so that for both measurements

Fig. 53.29—Eddy current principle.

there is zero voltage as long as no anomaly exists, but a signal will be produced when the quality of the casing is different below the two coils. The same sensor coils can be used for both measurements since two distinct frequencies are involved. A frequency of 2 kHz is used for the eddy current measurement, giving a depth of investigation of about 1 mm. The sensor pads are mounted on springs so that they are held in contact with the casing, facilitated through centralization of the sonde. Various sizes of magnet pole pieces are available and are selected according to the casing ID to optimize the signal strength for the flux leakage measurement.

Six measurements of flux leakage and eddy current distortion are made on each array, and the maximum signal from each array is sent uphole to the surface instrumentation. Four signals, the eddy current and flux leakage data from the two arrays, are recorded.

The flux leakage data correspond to anomalies located anywhere in the casing, while eddy current distortion occurs only at the inside wall of the casing. The standard presentation of the measurements is as shown in Fig. 53.31, with the data from the two arrays displayed in Tracks 2 and 3. Enhanced data are displayed in Track 1, making any anomalies more obvious.

Interpretation. The measurements are generally suitable only for qualitative interpretation. This is because any voltages induced in the sensor coils depend not only on the size of any flaws in the casing, but also on the magnetic permeability of the casing, the logging speed, and the abruptness of a defect. The measurement, therefore, is used primarily to locate the presence of small defects in the casing, such as pits and holes. Defects such as gradual decreasing of the wall thickness cannot be detected. To get a complete picture of the state of the casing the electromagnetic thickness tool also should be used to measure the casing wall thickness, since the PAT device will give zero signal in the two extremes of no casing and perfect casing (except at the collars).

Two sets of data are recorded, one set influenced by defects occurring anywhere in the casing, and the other by faults on the inner surface. By examining the log, therefore, it can be inferred whether the casing is damaged on the inner or outer wall, assuming that there is no defect within the casing. Although the magnetic flux bulges away from both sides of the casing at the location of a defect, the effect is greater on the side of the flaw, hence for the flux leakage measurement, smaller defects can be detected on the inner surface than on the outer surface. Because of the overlapping configuration of the two-pad arrays all of the inner surface of the casing is surveyed, but there is a casing-diameter-dependent defect size below which the flaw will be seen by only one array, and above which it will be seen by both arrays.

The eddy current measurements are not able to detect flaws smaller than about 0.39-in. diameter, while the flux leakage limit is somewhat lower (0.25 in.). This means that if an anomaly of less than $\frac{3}{8}$ -in. diameter is present it cannot be determined whether it is on the inner or outer surface. If a deflection is noted on the eddy current measurement but not on the flux measurement it is

Fig. 53.30— The pipe analysis tool.

Fig. 53.32—Pipe analysis log over a perforated section of casing.

assumed that the defect on the inner wall is less than 1 mm deep, and also usually can be ignored. In addition, events can be seen on the flux leakage readings that are not caused by casing damage but are a result of the presence of localized magnetization in the casing. This is one reason why a reference PAT survey should be run in new casing, so that a time-lapse technique can be applied to determine the casing damage.

The example of Fig. 53.32 includes sections of perforated casing (798 to 805 m, 807 to 819 m and 821 to 830 m), and there is a clear indication of damaged and undamaged casing. The flux leakage measurement (total wall) is responding strongly through the perforated intervals, the eddy current curve less so. This is probably a result of the diameter of the perforations being fairly close to the detection limit of the eddy current measurement. In the upper section the tool response is much lower, indicating a certain amount of corrosion on both surfaces of the casing, but probably nothing major. The large deflections occurring on all the curves are caused by the casing collars.

Casing Collar-Locator Log

The collar locator is used to locate casing collars, usually in conjunction with another cased-hole service such as a nuclear log or a perforating gun. Perhaps its most common use is in precisely locating perforating points. To do this the collar locator is run with a nuclear log (either the gamma-ray or neutron log) after the casing is set. This survey accurately positions casing collar in reference to the nuclear log. By correlating the nuclear log with logs run in an open hole, casing collars can be positioned accurately with reference to the openhole logs. The collar locator is then run with the perforating gun. The collars adjacent to the desired perforating interval are located and the desired interval perforated using the casing collars as reference points. Use of the collar locator makes it possible to locate perforations within a few inches of the desired interval.

Various types of collar locators are now in use. Some of the collar locators are sensitive enough to locate old perforations in casing. The collar locator also can be used to locate the casing shoe in openhole completions.

Chapter 54

Acidizing

A.W. Coulter Jr., Dowell-Schlumberger
A.R. Hendrickson, Dowell-Schlumberger
S.J. Martinez, U. of Tulsa *

Introduction

The use of acids to stimulate or to improve oil production from carbonate reservoirs was first attempted in 1895. Patents covering the use of both hydrochloric and sulfuric acids for this purpose were issued at that time. Although several "well treatments" were conducted, the process failed to arouse general interest because of severe corrosion of well casing and other metal equipment. The next attempts to use acid occurred between 1925 and 1930. These consisted of using hydrochloric acid (HCl) to dissolve scale in wells in the Glenpool field of Oklahoma and to increase production from the Jefferson Limestone (Devonian) in Kentucky. None of these efforts were successful and "acidizing" once again was abandoned.

The discovery of arsenic inhibitors, which allowed HCl to react with the formation rock without seriously damaging the metal well equipment, revived interest in oilwell acidizing in 1932. At that time, Pure Oil Co. and Dow Chemical Co. used these inhibitors with HCl to treat a well producing from a limestone formation in Isabella County, MI. Results of this treatment were outstanding. When similar treatments in neighboring wells produced even more spectacular results, the acidizing industry was born.

Throughout the years following those early treatments, the acidizing industry has grown to one using hundreds of millions of gallons of acid applied in tens of thousands of wells each year. Technology has developed with increasing rapidity, and many changes and innovations have been made to improve the effectiveness of acidizing treatments. Because of new techniques of application and development of additives to alter the characteristics of the acid itself, acidizing has become a highly skilled science. A knowledge of available materials, chemical reactions

at treating and well conditions, reservoir properties, and rock characteristics are required to design an effective and efficient acidizing treatment. Since it is beyond the scope of this text to cover all aspects of acidizing in detail, this discussion will be limited to a general description of materials, techniques, and design considerations. A bibliography is provided for those requiring a more detailed discussion of a particular subject. Also, the major well stimulation companies providing acidizing services offer literature and technical assistance for problem analysis and treatment design.

General Principles

The primary purpose of any acidizing treatment is to dissolve either the formation rock or materials, natural or induced, within the pore spaces of the rock. Originally, acidizing was applied to carbonate formations to dissolve the rock itself. Over a period of time, special acid formulations were developed for use in sandstone formations to remove damaging materials induced by drilling or completion fluids or by production practices.

There are two primary requirements that an acid must meet to be acceptable as a treating fluid: (1) it must react with carbonates or other minerals to form soluble products, and (2) it must be capable of being inhibited to prevent excessive reaction with metal goods in the well. Other important considerations are availability, cost, and safety in handling. While there are many formulations available, only four major types of acid have found extensive application in well treatments: hydrochloric, hydrofluoric, acetic, and formic acids.

Hydrochloric Acid (HCl)

An aqueous solution of HCl is most commonly used for acidizing treatments, for reasons of economy and because it leaves no insoluble reaction product. When HCl is

pumped into a limestone formation, a chemical reaction takes place, producing calcium chloride, CO_2 , and water. This reaction is represented by the following equation:

One thousand gallons of 15% HCl will dissolve approximately 10.8 cu ft (1,840 lbm) of limestone. It will liberate approximately 7,000 cu ft of CO_2 , measured at atmospheric conditions, and produce 2,042.4 lbm of calcium chloride. This salt is dissolved in the original water of the acid solution, plus 39.75 gal of water formed during the reaction. The specific gravity of this solution will be 1.181 (20.4% calcium chloride). While 15 wt% HCl has been the most commonly used, concentrations of 20 and 28% have become extremely popular over the past 2 decades. Regardless of the acid strength used, the reaction is the same and equivalent amounts of carbonate rock are dissolved. For example, 10,000 gal of 3% HCl solution will dissolve the same amount of rock as 1,000 gal of 28% HCl. Fig. 54.1 shows the effect of acid concentration on the amount of limestone dissolved. The main differences between the two solutions are their reaction rates (or spending times) and their physical volumes. Although lower concentrations of acid have greater equivalent volumes, their reaction times and depth of penetration into the reservoir, from the wellbore, are considerably less than those of the higher-strength solutions. Reaction rates and penetration will be discussed later.

Similar reactions occur when dolomite or impure limestone is treated with HCl. Dolomitic lime contains a large percentage of magnesium combined as calcium magnesium carbonate. Although it reacts more slowly, this mineral also dissolves in HCl, and the resulting magnesium chloride is soluble in the spent acid. Other impurities occurring in limestone and dolomite are often insoluble in acid, and if appreciable percentages of such components are present, special additives must be included in the acid solution to ensure their removal.

HCl ordinarily is manufactured in concentrations of 32 to 36 wt% HCl and is diluted at service company stations to 15, 20, or 28% for field use. The concentrated acid, the various chemical additives, and water are mixed in the tank truck used to haul the acid to the wellsite. Table 54.1 lists the weights of various concentrations of HCl. These data are useful in calculating mixing proportions for acid dilution, using the following equation:

$$V_{ca} = \frac{V_{da} C_{da} \gamma_{da}}{C_{ca(\text{HCl})} \gamma_{ca}}$$

where

V_{da} = final volume of dilute acid,

C_{da} = desired concentration of dilute acid,

γ_{da} = specific gravity of dilute acid,

V_{ca} = volume of concentrated acid required,

$C_{ca(\text{HCl})}$ = percent of HCl in concentrated acid, and

γ_{ca} = specific gravity of concentrated acid.

Approximate proportions of concentrated acid and water required for dilution are shown in Fig. 54.2.

Determination of acid strength can be estimated in the field using either a hydrometer or a field titration kit. The accuracy of hydrometer readings depends on the care and technique used by the field engineer. Both the hydrometer and the glass cylinder in which the test is made should be free from oil or dirt. The spindle should float freely in the acid, and all readings should be made at the lowest level of the acid meniscus. The temperature of the acid sample should be taken and the hydrometer reading corrected to 60°F.

Determination of acid strength by titration is simplified by the use of 0.59 *N* standard sodium hydroxide solution. If a 2-mL sample of the acid is titrated with this standard solution to a methyl orange end point, the burette reading (milliliters of sodium hydroxide used) will be equal to the acid strength (percent HCl).

Acetic and Formic Acids

Acetic acid (CH₃COOH) and formic acid (HCOOH) are weakly ionized, slowly reacting, organic acids. They are used much less frequently than HCl and are suitable primarily for wells with high bottomhole temperatures (BHT's above 250°F) or where prolonged reaction times are desired. The reaction of these acids with limestone is described by the following equation:

HAc is available in concentrations up to 100% as glacial HAc, while HCOOH is available in 70 to 90% concentrations. For field use, HAc solutions normally are diluted to 15% or less.

Above this concentration, one of the reaction products, calcium acetate, can precipitate from its "spent acid" solution because of its limited solubility. Similarly, the concentration of HCOOH normally is limited to 9 to 10% because of the limited solubility of calcium formate. At a 10% concentration, 1,000 gal HAc will dissolve 740 lbm of limestone, whereas 1,000 gal HCOOH dissolves 970 lbm. Where more dissolving power per gallon of acid is desired, HCl is sometimes mixed with HCOOH or HAc. Such blends still provide extended reaction times, when compared with HCl. HCOOH and HAc also may be blended together. Table 54.2 illustrates some of the more common acid strengths and blends.

Hydrofluoric Acid (HF)

HF is used in combination with HCl and has been referred to as "intensified acid" or "mud removal" acid, depending on the formulation and use. HF is used primarily to remove clay-particle damage in sandstone formations, to improve permeability of clay-containing formations, and to increase solubility of dolomitic formations. Its utility is based on the fact that some clays, silica, and other materials normally insoluble in HCl have some degree of solubility in HF. For example, 1,000 gal of an acid solution containing 3% HF and 12% HCl will dissolve 500 lbm of clay and up to 1,450 lbm of CaCO₃.

and

FORMULA FOR MIXING ACID IN ANY DESIRED CONCENTRATION:

$$\frac{\text{VOLUME OF STRONG} \times (\text{VOL OF WEAK}) \times (\% \text{WEAK}) \times (\text{SP. GR. OF WEAK})}{(\% \text{ OF STRONG}) \times (\text{SP. GR. OF STRONG})}$$

Fig. 54.2—Dilution of concentrated HCl.

Fig. 54.3—Solubility of bentonite in mud removal acid.

Fig. 54.4—Solubility of silica sand in mud removal acid.

Figs. 54.3 and 54.4 compare solubilities of bentonite and silica in HCl and HF acids.

In carbonates, application of HF/HCl mixtures must be controlled carefully because of cost and possible precipitation of reaction products such as calcium fluorides or complex fluosilicates, which have a very limited solubility. For reaction with silicates, such as natural clays or clays in drilling fluids, the blends usually contain 2 to 10% HF and 5 to 26% HCl. The concentration of HCl used in the blend should be equal to or greater than that of the HF.

The so-called "intensified acids" used in dolomitic formations are mainly HCl containing small concentrations of HF, usually about 0.25%. Intercrystalline films of silica, insoluble in HCl, often occur in the crystal structure of dolomite. When such are present, they prevent the acid from contacting the soluble portions of the rock. The presence of fluoride intensifier in the acid will destroy such films, allowing the acid to react more completely with the soluble portions of the rock. Fig. 54.5 illustrates the comparative reaction rates of HCl and intensified acid on dolomite formations.

More recent developments of HF involve the use of delayed-action agents in sandstone acidizing. The first of these was a self-generating mud acid system, reported by Templeton *et al.*¹ The system provides slow generation of acid from the hydrolysis of methyl formate, yielding methyl alcohol and HCOOH acid. The acid then reacts with ammonium fluoride to yield HF in situ. They attribute the success of the system to getting the HF reaction away from the wellbore into areas that conventional HF solutions normally do not reach before spending. Equally important factors are the techniques of application and of returning the well to production following treatment. The treatment technique involves use of an aromatic solvent and mud acid preflush, along with the self-generating mud acid (SGMA). The wells are returned to production by opening the choke gradually over a 90-day period and never allowing an excessive drawdown. The process is available from most service companies as SGMA.

A significant development in this area of slow-reacting, HF-supplying, clay-dissolving acid has been the fluoboric acid system reported by Thomas and Crowe.² This acid

hydrolyzes to form hydroxyfluoboric acid and HF, which will dissolve clays.

This reaction provides a slow-release source of HF, which can penetrate deeply before spending. Perhaps more important, the slowly generated hydroxyfluoboric acid reacts with clays to form a nonswelling, nondispersing product that stabilizes fine clays and holds fine particles of silica in place.

Acid Reaction Rates

A knowledge of the factors affecting the reaction rate of acids is important for several reasons. First, these factors, correlated with reservoir and formation characteristics, form a guide for the selection of acid type and volume for a given treatment. Next, a study of these factors can furnish an understanding of what parameters govern spending time, which will determine how far a given formulation can penetrate into the formation before spending. Many factors govern the reaction rate of an acid, such as pressure, temperature, flow velocity, acid concentration, reaction products, viscosity, acid type, area/volume ratio, and formation composition (physical and chemical). These factors have been the subject of extensively reported research for many years. Details of such studies are available in published literature. Only a brief general discussion will be presented here.

Pressure

Fig. 54.6 shows the effect of pressure on the reaction rate of 15% HCl with limestone and dolomite at 80°F. Above 500 psi, pressure has little effect on reaction rate. At bottomhole treating pressures, there is only a small difference (a factor of 1.5 to 2) in the comparative reaction of acid with limestone and dolomite compared to the rather large difference (a factor of about 10) at atmospheric pressure.

Temperature

Acid reaction rate increases directly with temperature. At 140 to 150°F, the reaction rate of HCl and limestone is

Fig. 54.5—Comparative reaction rates of conventional and intensified acids.

approximately twice that at 80°F. It must be recognized that the temperature controlling the reaction is affected by the injection temperature of the acid (a major factor), and by the heat liberated by the reaction itself (a minor factor). Computerized programs are used to estimate the bottomhole fluid temperature at various stages, allowing more effective acid treatment design.

Flow Velocity

Fig. 54.7 shows that increased flow velocity increases the reaction rate of 15% HCl with CaCO_3 . This velocity effect is more pronounced in narrower fractures. Reaction rate is a function of shear rate, $6v/b$, sec^{-1} as illustrated by the following equation:

$$R = [(28.5 v/b)^{0.8} + 184] \times 10^{-6}, \dots \dots \dots (1)$$

where R is the reaction rate in lbm/sq ft-sec , v is the flow velocity in fracture, ft/sec , and b is the fracture width, ft . (The reaction rate is for 15% HCl with marble at 80°F under 1,100 psi pressure.)

The flow velocity in fractures and channels depends on injection rate and actual geometry of the flow path.

$$v_{rf} = 0.18 i_{ac} / (r_f b) \quad (\text{radial fracture}), \dots \dots \dots (2a)$$

$$v_{lf} = 1.15 i_{ac} / (hb) \quad (\text{linear fracture}), \dots \dots \dots (2b)$$

$$v_{cc} = 17.2 i_{ac} / d^2 \quad (\text{cylindrical channel}), \dots \dots \dots (2c)$$

where

v = flow velocity in fractures and channels,
ft/sec,

i_{ac} = acid injection rate, bbl/min ,

r_f = fracture radius, ft ,

h = fracture height, ft ,

d = channel diameter, in. , and

b = fracture width, in.

Acid Concentration

Reaction rate increases with acid concentration up to 24 to 25% HCl, but not proportionally, as shown in Fig.

Fig. 54.6—Effect of pressure on reaction rate (15% HCl at 80°F).

Fig. 54.7—Effect of flow on reaction rate (15% HCl with CaCO_3).

54.8. Above 25% HCl, the reaction rate actually decreases because of reduced acid activity. As acid spends, the reaction rate decreases as a result of reduced acid concentration and the retarding effect of dissolved reaction products, such as calcium or magnesium chloride.

Area/Volume Ratio

Area/volume (A/V) ratio is one of the major factors affecting reaction rate spending time, and may vary over a wide range. This ratio, the area in contact with a given volume of acid, is inversely proportional to pore radius or fracture width. Fig. 54.9 shows the time required for 15% HCl to spend on marble, at 80°F and 1,100 psi, for three different A/V ratios.

The term “spending time” has very little meaning or value by itself. It must be related to flow geometry and, thus, to the distance the acid penetrates before it is spent. In matrix acidizing, extremely high A/V ratios may be encountered. For example, a 10-md, 20%-porosity limestone may have an A/V ratio of 28,000 to 1. In such a formation, it would be very difficult to obtain significant penetration before spending. A natural fracture, 0.001 in. wide, has an A/V ratio of 3,200:1. A 0.1-in. fracture has an A/V ratio of 32:1. The smaller ratios in wider frac-

2.0	300	6
2.0*	350	4

*With inhibitor acid.

tures allow greater penetration of the acid into the reservoir before spending is complete.

Formation Composition

Probably the most important factor that governs effectiveness of an acidizing treatment is the rock composition. Its chemical and physical characteristics determine how and where the acid will react with and dissolve the rock.

From the standpoint of chemical composition, there is little difference in the reaction rate of HCl on most limestones, all other factors remaining constant. The physical rock texture, however, can control pore size distribution, A/V ratio, pore geometry, and other properties. This, in turn, influences the type of flow channels created by acid reaction and is the key to acid response.

Fig. 54.9—Effect of A/V ratio on spending time (15% HCl, 80°F and 1,100 psi).

Two formations having the same acid solubility and permeability may respond differently to acid treatment because of variances in physical structure.

Acid Additives

The use of a corrosion inhibitor as an additive made possible the first commercially feasible acidizing treatments. Since that time, many auxiliary chemicals have been developed to modify acid solutions, influencing their application and recovery.

Corrosion Inhibitors

Inhibitors are chemical materials that, when dissolved in acid solutions, greatly retard the reaction rate of the acid with metals. They are used in acidizing to avoid damage to casing, tubing, pumps, valves, and other well equipment. Inhibitors cannot completely stop all reaction between the acid and metal; however, they do slow the reaction, eliminating 95 to 98% of the metal loss that would otherwise occur. Most inhibitors have practically no effect on the reaction rate of acid with limestone, dolomite, or acid-soluble scale deposits.

The length of time that an inhibitor is effective depends on the acid temperature, type of acid, acid concentration, type of steel, and the inhibitor concentration.

Organic inhibitors in HCl are effective up to 400°F, but above 200°F relatively large concentrations are required. The effect of temperature on corrosion inhibition is illustrated in Table 54.3.

Equations have been developed for estimating BHT's during acid treatments. By knowing these temperatures, adequate corrosion protection can be provided, even in wells with static BHT's up to 400°F.

Surfactants

Surfactants are chemicals used to lower the surface tension or interfacial tension of fresh acid or spent acid solutions. The use of a surfactant improves the treating efficiency in a number of ways.

The presence of a surfactant improves the penetrating ability of the acid solution entering a formation. This is extremely desirable in matrix acidizing treatments, be-

Fig. 54.10—Effect of surface-tension-reducing agent in facilitating return of spent acid.

cause it provides deeper penetration of acid into the formation. In addition, surfactants permit the acid to penetrate oily films clinging to the surface of the rock and lining the pores, so that the acid can come in contact with the rock and dissolve it.

The use of surfactants also facilitates the return of spent acid following the treatment (Fig. 54.10). Wetting of the formation is more nearly complete and there is less resistance to flow of the acid, so that the spent acid is readily returned through the treated section. This is especially important in low-pressure wells.

Another advantage in the use of surfactants in acid is the demulsifying action obtained. Many surfactants are capable of inhibiting the occurrence of emulsions or destroying those already formed.

Surfactants also promote dispersion and suspension of fine solids to provide better cleanup following treatment. These solids may be either mud solids or natural fines released from the formation. They are suspended and physically removed from the formation.

Special surfactants are used as antisludge agents. Some crudes form an insoluble sludge when in contact with acid. The sludge consists of asphaltenes, resin, paraffin, and other complex hydrocarbons. The acid reacts with the crude at the interface, forming an insoluble film. The coalescence of this film, which results on the sludge particles, can be avoided by use of proper additives. Ethylene glycol monobutyl ether is a mutual solvent surfactant used in matrix sandstone acidizing to water-wet the formation. This agent prevents particle migration and subsequent particle plugging. It improves cleanup by preventing the stabilization of emulsions by fine particles. Many different surfactants are used in acidizing. Type and concentration for a particular application should be selected on the basis of laboratory testing.

Silicate-Control Agents

Various silicate compounds, commonly known as clays and silts, usually are present in most limestones and dolo-

Fig. 54.11—Photograph showing effect of pH on the volume of silicate particles.

mites. One of the characteristics of these silicates is that they will swell in spent acid. Naturally, this is undesirable because swollen silicate particles may block formation flow channels, reducing well production.

Silicate-control additives are chemicals that prevent released silicate particles from adsorbing water. Some buffer the pH of the solution near the isoelectric point (where the volume of the swelled clays is at a minimum). Others cause shrinkage of the silicate particles by replacing the adsorbed water molecules with a water-repellent organic film. Thus, possible formation plugging is prevented, treating pressures are lowered, faster cleanup is provided, and the occurrence of particle-stabilized emulsions is minimized. This is illustrated in Fig. 54.11.

Iron-Control Agents

Iron control is approached two ways. The oldest and most common approach is to use sequestering agents, which act by complexing iron ions, thereby preventing precipitation when the acid spends. A second method is use of reducing agents that reduce any ferric ions (Fe^{3+}) to ferrous ions (Fe^{2+}), which do not precipitate as the hydroxide or hydrous oxide until the pH of the system is above 7. Since acids in contact with the formation rock will not spend to a pH that high, the hydroxide will not damage the well. Spent acid usually has a pH between 4.5 and 6.5, no higher.

Erythorbic acid is one of the most effective reducing agents that can be used for this purpose. The reduction of all the ferric iron to ferrous iron, however, does not prevent the precipitation of ferrous sulfide (FeS), which precipitates when the acid spends to a pH of 2, as it will readily in almost any formation. To protect fully against iron precipitation in a sour well, a complexing agent is needed. Citric, lactic, and acetic acids as well as EDTA or NTA are popular sequestrants. In some wells where H_2S can become mixed with the acid it also may be advisable to use both the reducing agent and the sequestering agents, since ferric iron can react with H_2S to

precipitate free sulfur, which itself can damage permeability. The loss of effectiveness of acetic acid at temperatures above 125°F and the possibility of precipitating calcium citrate also are factors that should be considered in guarding against iron precipitates.

Alcohols

Methyl and isopropyl alcohols sometimes are used at concentrations of 5 to 20 vol% of acid to reduce surface tension. Methyl alcohol is sometimes used at concentrations up to 66% to increase vapor pressure of the acid and spent acid solution. Use of alcohols thus improves both rate and degree of cleanup, which can be particularly helpful in dry gas wells.

Gelling and Fluid Loss Agents

Natural gums and synthetic polymers are added to acid to increase the viscosity of the acid solution.³ This reduces leakoff into large pore spaces and, to some extent, into natural hairline fractures. It also provides some degree of reaction rate retardation.

Other materials used to control leakoff are fine (100-mesh) sand⁴ and fine salt.⁵ These materials bridge in hairline fractures to reduce fluid flow out of the main fracture during fracture acidizing treatments.

Another successful fluid-loss control agent is a mixture of finely ground, oil-soluble resins.⁶ Originally designed as a diverting agent for use through gravel packs during sandstone matrix acidizing treatments, this agent was later shown to be effective as a fluid-loss agent in fracture acidizing, when used at higher concentrations.⁷

Liquefied Gases

Liquid nitrogen and liquid CO₂ sometimes are used in acid solutions to provide added energy for better well cleanup. Nitrogen also is used to make foamed acid, which provides excellent leakoff control in low permeability rock.^{8,9}

Retarded Acids

It is often desirable in acid fracturing treatments to retard the reaction rate of the acid to provide deeper penetration of active acid into the formation. Retardation may be accomplished by use of slower-reacting acids (HAc and HCOOH), by adding chemicals to reduce reaction rate, or by increasing concentration to extend spending time.

HAc and HCOOH are weakly ionized and sometimes are used to obtain longer reaction time. The additional cost of these acids may prohibit extensive use in certain formations. Deeper matrix penetration than would be obtained by HAc or HCOOH is obtained by the faster-reacting HCl because the channeling or wormhole effect produced by the HCl reduces the A/V ratio, thus prolonging reaction time. In fractures, the HAc and HCOOH would obtain deeper penetration than HCl; however, larger volumes would be required to dissolve an equivalent amount of rock.

Some chemicals, added to HCl, form a barrier on the rock surface, which interferes with its normal contact and "retards" the reaction rate of the acid. Acid-in-oil emulsions generally exhibit retarded reaction rates. The acid in the emulsion does not completely contact the rock sur-

face because of the presence of an interfering oil film. This is particularly true for emulsions with at least 20% oil as the outer phase. Certain surfactants recently have been found to be beneficial in reducing reaction rate and, thus, extending spending time and penetration distance. These surfactants, in the presence of oil, provide a hydrophobic or water-repellent, oil-like film on the rock surface that restricts acid/rock contact. Fluid-loss materials and gelling agents (acid-thickening additives) also tend to reduce the reaction of HCl by film development on rocks.

High concentrations of an acid provide longer reaction times than lower concentrations because (1) there is more acid to react, (2) the additional reaction products further retard reaction rates, and (3) the enlarged flow path, with reduced A/V ratio, extends the spending time and penetration of a high-concentration acid. For example, 28% HCl may take four to six times longer to react completely than does 15% HCl. In this case, the reaction time is extended in spite of the initially faster reaction rate of the 28% HCl.

Acidizing Techniques

There are three fundamental techniques used in acidizing treatments.

1. Wellbore Cleanup. This entails fill-up and soak of acid in the wellbore. Fluid movement is at a minimum, unless some mechanical means of agitation is used.

2. Matrix Acidizing. This is done by injecting acid into the matrix pore structure of the formation, below the hydraulic fracturing pressure. Flow pattern is essentially through the natural permeability structure.

3. Acid Fracturing. This is injection into the formation above hydraulic fracturing pressure. Flow pattern is essentially through hydraulic fractures; however, much of the fluid does leak off into the matrix along the fracture faces.

The technique selected will depend on what the operator wishes to accomplish with the treatment.

Matrix acidizing may be selected as a proper technique for one or more of the following reasons: (1) to remove either natural or induced formation damage, (2) to achieve low-pressure breakdown of the formation before fracturing, (3) to achieve uniform breakdown of all perforations, (4) to leave zone barriers intact, or (5) to achieve reduced treating costs.

The principal types of formation damage are mud invasion, cement, precipitates, saturation changes, and migration of fines. The effect of damage on injectivity or productivity is shown in Figs. 54.12 and 54.13. It can be seen that the greatest flow increase results from restoring the natural rock permeability. The magnitude of this primary flow increase depends on the extent (radius) of the damage. Further increase in pore size by matrix acidizing results in only a limited increase in flow (stimulation).

If the producing formation does not have enough natural permeability, then a hydraulic fracturing treatment should be considered. The primary purpose of fracturing is to achieve injectivity or productivity beyond the natural reservoir capability. An effective fracture may create a new permeability path, interconnect existing permeability streaks, or break into an untapped portion of the reservoir.

Fig. 54.12—Effect of damaged zone on flow.

The success of any fracturing treatment depends on two factors: fracture conductivity and effective penetration, as illustrated in Fig. 54.14. If enough etched fracture conductivity can be achieved, then increased penetration becomes important. For any given formation, there will be an optimum conductivity and penetration, which will be controlled by cost. In other words, there will be some point where production increase per dollar spent will be a maximum. This must be determined by pretreatment design.

Laboratory Testing

The physical and chemical characteristics of the formation rock often affect the results of an acidizing treatment. In some cases, the use of special additive chemicals will improve the action of the acid or avoid cleanup difficulties in returning the spent acid following the job. It is important, therefore, that samples of the formation rock (either cores or cuttings) and, if possible, samples of the crude oil and formation brine be subjected to laboratory testing before acidizing to design the most effective treatment.

Customarily, permeability, porosity, and oil- and water-saturation tests are run on formation core samples, using standardized core-analysis procedures. In addition, acid-solubility tests are run to determine to what extent the formation will respond to an acidizing treatment.

Formation solubility may be determined two different ways. In the first method, a weighed chunk of the rock is immersed in an excess of acid and maintained at formation temperature. After an hour, any insoluble residue is washed, dried, and weighed. With samples known to contain silicates, additional tests may be run in which the rock is exposed to the dissolving action of combined HCl and HF.

A more rapid test, suitable for samples known to consist largely of limestone or dolomite, entails dissolving a weighed sample of the rock in an excess of HCl and measuring the volume of CO₂ gas evolved during the reaction. A simple apparatus for conducting this test is shown in Fig. 54.15.

In addition to these tests of the formation rock, the emulsifying tendencies of the formation crude should be determined whenever possible. Samples of the crude are mixed

Fig. 54.13—Effect of permeability changes on radial flow.

Fig. 54.14—Relationship of conductivity and penetration to productivity increase. J = productivity index of well after stimulation, J_0 = productivity index before stimulation, r_i = radius of fracture (ft), r_o = drainage radius (ft), k_f = permeability of fracture (md), k_o = permeability of formation (md), and b = fracture width (in.).

with the acid to be used in the acidizing treatment and then are shaken. The mixture is allowed to stand, and the time required for the oil and acid to separate is observed. Additional tests are run on mixtures of the crude oil with acid that has been spent completely on pulverized formation rock. If the formation crude shows a tendency to emulsify with either the fresh acid or the spent acid, the use of an appropriate surfactant is indicated.

Similar tests using a mixture of crude and acid are made to determine acid sludging tendencies. Sludge is identified by filtering the mixture through a small mesh screen. Appropriate surfactants that are added to the acid to prevent sludge formation are evaluated.

Other determinations of rock characteristics include tests for clay swelling tendencies and tests to determine rock composition (such as X-ray diffraction analysis) to indicate need for stabilizers, sequestering agents, or other acid additives.

Fig. 54.15—Laboratory solubility tester (carbon dioxide evolution method).

Acid Treatment Design

Three techniques of acidizing have been described previously. Wellbore cleanup treatments normally do not require complicated design procedures. Matrix and fracture acidizing treatments, on the other hand, can involve extensive predesign laboratory testing and complicated design procedures and calculations.

Matrix Acidizing—Carbonate Formations

Matrix acidizing in carbonates normally is used to break down all perforations and to remove damage. Plugging materials can be removed and permeability restored in two ways: (1) by dissolving the damaging material itself or (2) by dissolving part of the rock in which the damage exists. In carbonate rocks with acid solubilities greater than 50%, the latter method is often most effective. The dislodged solid particles or liquids then can be removed physically by the return of the spent acids to the well.

HCl normally is used in matrix treatments of carbonates, but HAc and/or HCOOH should be considered

TABLE 54.4—FLOW THROUGH PORES OF VARIOUS SIZES

Diameter of Pore (μm)	Pore Volume (%)	Flow Through Pores (% of Total Flow)
< 1	60	10
1 to 2	25	15
2 to 5	12	30
5 and above	3	45

for wells with temperatures in excess of 250 to 300°F. Any acid solution should be modified by use of proper additives to meet special situations.

Acid inhibitor selection must be based primarily on treating temperature and, to some extent, on the type of acid formulation.

Surfactant type and concentration should be selected to minimize emulsion tendencies and, perhaps, to aid in dispersing fine undissolved solids. These may be drilling mud, cement solids, or natural clay particles released from the formation. Suspension and removal of these materials can play an important part in the overall treatment results.

Diverting agents may be used to promote uniform penetration in long sections. Acid-swellable synthetic polymers, controlled-solubility particulate solids, perforation ball sealers, gel slugs, etc., have been used successfully to provide more uniform injectivity. Assuring the distribution of acid into the entire interval is a critical part of carrying out a matrix treatment. Otherwise, large portions of the interval may get very little, if any, acid.

In matrix acidizing, injection rates should be controlled so that the formation is not fractured. The use of as high a rate as possible without exceeding the fracturing pressure is recommended. In certain cases, it may be necessary to create a fracture to open perforations, after which pressure can be reduced below fracturing pressure, thus providing a matrix flow pattern.

Controlling the injection pressure is the primary concern. Maintaining bottomhole pressures below hydraulic fracturing pressures may restrict injection rates to only fractional barrels per minute. An increasing rate may then be possible as the treatment progresses.

Because of differences in the size and shape of the pores, penetration of acid in a carbonate rock is far from uniform. Porosity anomalies may result from vugs, hairline fissures, or tortuous capillary-like pores. Because of these heterogeneities, a "channeling" or "wormholing" occurs with most acid formulations. The resultant effect is the attainment of much greater acid penetration of matrix than expected.

The wide distribution of flow in a rock of varying pore diameters (Table 54.4) is further accentuated by acidizing. As discussed in a preceding section, the fast-reacting HCl may provide greater penetration of the limestone matrix than the slow-reacting acetic acid, but not as great as with the emulsified or gelled acids. Evidently, the slow reaction of acetic acid does not change the flow distribution rapidly enough to "channel," but rather results in several small pore enlargements for short distances as opposed to a few large, long channels.

Since the formation damage normally does not exist for a great distance from the wellbore, the volume of acid needed is small. With a formation porosity of 10%, 60

gal of acid per foot of section will fill the porosity to a radius of 5 ft. Usually, matrix treatment volumes range from 50 to 250 gal per foot of section. If damage is deeper than 5 to 10 ft, then larger volumes of acid, a means of retarding the reaction rate, or, perhaps, fracturing techniques, may be required. Very little rock must be dissolved to result in a significant amount of damage repair or permeability increase. Removal of only 1% of limestone or dolomite rock for a distance of about 5 ft from the wellbore requires only 70 gal of 15% HCl/ft of vertical interval.

An overflush in the matrix acidizing treatment is recommended. This will ensure efficient displacement of the acid into the matrix. A minimum shut-in time is recommended before returning the spent acid to the well. Since the spending time of acid is short, a long shut-in time of several hours is not necessary, even for the so-called "retarded acid." The overflush fluid may be brine, water, oil, or a weak acid. Enough volume should be used to ensure maximum penetration of the last portion of the acid, before it is spent.

Matrix Acidizing—Sandstone Formations

The purpose of sandstone acidizing is to restore permeability by dissolving away formation-damaging clay-like minerals or other acid-soluble materials. The clay may be inherent in the formation or may be the result of drilling mud or workover fluid invasion.

The type of acid used most often in sandstones is a mixture of HF and HCl. These mixtures commonly are referred to as mud acids or mud removal acids. As previously discussed, fluoboric acid also has become popular in sandstone formations. Concentrations of 2 to 6% HF and 8 to 12% HCl normally are used. If a significant amount of calcium carbonate is present in the formation (5 to 10%), a spearhead of HCl should be used to react with it before the HF/HCl is injected. With carbonate content above 20%, HF acid probably is not needed, except to give entry through clay damage.

As in any matrix-type treatment, injection of the HF/HCl should be below fracturing pressure. The volume of acid required depends on the depth and severity of the damage. A total of 50 to 250 gal of acid per foot of interval is the normal treatment volume, if damage is not extensive. An acid solubility test may not be a realistic evaluation of acid requirements.

Results of a field study by Gidley *et al.*¹⁰ confirmed some earlier recommendations based on laboratory core flow studies. These results showed much greater success when more than 125 gal/ft acid was used.

The reported core flow test showed what response the formation will have to acid. This is illustrated in Fig. 54.16. Although some of these formations have approximately the same acid (HF/HCl) solubility, permeability, and porosity, the response to acid is quite different.

Initial reduction in permeability is a common occurrence observed with many formation core flow tests. It is attributed to sloughing particles (clays, silica, fines, etc.) that apparently bridge in the flow channels and restrict flow, before their further reaction with the acid. An inadequate acid volume treatment could lead to a restricted permeability in a formation, if the bridging is severe.

Since secondary reactions may occur, resulting in possible precipitation of damaging reaction products, mud

Fig. 54.16—Response of cores from producing formations to mud acid.

acid should be returned to the wellbore as soon as the initial spending time has elapsed. The spent HF/HCl acids should not be allowed to mix with formation brine, if at all possible because of the danger of precipitates.

Inhibitors, surfactants, and diverting methods should be selected just as in an HCl acid treatment. As in the case of matrix acid treatment in carbonates, an overflush is recommended. Suitable fluids include weak acid, oil, or water. Formation brine should not be used to overflush HF/HCl. Short shut-in times should be used—a few hours at the most.

Fracture Acidizing—Carbonate Formations

The primary purpose of an acid fracturing treatment of a carbonate formation is to achieve productivity or injectivity beyond the natural capabilities of the reservoir. It is most applicable in formations with a low and/or ineffective permeability structure. The effectiveness of an induced hydraulic fracture is a function of both its conductivity and the extent of penetration of the drainage radius of the well.

These factors will depend on well and reservoir properties, formation characteristics, injection rate, type and volume of acid used, and shape and orientation of the fracture. All these factors have been correlated by several companies into "guides" to acid fracture treatment design. Such guides provide mathematical relationships for determining the fracture area and conductivity achieved by different volumes of specific acid formulations at various injection formulations. These guides are programmed for computer calculation, so that rapid comparison of various treatment designs can be made for selection of best results per dollar of treatment cost. These guides are not sufficiently similar to get clear comparison between different companies but should be compared only with other calculations from the same system.

Critical Wells

In ultradeep, high-temperature wells, many factors must be considered in the stimulation treatment design. First, the high BHT can drastically affect reaction rate of acid, inhibition, and other properties of the acid formulation.

These effects can be partially offset by formation cool-down techniques. Basically, this consists of pumping a pad volume of fluid (generally gelled water) into the formation to cool the rock to a more normal treating temperature. Most companies have computer programs available to calculate pad volumes required for a given temperature reduction.

Another problem is created when fluids with temperatures lower than BHT's are used. This problem is mechanical and involves tubing movement. In ultradeep wells, such contraction can create stress in the tubing greater than tubing strength, resulting in a parted string. The solution to this problem is to slack off or to release tension at the top of the tubing string as the job progresses. Again, computer programs are available from most service companies to predict tubing movement under given conditions.

Summary

In summary, acidizing is a process that uses reactive materials to increase well production by dissolving either the reservoir rock or damaging materials blocking the pore spaces of the rock. Different kinds of acids and additives are available, so that treating fluids can be tailored to meet individual well needs. Acid formulations may be applied in either matrix- or fracture-type treatment, depending on the degree of stimulation or production increase desired. While acidizing, and acidizing treatment design, in detail are beyond the scope of this text, published literature offers answers and assistance in solving many of the problems encountered. The General References cover many of the recent technical developments in this field. In addition, most service companies providing acidizing service offer laboratory facilities, technical assistance, and computer programs for problem analyses and treatment design.

Chapter 55

Formation Fracturing

S.J. Martinez, U. of Tulsa *

R.E. Steanson, Dowell Schlumberger **

A.W. Coulter, Dowell Schlumberger **

Introduction

Fracturing techniques were developed in 1948 and the first commercial fracturing treatments were conducted in 1949. The process rapidly gained popularity because of its high success ratio, and within a very few years, thousands of wells per year were being stimulated by hydraulic fracturing treatments.

Early treatments consisted of pumping 1,000 to 3,000 gal of fracturing fluid, containing about 1 lbm of 20/40-mesh sand/gal, at rates of 1 to 2 bbl/min. Today, a single treatment can require several hundred thousand gallons of fluid and more than a million pounds of propping agent. Although injection rates have exceeded 300 bbl/min in some instances, rates of 20 to 60 bbl/min are about average. Materials, equipment, and techniques have become highly sophisticated. A bibliography is presented at the end of this chapter for those interested in a detailed discussion of particular technologies. This discussion is limited to a generalized description of fracturing theory, materials, techniques, equipment, and treatment planning and design.

Hydraulic Fracturing Theory

Oil and gas accumulations occur in the pore spaces or natural fractures of a subsurface rock where structural and/or stratigraphic features form a trap. When a well is drilled into an oil-bearing rock, the fluids must flow through the surrounding rock into the wellbore before they can be brought to the surface. If the pore spaces of the rock are interconnected so that channels exist through which the oil can flow, the rock is "permeable." The ease with which fluid can flow through a rock determines its degree of permeability. It has high permeability if oil, gas, or water can flow easily through existing channels and

low permeability if the connecting channels are very small and fluid flow is restricted.

In the case of high permeability, drilling fluids may enter the flow channels and later impair flow into the wellbore. In the case of low permeability, the flow channels may not permit enough flow into the wellbore. In either case, the well may not be commercial because fluid cannot flow into the wellbore fast enough. It then becomes necessary to create an artificial channel that will increase the ability of the reservoir rock to conduct fluid into the wellbore. Such channels often can be created by hydraulic fracturing.

During hydraulic fracturing treatments, what actually happens when a rock ruptures, or fractures, can be explained by basic rock mechanics. All subsurface rocks are stressed in three directions because of the weight of overlying formations and their horizontal reactions. Whether one of the horizontal stresses or the vertical stress is the greatest will depend on the additional stresses imposed on the rock by prior folding, faulting, or other geological movement in the area. These tectonic stresses will control the direction of the fracture and determine whether the fracture plane will be horizontal, vertical, or inclined.

Every formation rock has some measure of strength depending on its structure, compaction, and cementation. It has tensile strength in both vertical and horizontal directions. The forces tending to hold the rock together are the stresses on the rock and the strength of the rock itself. When a wellbore is filled with fluid and pressure is applied at the surface, the pressure of the fluid in a perforation or even in the pore spaces of the rock will increase. This hydraulic pressure is applied equally in all directions. If the pressure is increased, the forces applied by the fluid pressure in the rock will become equal to the forces tending to hold the rock together. Any additional pressure applied will cause the rock to split or fracture. The fracture will extend as long as sufficient pressure is applied by injection of additional fluids.

*Deceased; this author also wrote the original chapter on this topic with coauthor P.E. Fitzgerald.

**Retired

When the treatment is complete and flow is reversed to produce the well, pressure will gradually return (decline) to reservoir pressure. As this occurs, the forces tending to hold the rock together come into play again and the fracture will close or "heal." To prevent closure, some solid material must be placed in the fracture to hold it open. Such materials are called "propping agents." Since the permeability of these propping agents is much higher than that of the surrounding formation, the ability of the propped fracture to conduct fluids to the wellbore can result in good production increases. In fact, fracturing has made profitable production possible from many wells and fields that otherwise would not have been profitable.

Formations Fractured

Fracturing has been used successfully in all formations except those that are very soft. Fracturing has proved successful in sand, limestone, dolomitic limestone, dolomite, conglomerates, granite washes, hard or brittle shale, anhydrite, chert, and various silicates. The plastic nature of soft shales and clays makes them difficult to fracture.

Fracturing has helped wells producing from formations that have such a wide range of permeabilities that it is impossible to set upper and lower permeability limits of formations that might be helped by fracturing. Production increases have been obtained from zones having permeabilities ranging from less than 0.1 to as high as 900 md.

Fracture Planes

Analysis of pressures encountered on many thousands of fracturing treatments has shown that the bottomhole pressures (BHP) recorded during the injection of fracturing materials range from 0.40 to 1.80 psi/ft depth.¹ Only in a few treatments have fracturing pressure gradients been outside of this range. Those were almost all in shallow experimental treatments. The fracture gradient g_f is calculated from treatment data by Eq. 1:

$$g_f = \frac{p_h + p_s - p_f}{D}, \quad \dots \dots \dots (1)$$

where

- g_f = unit fracture gradient, psi/ft,
- p_h = total hydrostatic pressure, psi,
- p_s = total surface treating pressure, psi,
- p_f = total friction loss, psi, and
- D = depth of producing interval, ft.

Analysis of thousands of treatments plus experimental work in reservoirs with known fracture gradients indicate that horizontal fractures are produced in reservoirs having fracture gradients of 1.0 or higher. This is generally in shallow wells less than 2,000 ft deep. Vertical fractures are produced in reservoirs having fracture gradients of 0.7 or lower. Such gradients are normally encountered in wells deeper than 4,000 ft. Very few cases have been found where formations have gradients in the intermediate range between 0.7 and 1.0. Consequently, the use of fracture gradients to predict the general inclination of fractures should be useful in almost every case.

With few exceptions, wells in the same reservoir will have nearly identical fracture gradients. Thus, the gradient from one well generally will serve as a guide for the entire pool.

Fracture Area

In 1957, Howard and Fast² presented a mathematical equation to determine the surface area of a newly opened fracture. The equation, based on the quantity of fracturing materials used and the rate at which they are injected into the formation, takes into account the physical characteristics of the fracturing fluids and the specific reservoir conditions. This equation is:

$$A_t = \frac{ib}{4\pi K^2} \left[e^{x^2} \cdot \operatorname{erfc}(x) + \frac{2x}{\sqrt{\pi}} - 1 \right], \quad \dots \dots \dots (2)$$

where

$$x = \frac{2K\sqrt{\pi t}}{b},$$

and

- A_t = total area of one face of the fracture at any time during injection, sq ft,
- i = constant injection rate during fracture extension, cu ft/min,
- t = total pumping time, minutes,
- b = fracture width (breadth), ft,
- K = fluid coefficient, a constant that is a measure of the flow resistance of the fluid leaking off into the formation during fracture operations, and
- $\operatorname{erfc}(x)$ = complementary error function of x .

Essentially, during a fracturing treatment, only the volume of fracturing fluid that remains within the wall of the fracture is effective. The fluid that leaks off into the pores of the rock is lost insofar as added fracture extension is concerned.

When the width of a fracture is known or assumed (fracture width is normally calculated using either Perkins and Kern³ or Khristianovitch and Zheltov⁴ models), the volume of the fracture can be calculated. With these data, it is possible to plot the controllable variables of a fluid volume and injection rate against the fracture area produced for any particular fluid coefficient. Examples of such graphs, for various injection rates, are shown in Figs. 55.1 through 55.5.

The rate of fluid leakoff into the formation, as expressed by the fluid coefficient, is controlled by three variables: the viscosity and compressibility of the reservoir fluid, the viscosity of the fracturing fluid, and the fluid-loss characteristics of the fracturing fluid.

Reservoir-Controlled Fluids

This group includes those fracturing fluids having low viscosity and high fluid-loss characteristics, in which the rate of leakoff is controlled by the compressibility and viscosity of the reservoir fluid.

Fig. 55.1—Effect of fluid coefficient and volume on fracture area at constant injection rate of 10 bbl/min.

Fig. 55.2—Effect of fluid coefficient and volume on fracture area at constant injection rate of 20 bbl/min.

Fig. 55.3—Effect of fluid coefficient and volume on fracture area at constant injection rate of 30 bbl/min.

Fig. 55.4—Effect of fluid coefficient and volume on fracture area at constant injection rate of 40 bbl/min.

Fig. 55.5—Effect of fluid coefficient and volume on fracture area at constant injection rate of 50 bbl/min.

The coefficient for this type of fracturing fluid may be determined from Eq. 3.²

$$K_c = 0.0374 \Delta p \sqrt{\frac{k_e \phi_e c_R}{\mu_R}}, \quad \dots \dots \dots (3)$$

where

- K_c = fluid coefficient (compressibility-viscosity controlled), ft/min^{1/2},
- Δp = differential pressure, across the face of the fracture, psi,
- k_e = effective formation permeability, darcies,
- ϕ_e = effective formation porosity, %,
- c_R = isothermal coefficient of compressibility of the reservoir fluid, psi⁻¹, and
- μ_R = reservoir fluid viscosity, cp.

Compressibility considerations are generally found to be most applicable in high-pressure, low-volume-factor wells that have high saturations.

Viscosity-Controlled Fluids

This group includes those fracturing fluids in which the rate of leakoff is controlled by the viscosity of the fluid itself. The coefficient for this type of fracturing fluid is expressed by Eq. 4.²

$$K_v = 0.0469 \sqrt{\frac{k_e \Delta p \phi_e}{\mu_f}}, \quad \dots \dots \dots (4)$$

where

- K_v = fluid coefficient (viscosity controlled), ft/min^{1/2},
- k_e = effective formation permeability, darcies,
- Δp = differential pressure across the face of the fracture, psi—this is the product of the fracture gradient and depth, minus normal reservoir pressure, $(g_f \times D) - p_R$,
- ϕ_e = effective formation porosity, %, and
- μ_f = fracturing fluid viscosity, cp.

Fig. 55.6—Increased fracture penetration by containment of the fracture in the productive interval can provide much greater production increases.

The effective porosity represents the space in the matrix into which fracturing fluid will leak off. In figuring effective porosity, the effects of residual oil and water saturation should be considered. The permeability factor in the equation almost always will be the permeability of the water-wet formation, but it could be that of an oil-wet formation. The average md-ft of exposed section also is considered.

Fluid-Loss-Controlled Fluids

This group includes fracturing fluids containing special fluid-loss additives designed to reduce the loss of fluid taking place during a fracturing treatment.

The fluid coefficient for this type of fracturing fluid is based on Eq. 5.²

$$K_l = 0.0328 \frac{m}{2A}, \quad \dots \dots \dots (5)$$

where

- K_l = fluid coefficient, wall building (fluid-loss additive), ft/min^{1/2},
- m = the slope of the fluid-loss curve, plotting cumulative filtrate volume vs. the square root of flow time, mL/min^{1/2}, and
- A = cross-sectional area of test media through which flow takes place, cm².

In this case, the coefficient is obtained from an experimental test to determine the fluid loss resulting from the use of a particular fluid-loss additive in a particular fracturing fluid. The test must be performed at, or corrected to, bottomhole temperature (BHT) and pressure conditions. Spurt loss is the leakoff occurring while the fluid-retaining wall (filter cake) is being built up. It can be determined from this test by extrapolating the straight-line portion of the curve back to zero time on the ordinate. The value at this intercept is the spurt loss.

Stimulation Results

The increased production obtained following a fracturing treatment is the result of increased fracture penetration and conductivity. The greater penetration produces a larger drainage area from which reservoir fluids can be produced. Increased fracture conductivity results from the lowered resistance to flow through the fracture, permitting greater production of fluid under reservoir energy conditions.

Fig. 55.6⁵ shows the relationship between fracture penetration, fracture conductivity ratio, and production increase. These curves represent fracture penetration as a decimal fraction of the drainage radius. If a good conductivity ratio can be achieved, then a fracture penetrating 100% of the drainage radius can provide as much as a 13-fold increase in the production.

Fracture conductivity is controlled largely by propping agent permeability, size, and placement. Strength of the propping agent is also very important. The effect of these properties on fracture conductivity will be discussed later.

Fracture penetration is related directly to fracture-fluid efficiency and containment of the fracture within the production zone. A good fracturing fluid should be relatively low in cost and have low fluid loss, low friction loss,

good proppant transport characteristics, temperature stability, ability to thin for good cleanup, and compatibility with reservoir rock and fluids. Containment of the fracture within the productive interval is a function not only of fluid properties but also of technique.

Fracturing Materials

Fracturing Fluids

Fracturing fluids may be divided into three broad divisions: oil based, water based, and mix based. Classification depends primarily on the main constituent of the fracturing fluid. The aqueous-based fluids are either water or acid, and the mix-based fluids are emulsions.

Oil-Based Fluids. In the past, refined oils, crude oils and soap-type gels of crude, kerosene, or diesel oil were quite common. Because of safety considerations, lack of temperature stability, and cost of tailoring these materials to be efficient fluids, they are seldom used today. A new thickened and crosslinked hydrocarbon gel, made from either light refined oils or crude oil, is used extensively in hydraulic fracturing of oil- and gas-condensate wells producing from reservoirs adversely affected by water or brine. These gels exhibit all the characteristics of an efficient fracturing fluid.

Water-Based Fluids. Gels. Water-based fluids are natural or synthetic polymer gels of water or hydrochloric acid. They may be either linear or crosslinked gels. The water-based fluids are used almost exclusively except in those extremely water-sensitive reservoirs previously mentioned. The popularity of aqueous fluids is based on many factors, including these four: (1) they are safe to handle, (2) their cost is low in comparison to oil-based fluids, (3) they are, or can be formulated to be, compatible with nearly all reservoir fluids and conditions, and (4) they can be tailored to meet almost any treating requirements. Rheological properties, friction pressure, fluid loss, and break time can be closely controlled to provide an efficient fracturing fluid over a wide range of well and reservoir conditions. The primary disadvantage of aqueous fluids is that they may not be applicable in formations that are adversely affected by water.

Waterfrac services use linear (uncrosslinked) gels of fresh water, salt water, or produced brine as efficient and economical fracturing fluids. Guar and hydroxypropyl guar thickening agents are available to satisfy the requirements of a wide range of reservoir properties. They can be used in either batch- or continuous-mix techniques. A cellulose derivative thickener is available for applications in which fluids with extremely low residue are required.

The viscosity of fluids used in waterfrac services is controlled by thickening-agent concentration.

High-viscosity fracturing fluids have been developed that contribute directly to wider, better-propped, and more-conductive fractures. Fracture width is increased by increasing the viscosity of the fracturing fluid. Wider fractures permit use of larger proppant, which has greater permeability. These viscous fluids also have the proppant-transport properties required to carry higher concentrations of proppant deeper into the fracture. They achieve their high viscosity at gel concentrations in the same range as the traditional waterfrac fluids by using

special crosslinking systems and stabilizers. The high-viscosity gels are particularly useful in deep wells because of their temperature stability. They are able to create wide, deeply penetrating fractures at lower rates and can maintain their viscosity over the longer pumping times required in deeper wells. Fig. 55.7 shows the viscosity profile of one such fluid.

Two other characteristics of fracturing fluids normally are reported and are used in computer job design. These are the consistency index, I_c , and the behavior index, I_b . The power law model is used to calculate these characteristics. The consistency index is based on pipe flow geometry. The power law parameters are defined as follows:

I_b = behavior index; log slope of the shear stress vs. shear rate curve,
dimensionless, and

I_c = consistency index; shear stress at 1 sec^{-1} ,
 $\text{lbf-sec}^{-1}/\text{ft}^2$.

Apparent viscosity is related to the consistency index and behavior index as follows:

$$\mu_a = \frac{47,880 I_c}{\dot{\gamma}^{1-I_b}},$$

where

μ_a = apparent viscosity, cp, and
 $\dot{\gamma}$ = shear rate, sec^{-1}

Since shear history (shear rate and time at shear) adversely affects the rheology of some crosslinked gels, test methods have been developed that more accurately describe the fluids at the time they enter the fracture. Table 55.1 compares data developed by the API test method and shear history method.⁶ The data provided by the shear history method give more reliable prediction of friction losses while pumping. Such information is a requisite in job design to predict fracture geometry and reduce

*Shear history simulation method.

the possibility of premature screenout. Figs. 55.8 through 55.13 are examples of friction-loss data for various fluids.

In many of the high-viscosity fluids, shear history effects are minimized by using additives to delay crosslinking until the fluid reaches the bottom of the hole. This technique also reduces friction losses since high viscosity does not develop until after the fluid has passed through the tubulars.

Foams. During recent years, foams have become extremely popular as fracturing fluids. Normally classed as water-

based fluid, foam is a dispersion of a gas, usually nitrogen, within a liquid. A surfactant is used as a foaming agent to initiate the dispersion. Stabilizers are used where high temperatures or long pumping time occur. The volumetric ratio of the gas to the total volume of the foam, under downhole conditions, is called the quality of the foam. Quality is expressed as a number equal to the percentage. A 75-quality foam is 75% gas by volume at downhole temperature and pressure. In fracturing, foam quality usually ranges from 65 to 85 (compositions containing less than 52% gas are not normally stable foams).

Fig. 55.8—Typical friction-loss curves for linear gel of fresh water or brine using guar or hydroxypropyl guar thickeners.

Fig. 55.9—Typical friction-loss curve of linear aqueous gel using cellulose thickener.

Fig. 55.10—Typical friction-loss curve for crosslinked aqueous gel using guar-based thickener.

Fig. 55.11—Typical friction-loss curve for gelled oil fracturing fluid.

Foam is designed primarily for low-permeability or low-pressure gas wells. However, it may have equal advantages in low-pressure oil wells. In oil wells it may be necessary to use a different foaming agent that is compatible with reservoir fluids and reduces the possibility of emulsions.

Some advantages of foam are: (1) good proppant transport, (2) solids-free fluid-loss control, (3) low fluid loss, (4) minimum fluid retention owing to its low water content, (5) compatibility with reservoir fluids, and (6) low hydrostatic pressure of returned fluids, which gives rapid

cleanup and allows quicker well evaluation (gas in foam helps return liquids to the wellbore).

Some disadvantages of foam are: (1) more surface pressure is required because of low hydrostatic head; and (2) there is the added expense of gas, especially under high pressure where volume is reduced.

Mix-Based Fluids. Mix-based fluids are oil-in-water dispersions or emulsions that serve as highly efficient water-based fracturing fluids.

Fig. 55.12—Typical friction-loss curve for oil-in-water dispersion-type fracturing fluid.

Fig. 55.13—Typical friction-loss curve for heavy oil-in-water emulsion-type fracturing fluid.

Fig. 55.14—Effect of closure stress on permeability of various propping agents.

The viscous emulsions are water-outside-phase emulsions containing two parts oil (crude or refined) and one part water or brine. These are commonly called "poly-emulsions" and are designed to provide high-viscosity fracturing fluids at temperatures up to 350°F. They are seldom used because of fire hazard and cost.

A crosslinked gel provides high viscosity in the water volume (95%), and a 5% oil phase is dispersed throughout the mixture to give excellent fluid-loss control properties without requiring the addition of solids. The leakoff control is the result of two-phase fluid flow that reduces the relative permeability of the formation more than conventional fracturing fluids do over a wide permeability range. The fluid is highly efficient even when compared to viscous-emulsion fracturing fluids. Normally, the 5% oil content is low enough to avoid significant effects on either friction pressure or hydrostatic head, even when used with the highly viscous water or brine gels.

Fracturing fluid composition is normally proprietary information of the service company supplying it. While competitive fluids are available from most of the service companies, rheological and friction-loss data will vary according to the fluid. Therefore, handbooks provided by the service companies should be used to obtain data for job design.

Propping Agents

Propping agents are used to maintain fracture-flow capacity after completion of a hydraulic fracturing treatment. The amount of proppant used, the manner in which it is placed in the fracture, and the properties of the material itself all play a vital role in maintaining productivity throughout the life of the well. The selection of the propping agent and scheduling of the proppant during the treatment are important parts of the overall completion and treatment design.

The six physical properties of propping agents that affect the resultant fracture conductivity are grain strength, grain size, grain size distribution, grain roundness factor, quality (amount of fines and impurities), and proppant density.

Grain Strength. While all these physical properties have a decided effect on fracture conductivity, quality standards

have been established so that the main considerations are grain strength and grain size. If a proppant is not strong enough to withstand closure stress of the fracture, it will crush, and permeability will be reduced greatly. Also, as reservoir pressure is reduced by fluid production, the closure stress will increase. Therefore, it is important that proppant strength be selected for the stress that will be present during the later life of the well. Fig. 55.14 shows the effect of closure stress on permeability of various propping agents when the formation is a hard, competent rock. Sand is an acceptable propping agent at closure stresses up to 6,000 psi. At stresses greater than this, high-strength proppants such as sintered bauxite particles or plastic-coated sand grains should be used.

In soft formations, the proppant will tend to embed into the formation under closure stress and reduce fracture width. This, in turn, reduces fracture flow capacity. In the past, deformable proppants such as rounded walnut shells and aluminum pellets have been used in an attempt to overcome this problem. By deforming or spreading out, these proppants presented a larger surface area to the face of the fracture and resisted embedment. The low density and malleability of these proppants caused both pumping and placement problems, and they were never widely accepted. There was also a corrosion or oxidation of the aluminum that resulted in loss of pack permeability.

A better solution to embedment is a wide, packed fracture. In such a fracture, width reduction resulting from embedment is a small percentage of total fracture width, and adequate flow capacity is maintained even after embedment occurs.

Grain Size. A large proppant grain size provides a more permeable pack under low closure stress conditions and can be used in shallow wells. However, dirty formations or those subject to significant fines migration are poor candidates for large-size proppants. The fines tend to invade the proppant pack, causing partial plugging and rapid reduction in permeability. In these cases, smaller sizes of proppant that resist invasion of fines are better.

Larger grain sizes are generally not considered for deeper wells because of greater susceptibility to crushing.

Proppant Placement. The manner in which a propping agent is placed in a fracture is also important. As previously stated, soft or high-permeability formations need a wide, fully packed fracture. In very-low-permeability formations, only a thin fracture may be necessary. However, fracture length becomes important in such formations because the greater the surface area of formation exposed to the propped fracture, the greater the volume of oil or gas that can drain into the fracture. Since fluid enters the fracture along its entire length, long fractures must be wider at the wellbore than at the tip to accommodate the increasing amount of fluid as the fracture nears the wellbore. To accomplish this fracture geometry, the proppant must be scheduled so that its concentration in the fracture fluid increases steadily as the treatment progresses.

Fracturing Techniques

Although fracturing treatments usually are performed by pumping materials down the casing or tubing at rates as high as well limitations and economics will permit, spe-

cial techniques sometimes are used to help control vertical fracture growth. Such control is directly related to fracturing efficiency. In the case of massive zones, adequate fracture height to cover the entire zone is desirable. With narrow zones, containment of the fracture within the productive zone improves efficiency and penetration and prevents fracture growth into undesirable zones.

While vertical growth can be controlled to some extent by controlling injection rate, more sophisticated techniques are required for optimum efficiency.

A Limited Entry® technique involves designing the number and size of perforations to match an economically feasible pump rate so that all perforations are forced to accept fluid during the treatment.

Another specialty technique to limit downward growth of a vertical fracture involves building an artificial lower barrier. This is done by using low injection rates and fluids with poor proppant transport characteristics at the beginning of the treatment. Propping agent can create a proppant pack at the bottom of the fracture. A pressure drop will exist across this pack and will divert the fluid that follows outward and upward, thus slowing or even stopping downward fracture growth.

Similarly, a buoyant propping agent can create an artificial upper barrier by floating to the top of the fracture and bridging to form a proppant pack. In this case also, the pressure drop across the pack will force subsequent fluids outward to increase fracture length.

Multiple-Zone Fracturing

Where multiple zones are open to the wellbore, mechanical devices such as packers or bridge plugs can be used to isolate zones so that each can be treated individually. Where it is desirable to fracture more than one zone in a single treatment, sized particulate materials or perforation ball sealers can be used. The particulate materials usually are suspended in a viscous fluid and filter out at the fracture entrance. After treatment, they generally flow back with produced fluids. They also can break down through chemical reaction. Ball sealers seat in perforations and divert fluid flow. They are unseated by reverse flow and either fall to the bottom or are produced along with the returning fluids. When ball sealers are used, a mechanical device to catch the balls should be used at the surface to prevent the balls from plugging valves or other surface equipment.

Fracturing Equipment

Hydraulic fracturing equipment consists of pumps and blenders, high-pressure manifolds and treating line, remotely controlled master valves, and tree savers.

Pumping equipment is the conventional triplex pump, quintuplex pump, or a pressure-multiplier type of pump. The latter employs an entirely different pumping concept from the triplex pump. It operates by using a low-pressure working fluid to push a large piston. This large piston is directly connected to a smaller piston, or ram, which handles the treating fluid. Because of a slow cycle speed, the pressure multipliers are capable of long pumping times at high pressures. Both the triplex and pressure multiplier are capable of high-pressure operation. Above 12,000-psi treating pressure, however, the multiplier is preferred. These units are capable of operating at pressures slightly in excess of 20,000 psi.

Individual pumping units are powered by engines ranging from less than 100 to more than 1,300 hp. For high horsepower requirements, multiple units are used.

Fluids used in hydraulic fracturing are mixed in blenders. They are either batch mixed before a job and stored in tanks on location or continuously mixed during the job. Blenders are capable of metering both dry and liquid additives into a fluid, mixing the fluid and additives, and metering and mixing propping agent into the fluids. After mixing and blending, the slurries are supplied by the blender to the suction on the high-pressure pumps under pressure. Blending units capable of handling volumes in excess of 100 bbl/min are available.

Liquid nitrogen is the gas normally used for foam or energized fluid. Special transport and pumping equipment is required to handle the nitrogen, which generally is metered into the treating line on the downstream (high-pressure) side of the triplex or multiplier pumps.

Another piece of equipment recently added to fracturing fleets is the treatment monitoring vehicle. This vehicle gathers data, uses a computer to analyze them, and presents the results as they occur, or in "real time." The data are presented by a printer, plotter, and on a CRT screen. Real-time analysis and presentation of data allow positive control of a treatment. Ample warning of problems normally is available so that changes can be made to permit successful completion of the job. Also, the equipment can be used to monitor a minifrac job before the main treatment. Analysis of the minifrac can either verify job design or indicate needed design changes before the main treatment.

Treatment Planning and Design

Success of a hydraulic fracturing treatment depends on creating a deeply penetrating, highly conductive fracture in the producing zone. Research, engineering studies, and experience have provided reliable planning or treatment design guides. Job calculations with these guides are based on reservoir conditions, laboratory tests, theoretical data, well information, and experience in a given area. Most service companies and many oil-producing companies have job-design calculations computerized to aid in rapid and accurate design comparisons. Special computer programs are available also to calculate tubing expansion and contraction, bottomhole cool-down (fluid temperature at the wellbore and in the fracture), proppant scheduling to provide best propped fracture geometry, and anticipated productivity increase.

Evaluating and selecting optimal treating conditions for any individual well includes several steps. First, accurate reservoir and well-completion data must be accumulated to provide a sound basis for engineered treatment preplanning. Next, the fracture area and the extent of formation penetration necessary to provide the desired productivity increase are calculated. The fracture conductivity, as related to the permeability of the matrix, is determined also.

After this, the comparative efficiency of various fracturing fluids, based on specific well conditions, is determined, as well as the volumes and injection rates necessary to provide the desired fracture extension. Horsepower requirements for each type of treatment then can be calculated; and fracturing materials and techniques can be selected that, theoretically, will most efficiently and eco-

nomically produce the desired productivity increase. Only when all these factors are considered collectively can a well-integrated fracturing treatment be carried out.

Nomenclature

- A = cross-sectional area of test media through which flow takes place, cm^2
 A_f = total area of one face of the fracture at any time during injection, sq ft
 b = fracture width (breadth), ft
 c_R = isothermal coefficient of compressibility of the reservoir fluid, psi^{-1}
 D = depth of producing interval, ft
 $\text{erfc}(x)$ = complementary error function of x
 g_f = unit fracture gradient, psi/ft
 i = constant injection rate during fracture extension, cu ft/min
 I_b = behavior index; log slope of the shear-stress vs. shear-rate curve, dimensionless
 I_c = consistency index: shear stress at 1 sec^{-1} , $\text{lbf-sec}^{-1}/\text{ft}^2$
 k_e = effective formation permeability, darcies
 K = fluid coefficient, a constant that is a measure of the flow resistance of the fluid leaking off into the formation during fracture operations
 K_c = fluid coefficient (compressibility-viscosity controlled), $\text{ft/min}^{1/2}$
 K_l = fluid coefficient, wall building (fluid-loss additive), $\text{ft/min}^{1/2}$
 K_v = fluid coefficient (viscosity controlled), $\text{ft/min}^{1/2}$
 m = slope of fluid-loss curve, plotting cumulative filtrate volume vs. square root of flow time, $\text{mL/min}^{1/2}$
 p_f = total friction loss, psi
 p_h = total hydrostatic pressure, psi
 p_R = normal reservoir pressure, psi
 p_s = total surface treating pressure, psi
 Δp = differential pressure across face of fracture, psi
 t = total pumping time, minutes
 γ = shear rate, sec^{-1}
 μ_a = apparent viscosity, cp
 μ_f = fracturing fluid viscosity, cp
 μ_R = reservoir fluid viscosity, cp
 ϕ_e = effective formation porosity, %

Key Equations in SI Metric Units

$$K_c = 1.9203 \times 10^{-4} \Delta p \sqrt{\frac{k_e \phi_e c_R}{\mu_R}}, \dots \dots \dots (3)$$

$$K_v = 2.41 \times 10^{-4} \sqrt{\frac{k_e \Delta p \phi_e}{\mu_f}}, \dots \dots \dots (4)$$

and

$$K_l = 0.001076 \frac{m}{2A}, \dots \dots \dots (5)$$

where

- K_c, K_v , and K_l are in $\text{m/s}^{1/2}$,
 Δp is in kPa ,
 k_e is in μm^2 ,
 ϕ_e is in percent,
 c_R is in kPa^{-1} ,
 μ_R is in $\text{Pa} \cdot \text{s}$,
 m is in $\text{mL/s}^{1/2}$, and
 A is in m^2 .

Chapter 56

Remedial Cleanup, Sand Control, and Other Stimulation Treatments

A.W. Coulter Jr., Dowell Schlumberger*

S.J. Martinez, Information Services Div., U. of Tulsa*

K.F. Fischer, Dowell Schlumberger*

Introduction

Although fracturing and acidizing are the most common types of well stimulation used today, other types of stimulation treatments also are used. Some of these treatments use acid-type materials but are not generally classed as acidizing jobs. These treatments are specifically designed for the removal of a blocking agent such as gypsum (gyp), drilling mud, paraffin, formation silicate, particles, or other materials on the wellbore face and in the formation immediately adjacent.

The first stimulation treatments used in oil and gas wells involved explosives such as dynamite or nitroglycerin. This method was used for many decades before being discontinued for safety reasons. More recent attempts to stimulate with explosives involved displacement of explosive material into the producing formation in a fracture-type treatment. The material was then detonated. Because this method was hazardous, research involving explosives has been discontinued.

Reperforation

In some cases it is useful to reperforate a well in the same zone in which it was originally perforated. The detonation of the gun loosens blocking materials in the formation adjacent to the well and in the previous perforations, and simultaneously creates more drainage holes into the wellbore. Also, over a period of time, some of the original perforation tunnels might become totally blocked by migratory fines, scale, gyp, or paraffin. Reperforation in such cases could greatly increase drainage area into the wellbore.

Abrasive Jet Cleaning

Another method used to clean up shot holes or to remove gyp contaminating the formation near the wellbore makes

use of a jetting tool. One or more streams of sand-laden fluid are forced through a hardened, specially designed nozzle at pressures of 1,000 psi and up, to impinge against the wall of the borehole.

These jets, striking against the face of the open hole, loosen and break up gyp deposits, and may penetrate the formation. If the tool is moved up and down while jetting, the entire borehole can be cleaned. This same tool may be used for perforating pipe; the high-pressure jets of sand-laden fluid are able to cut through $\frac{1}{4}$ -in.-thick steel pipe in 15 to 30 seconds. They can then penetrate the formation to a depth of 12 or 15 in. in another 5 minutes or so, forming large unobstructed channels for the production of reservoir fluids.

Mud Removal

Several materials are used to remove drilling mud from the borehole and the adjacent formation. The most commonly used material is a mud-dissolving acid consisting of inhibited hydrochloric acid (HCl) with an added fluoride. This material dissolves part of the mud and loosens the remainder so that it may be flushed out. Mud-removal agents are often used ahead of fracturing, acid jobs, or cement, to clean the face of the pay, to allow a lower breakdown pressure, and to minimize mud contamination.

Acid cleanup solutions, containing special surfactants that increase penetration and provide special mud-dispersing properties, are also used when an infiltration of mud into the formation is suspected.

Other solutions, containing phosphates or other chemicals, may be used to loosen and disperse mud particles so they can be more easily flushed from their position in or adjacent to the wellbore.

Special blends of surfactants, iron chelating agents, and mud-dispersing agents also have been effective in removing mud from the formation.

*Authors of the original chapter on this topic in the 1982 edition were S.J. Martinez and P.E. Fitzgerald (both now deceased).

Water Blocks and Emulsions

Oil- and/or water-based solutions containing low-surface-tension, emulsion-breaking agents have been used successfully to remove water blocks or emulsions from a formation. More recently, solutions of special surfactants and alcohols have become popular. These materials are pumped into the formation to contact the water or emulsion block. By changing the blocking material's physical characteristics, the solution enables the blocking fluid to be produced. Treatments of this type usually consist of a specialized, commercially available product with an oil-carrying agent. If a large zone is to be treated, diverting agents, ball sealers, or packers should be used to ensure that the solution contacts the blocking fluids. Otherwise, the chemicals will probably enter the more permeable and nonblocked portions of the formation and miss the blockage completely.

Scale Deposits

When a well produces some water, gyp deposits may accumulate on the formation face and on downhole equipment and thereby reduce production. These deposits may have low solubility and be difficult to remove. Solutions of HCl and ethylenediaminetetraacetic acid (EDTA) can often be used to remove such scales. Soluble portions of the scale are dissolved by the HCl while the chelating action of EDTA breaks up and dissolves much of the remaining scale portions. When deposits contain hydrocarbons mixed with acid-soluble scales, a solvent-in-acid blend of aromatic solvents dispersed in HCl can be used to clean the wellbore, downhole equipment, and the first few inches of formation around the wellbore (critical area) through which all fluids must pass to enter the wellbore. These blends are designed as a single stage that provides the benefits of both an organic solvent and an acid solvent that contact the deposits continuously.

Paraffin Removal

Several good commercial paraffin solvents are on the market. These materials can be circulated past the affected parts of the wellbore or simply dumped into the borehole and allowed to soak opposite the trouble area for a period of time. Soaking, however, is much less effective because the solvent becomes saturated at the point of contact and stagnates.

In the past, many paraffin solvents have contained chlorinated materials having an organic chloride ion. Presumably such materials have been taken off the market because of problems encountered in refineries with poisoning of certain catalysts by organic chlorides. The nonorganic chloride ion from HCl is water soluble, and it can be readily extracted from the oil during refining processes. Therefore, the problem of catalyst poisoning does not arise when HCl is used in paraffin-removal formulations such as acid dispersions.

Hot-oil treatments also are commonly used to remove paraffin. In such a treatment, heated oil is pumped down the tubing and into the formation. The hot oil dissolves the paraffin deposits and carries them out of the wellbore when the well is produced. When this technique is used, hot-oil treatments are usually performed on a regularly scheduled basis.

Paraffin inhibitors are a recent development. These are designed to create a hydrophilic surface on the metal well

equipment. This in turn minimizes the adherence of paraffin accumulations to the treated surfaces.

Large-Volume Injection Treatments

A simple technique often used to free or to open blockages within the formation consists simply of pumping large volumes of crude oil, kerosene, or distillate into the formation. These treatments are especially effective when the formation is blocked by fine silicates or other solids. Pumping the oil into the formation may rearrange these fine particles so that flow channels to the wellbore are reopened. Sometimes it is helpful to add surface-active agents or emulsion-breaking agents to the oil.

Steam Injection

In some areas where low-gravity crude is produced, steam is used to heat and reduce the viscosity of the oil and thereby allow the oil to move more easily to the wellbore. Two types of steam injection are used. In some areas, steam is injected into a central injection well and the oil produced from adjacent or surrounding wells.

The other type of injection is often referred to as "huff 'n' puff." This consists of alternate steam-injection and oil-production cycles from the same well.

General Comments

In any case of production decline, it is important to have all available facts and to make the best possible analysis from these facts as to the factors contributing to the decline. If the problem is not analyzed as completely as possible before treatment, a great deal of money may be wasted in the use of an incorrect treatment. Also, whenever a fluid is to be pumped into a specific part of a zone, some chemical or mechanical method should be used to ensure that the fluid enters the proper zone.

Sand Control

Sand Formation Properties and Geology

Most oil and gas wells produce through sandstone formations that were deposited in a marine or detrital environment. Marine-deposited sands, where most of the hydrocarbons are found, are often cemented with calcareous or siliceous minerals and may be strongly consolidated. In contrast, Miocene and younger sands are often unconsolidated or only partially consolidated with soft clay or silt. These structurally weak formations may not restrain grain movement. When produced at high flow rates, they may produce sand along with the fluids.

Why Sand is Produced

Fluid movement through sandstone reservoirs creates stresses on the sand grains because of fluid pressure differences, fluid friction, and overburden pressures. If these stresses exceed the formation-restraining forces, then sand grains and fines can move and may be produced with the fluid. Rapid changes in fluid production rates and fluid phases cause unstable conditions that can result in increased sand production. When a well starts to produce water, it will often start to produce sand. Muecke¹ demonstrated that particle movement takes place in a multiphase system when the wetting phase starts to move.

Even consolidated sandstone can be mechanically and chemically damaged with time as the reservoir is produced. Overburden stress on sand grains increases as the

reservoir pressure decreases. Water movement can dissolve minerals that cement sand grains as well as change the carrying capacity of the formation fluids. Fines migration can reduce the permeability in the perforation tunnels. This can result in a higher pressure drop into the wellbore and a change in formation stresses. A calcite-cemented formation can be damaged by an improperly designed acid treatment, and increased sand production can result.

Consequences of Sand Production

Sand movement in unconsolidated formations and its ultimate production with oil and/or gas creates a number of costly and potentially dangerous problems. Most common among these problems are the following.^{2,3}

1. Production interruptions can be caused by sand plugging the casing, tubing, flowlines, or separator.
2. Casing collapse can be caused by changes in overburden pressure and stresses within the formation.
3. Downhole and surface equipment can be destroyed, resulting in downtime for equipment replacements, spills, cleanup or even an uncontrolled blowout.
4. Disposal of produced sands is costly because regulations require the disposed sands to be essentially oil-free.

Methods of Sand Control

Higher allowable production rates have increased the need for more effective and durable sand-control systems, which exhibit minimal permeability impairment. Experience indicates that sand control should be implemented before the formation is seriously disturbed by sand removal.⁴ Four general types of sand-control methods have been developed to reduce or to prevent the movement of formation sands with produced fluids.

1. In some cases, sand production can be prevented merely by restricting the production rate and thus reducing the drag forces on the sand grains.⁴ This simple approach is usually uneconomical. Increasing perforation size and density along with the use of clean, nondamaging completion fluids will help to decrease fluid velocity and drawdown pressure at higher production rates.
2. Gravel packing is the oldest, simplest, and most consistently reliable method of sand control. It has wide application both on land and offshore. Advances in gravel-pack technology, which use a viscous fluid to carry high gravel concentrations around a screen, have resulted in faster and more productive gravel packs. Improved completion tools and through-tubing tools that eliminate the need for costly workover rigs have expanded the application of gravel packing.
3. Sand consolidation plastic treatments inject resins into the producing interval, binding the formation sand grains together while leaving the pore spaces open. With use of special preflush systems and diverting agents, intervals up to 30 ft thick have been successfully consolidated and provided with the strength necessary to allow high production rates.
4. Resin-coated gravel packing places gravel coated with a resin both inside and outside the perforations and in the casing. As the resin cures, the sand grains are bound together. A strong, highly permeable, synthetic sandstone filter results. After curing, the excess resin-coated gravel is drilled from the casing, resulting in a full-open wellbore. This gravel pack can be used with or without a

screen, in primary or remedial work, and through coiled or concentric tubing.

The type of sand-control method selected will depend on the specific well conditions. Important variables such as grain-size distribution, clay content, interval length, bottomhole temperature, wellbore deviation, mechanical configuration, bottomhole pressure, anticipated production rates, and cost should be considered before deciding on the method of sand control best suited to the well.

Formation Sampling

The most important design parameter in sand control is the formation sand grain size. The success of gravel-pack methods relies upon formation particles being restrained by the larger pack gravel. Chances for a successful sand control job are highest when representative samples of the formation are available for sieve analysis. This enables selection of the proper size of gravel.

The most representative formation samples are obtained from rubber-sleeve core barrels. Sidewall cores, although they contain crushed grains and mud contamination, are the second choice. Bailed or separator samples are not representative since sand grains may have been segregated—the larger grains remaining in the hole and the smaller grains being produced with the well fluids.

Formation Analysis

Formation sand sieve analyses should be conducted to determine formation properties under bottomhole conditions. Treatment steps in acidizing, clay stabilization, and sand control can be determined. Typical sandstone analyses include permeability, porosity, response to acid, mineralogy, petrographic analysis, scanning electron microscope analysis, X-ray diffraction analysis, and optical emission spectrographic analysis.

Well Preparation

A successful sand-control installation is dependent on following the recommended procedures for all phases of the drilling and completion operations. Selection of the proper gravel size or resin, use of nondamaging drilling and completion fluids, perforation density and cleanliness, and gravel placement are among the important factors affecting well productivity. The following are some of the factors that should be considered before any sand control procedures are initiated.

Cleanliness. Clean Tubing. Steps must be taken to ensure that new or used tubing is as free as possible of rust, scale, mill varnish, and other contaminants or obstructions. Many of the contaminants can be removed chemically through the use of solvents or mechanically by "rabbeting" the joints before running.

Acidizing the tubing string after it has been run will remove rust and some of the pipe dope that accumulates (see next section) inside the tubing. The string can be acidized by pumping HCl down the string to within 100 to 200 ft of the bottom and then immediately reverse-circulating the acid out. Complexing or reducing agents should then be used. The acid should not be allowed to exit the tubing string nor to reach the perforations. Any iron present in the ferric state could precipitate as gelatinous ferric hydroxide (FeOH), which can be extremely damaging to the formation.

TABLE 56.1—PRESSURE DROP ACROSS A SAND-FILLED PERFORATION

Gravel	Flow Rate, q (BPD/perforation)	Δp (psi) With Perforation Diameter of			
		3/8 in.	1/2 in.	3/4 in.	1 in.

	10	27,760.0	9,280.0	2,091.0	808.00

Pipe Dope. Pipe dope, when improperly applied, may be squeezed inside the tubing at the joints and can be transported into the formation by treatment fluids or become lodged in the screen or liner slots, resulting in decreased production. It is virtually impossible to remove the solids found in pipe dope from an oil or gas well chemically. Pipe dope should therefore be applied sparingly to the pin end of the tubing. It should not be used inside the collar where it can be squeezed into the tubing string when the joint is made up.

Filtering of Fluids. Significant reduction of oil and gas production can be caused by formation damage caused by solids in the fluids used in well completion or work-over operations. Clays, silt, or organic solids injected into a perforated interval can become trapped in the formation matrix or in the perforation tunnels where they can act as a low-permeability choke, reducing the productivity of the well.

Cement Bond. A good bond between the cement and the formation and between the cement and the casing is essential to isolate the producing zone. Primary cementing is one of the most critical phases in a successful well completion, and good cementing practices should be followed.

Fig. 56.1—Higher perforation density increases the success ratio for sand consolidation treatments.

An in-gauge borehole is important, and the string should be equipped with adequate centralizers, particularly in deviated holes. Spacer fluids and cement slurry properties must be controlled. The string should be equipped with scratchers through critical zones and either rotated or reciprocated during placement of the slurry. Turbulent flow is recommended.

If there is any indication of poor bonding, a squeeze cement job should be performed. Intervals to be treated separately should be effectively isolated by bonded cement to reduce the possibility of communication between zones.

Perforations. The success of sand-control treatments in cased holes, measured in terms of well productivity and treatment life, is greatly affected by perforation size and density and by perforating damage. Perforation tunnels must be open so they can be filled with pack gravel to prevent filling with formation sand. If perforations are plugged, gravel cannot be deposited in the tunnels (as carrier fluids flow into the formation) and formation consolidation chemicals cannot be injected.

If formation sand is lodged in the perforation tunnels, the pressure drop within the perforation can be excessive, even though the permeability of the formation sand is relatively high. Experimental results indicate that fluid flow can be turbulent in gravel-filled perforation tunnels with pressure drops far greater than those predicted by Darcy's linear flow equations. As shown in Table 56.1, pressure drop within a gravel-filled perforation tunnel can be quite significant.^{4,6}

The greater the perforation density, the less the drawdown through each perforation tunnel and the less the velocity through each effective perforation. Intervals perforated 4 shots/ft show cumulative production before sanding to be seven times greater than intervals perforated with only 1 shot/ft. Two perforations per foot show two-thirds the capacity of 4 shots/ft.⁷

In wells gravel-packed effectively, the lower fluid velocity resulting from high perforation density and large-diameter perforations reduces screen erosion and increases the life of the sand-control treatment. Pressure drop

through higher-density, large-diameter perforations also is reduced, resulting in higher wellhead pressure and greater oil or gas production.

For sand consolidation, closely spaced perforations (8 to 12 shots/ft) increase the likelihood of a uniform plastic pattern around the wellbore, even if some of the perforations are plugged. Fig. 56.1 illustrates what can happen when a perforation is plugged. Note that the sand is not consolidated behind the plugged perforation on the right side of Fig. 56.1(a), and that this is the spot where a failure is most apt to occur.

Perforation Cleaning. The high-pressure jet from a perforating gun pierces the casing and forms a hole by pulverizing cement and formation into compacted particles. Cement and material from the jet charge are mixed with the formation material in the compacted zone while loose debris fills the perforation tunnel. It is necessary to remove this debris from the perforation tunnel to increase the probability of success in sand consolidation or gravel packing. Fig. 56.2 shows the damage that can occur in the perforation and on the face of the formation during drilling and perforating.⁸

Perforation-cleaning methods include backflow, underbalanced perforating, backsurfing, washing, and acid stimulation, or combinations of these. These methods are discussed next.

Backflow. Flowing the well may not clean up more than a few perforations and, if enough differential is available to purge debris from the perforations, the well may sand up. Backflow must be done slowly and carefully.

Underbalance. Perforating with hydrostatic pressure less than formation pressure allows tunnel debris to be carried into the wellbore with the first surge of fluid from the formation.

Backsurfing. Backsurfing techniques dislodge gun debris and loose material from perforation tunnels by sudden exposure of a perforated zone to an open chamber at atmospheric pressure. The differential pressure created causes formation fluids to surge through the perforations into the casing, flushing the perforation tunnels. Backsurfing has proved to be very successful in improving productivity.

Perforation Washing. Washing is achieved by straddling a small increment of the perforated interval with a special tool and injecting nondamaging fluids into the perforations in the increment. The fluid circulates outside the casing and back through the perforations nearest the tool seals, removing debris and formation sand from the perforations and from behind the casing. The tool is moved in increments equal to the seal spacing until the entire perforated interval is washed.

After the perforations are washed or surged and debris is circulated out, a positive-depth indicator is placed in the well below the perforations to establish a reference point from which the string is accurately spaced out. This is especially important in multiple completions with closely spaced producing intervals.

Matrix Acid Stimulation. The purpose of matrix acidizing is to penetrate the formation at less than fracturing pressure and to remove damage from perforation tunnels and the critical area surrounding the wellbore. Mud filter cake, silt, and clay are typical damaging materials that may be removed by mud acid to restore a well's natural productivity.

Fig. 56.2—Drawing of a perforation tunnel showing fluid invasion from the wellbore into the formation, and debris in the perforation and the compacted zone surrounding the perforation tunnel.

The formation solubility should be determined in both mud acid and HCl. If mud acid is used, a formation solubility at least 10% greater in mud acid than in HCl is preferred. Moreover, the formation solubility in HCl should be less than 20% to avoid calcium fluoride precipitation.

A typical three-step acid stimulation consists of an HCl preflush, matrix treatment with mud acid, and an HCl overflush.

HCl Preflush. A preflush of 50 to 100 gal/ft of perforations is advisable. The HCl is used to prevent contact of mud acid with calcareous materials or formation brine. This prevents or reduces the chances of precipitation of calcium fluoride and various fluosilicates.

Matrix Treatment With Acid. The proper volume of mud acid should be injected to remove damage near the wellbore. Usually 50 to 200 gal/ft of perforations is required. Success in matrix acidizing depends on acid contacting the entire production interval. This is achieved through the use of diverting agents.

A mutual solvent comprised of ethylene glycol monobutyl ether^{9,10} is sometimes needed to achieve good results. It is an effective water-wetting agent, demulsifier, and interfacial-tension reducer.

Overflush. Completion or workover brine should not be used as an overflush for mud acid because of the possible precipitation of sodium, potassium, or calcium fluosilicates. The use of dilute HCl, ammonium-chloride solution, light oil, or nitrogen as the overflush agent is recommended.

Clay Control

In many cases, formation permeability may be damaged by the various clay materials present. Many clays are water sensitive, and contact with foreign fluids may cause damage by two mechanisms. The first, and probably the more critical, mechanism is dispersion and migration of the clay particles. Dispersion may be caused by charge differences or by fluid movement. The dispersed clays are then free to move through the formation until they enter an opening too small to pass, thus lodging and reducing permeability. The second mechanism is expansion or swelling of the clay particles. Water absorbed between

Fig. 56.3—Gravel-pack permeability impairment caused by formation sand invasion is illustrated by curve of change in ratio of increases. A ratio of 5 to 6 is the largest gravel that will stop all sand entry. Theoretical curve beyond 14 indicates sand flowing freely through gravel (after Ref. 12).

TABLE 56.2A—AVAILABLE GRAVEL SIZES

Gravel Size (in.)	U.S. Sieve Number	Approximate Median Diameter (in.)
0.006 to 0.017	40/100	0.012
0.008 to 0.017	40/70	0.013

400	98.3	90.0
PAN	100.0	100.0

the clay particles causes the particles to expand, with a corresponding decrease in pore volume and the plugging of pore channels.

To avoid a production decrease, it is important to stabilize clays before or along with a sand-control treatment.

Gravel Selection

Gravel should be sized to prevent invasion of the pack by the finest formation sand.¹¹⁻¹³ For example, if 20% of a gravel pack is fine sands, the permeability will be 35% less than if no fines were present.^{13,14}

A gravel size should be selected that will restrict the movement of fine formation sand but will not reduce the flow of fluids to uneconomical rates. Saucier¹² suggests that the gravel size for controlling uniform sands should be five to six times the diameter of the mean (median) formation sand grain size. Degree of pack impairment is illustrated in Fig. 56.3, which shows the ratio of effective to initial pack permeability vs. the ratio of the pack median diameter to the formation median diameter.

Proper gravel size is determined by the following steps.

1. Obtain a representative formation sample; closely spaced samples from rubber-sleeve cores provide the best design bases.

2. Perform a sieve analysis.

3. Plot the sieve analysis data on either a cumulative logarithmic diagram (S-plot) or a logarithmic probability diagram.

4. Calculate the gravel median grain diameter using a five-to-six multiple of the 50-percentile formation grain diameter. When multiple cores from a single zone are provided, they should be analyzed and plotted separately. The samples should not be mixed. The sample with the smallest 50-percentile grain diameter is used to select the gravel. Tables 56.2A and 56.2B list some of the commercial gravel sizes available. Gravel should be screened and checked to verify size and distribution.

Sieve analysis data for two rubber-sleeve, core-barrel samples, taken from the same zone, are tabulated and are plotted in Figs. 56.4 and 56.5. Note that Sample A is from a portion of the zone that contains coarser sand than the portion from which Sample B was taken. If Sample A alone had been taken, a coarser gravel would have been selected, and a gravel-pack failure could have resulted.

In Fig. 56.6, produced, bailed, and core-barrel samples from the same well zone have been plotted. The core-barrel sample plots as a straight line (minor variations are typical, however). The dashed variation shown could indicate a sieving or weight problem. A bailed sample would typically rise on the left because finer formation grains would have been produced, leaving the larger grains in the wellbore. Conversely, a produced sample would rise on the right, indicating an excess of fines.

The same data are shown in an S-plot (Fig. 56.7). Each of the curves is typically S-shaped, and any curve plotted by itself would not readily be interpreted as varying from the norm. An error in gravel selection could result if the sample type were not known.

Gravel Quality. Studies have indicated that gravels containing fine particles outside the specified range will have lower permeability.¹⁴ Some supply sources furnish gravel with excessive amounts of particles smaller than specified. Angular gravels may be broken during shipping and

Fig. 56.4—Data from sieve analyses of Formation Sand Samples A and B, taken from the same zone, are plotted here. Note that using Plot A would result in the selection of 20/40-mesh gravel rather than the better choice of 40/60-mesh gravel for packing this zone, as indicated by Plot B.

handling, thereby creating fine particles that reduce the quality of the gravel. Rounded gravels provide tighter, more uniform compaction and somewhat higher permeability than angular gravels.

Screen Selection

Many types of wire-wrapped screens are available, including ribbed, all-welded, grooved, and wrapped-on-pipe. The all-welded screen has the wrapping wire resistance-welded to wire ribs at each point of contact. Spacer lugs, solder strips, and weld beads are not required and, therefore, the all-welded screen is stronger and more

Fig. 56.5—Data for Samples A and B are again plotted here. Sieve-analysis data for sands with a normal grain-size distribution will plot as a straight line on a log probability grid. The logarithmic probability diagram has an advantage over the S-plot in that sampling errors are more readily detected. Variations from the straight-line plot could be caused by sieving and weighing errors, incorrect sample preparation, or by the sampling method itself.

Fig. 56.6—Logarithmic probability diagram of produced, bailed, and core-barrel samples from the same well.

corrosion-resistant; it also has a lower pressure drop, and it will not unravel if the wire is eroded or broken.

The wrapping wire on these screens is usually made from 304 stainless steel while the pipe core is Pipe Grade S or K. Other wire and pipe materials are available.

The configuration of the openings in all screens is very important. If the sides of the slots are parallel, plugging may occur as the small sand grains bridge the slot. To reduce the chance of this occurring, the wire used to wrap the screen is wedge-shaped.

Fig. 56.8 shows the construction features of an all-welded screen.

For gravel packing, the gauge of the screen should be small enough to prevent the passage of the gravel-pack sand. Slot width is usually taken as one-half to two-thirds of the diameter of the smallest gravel-pack grains.

Fig. 56.7—Cumulative log diagrams (S-plot) of produced, bailed, and core-barrel samples from the same well. Note that a bailed sample would result in the selection of a coarser gravel.

Fig. 56.8—All-welded screen.

The screen diameter should be as large as possible and yet leave adequate room for packing gravel. Table 56.3 shows the dimensions and inlet areas for several sizes of wire-wrapped screens. Screens are available with slot openings from 0.006 to 0.250 in. in 0.001-in. increments.

The screen length should overlap the perforated interval both above and below by 3 to 5 ft. Blank pipe should be run above the screen to provide a reservoir for extra gravel. Blank pipe length should be three to four times the screen length with a minimum length of 60 ft.

Gravel Packing

Methods. The term "gravel," as used here, refers to a uniform, graded, commercial silica sand that is placed in the wellbore and perforation tunnels for the purpose of mechanically retaining formation sands. These are described next.

Circulating gravel packs are done in two steps: an outside pack and an inside pack. The outside pack or pre-pack places gravel outside the perforations, where voids may exist in the formation surrounding the casing and in the perforations. An outside pack is, of course, not used in openhole completions. The outside pack is usually attained by pumping a gravel slurry through an open-ended workstring with the application of fluid pressure. To achieve good gravel placement, fluid must be lost to the formation.

The inside pack is achieved by pumping a slurry containing from $\frac{1}{4}$ to 15 lbm of gravel per gallon of fluid down the workstring and through a crossover tool into the annular space between the screen and the casing. The gravel is held in place by the screen while the carrier fluid

(brine, diesel oil, etc.) flows through the screen and crossover tool into the tubing/casing annulus and back to the surface.

A wash pipe extends from the crossover tool, inside the blank pipe and screen, to the bottom of the screen. Returns are taken through the wash pipe. It is recommended that the wash pipe outside diameter be 0.6 times the screen liner inside diameter and made up with flush joints. This ratio of wash pipe outside diameter to liner inside diameter optimizes gravel distribution along the screen in deviated holes.

The screen and blank pipe should be centralized every 15 ft, and the length of the screen should be such that it extends above and below the perforated interval by 3 to 5 ft. A calculated quantity of a high-density slurry at 15 lbm of gravel per gallon of fluid (density of 13.89 lbm/gal if fluid is water) is circulated into place. As the gravel settles out and packs in the hole outside the screen, injection pressure will increase. When the injection pressure has increased to between 750 and 1,500 psi above the originally established injection pressure, pumping is stopped. When the sandpack causes such a pressure increase, the condition is called a screenout.

The slurry remaining in the reservoir above the screen (established by the blank pipe) will settle out so that ample gravel exists above the top of the screen. Since about 60% of the slurry volume consists of gravel, 100 ft of slurry will result in 60 ft of settled gravel.

In gravel packing intervals with the circulating method and a high-density slurry, a lower tell-tale is recommended. The lower tell-tale is a short section of screen, not less than 5 ft long, located below the production screen. A seal sub, installed between the lower tell-tale and the production screen, seals the wash pipe. Returns are thus taken only through the lower tell-tale. By this method, gravel is placed at the bottom of the screen, and a denser pack can be achieved. After screenout of the tell-tale screen, the wash pipe is pulled up into the production screen to complete the gravel pack.

Squeeze gravel packing uses a gravel slurry consisting of 15 lbm of gravel added to a gallon of viscous carrier fluid. This gives a high-density (13.89 lbm/gal) slurry. The carrier fluid transports the gravel into place and is squeezed away into the formation. A viscosity breaker in the carrier fluid reduces the viscosity according to a preplanned schedule; this allows for fast well cleanup.

Reverse circulating gravel packing is a low-density method using $\frac{1}{4}$ to 2 lbm of gravel per gallon of carrier fluid. The slurry is circulated down the tubing/casing annulus. The gravel is retained on the outside of the screen while the carrier fluid flows through the screen and to the surface through the tubing. After the pack is completed and all the gravel in the annulus has settled, the tubing is pulled out of the hole, leaving the screen assembly with a polished nipple on top in the hole. A production packer with an overshot seal assembly is then run over the polished nipple. If the pack is done in perforated casing, a prepack is usually done first.

Several disadvantages associated with a reverse circulating gravel pack include (1) long rig time, (2) pack voids, (3) slurry pumped down the annulus scouring dirt and mill scale from the inside of the casing and the outside of the tubing, and (4) possible formation damage caused by large amounts of dirty fluid circulated and lost to the formation.

10 3/4	5 to 5 1/2

Openhole Completion

Casing (in.)	Openhole Diameter (in.)	Screen Pipe Size (in.)
5 1/2	12	2 7/8
6 5/8 to 7 3/4	14 to 16	4
7 5/8 to 8 5/8	14 to 18	5 1/2
9 5/8 to 10 3/4	16 to 20	7

Wash-down gravel packs are done by dumping the gravel down the casing, allowing it to settle, and then running a screen-and-wash pipe assembly with a wash-down set shoe into the hole. Circulation is established through the shoe, and the screen assembly is lowered as the gravel is washed up the annulus. When the shoe tags bottom, circulation is immediately stopped, and the gravel allowed to settle around the screen. The screen is then released, and a production packer with a seal sub is run into the hole to seal the production string.

Chapter 57

Oil and Gas Leases

Joe B. Clarke Jr., Vermilion Oil and Gas Corp.*

The Landowner's Interest

Property

All property can be classified as either real or personal. Real property is land and that which is affixed or appurtenant to land. Personal property is every kind of property that is not real property. Oil and gas in place are considered to be a part of the land and are therefore a form of real property. When oil and gas are reduced to possession by being brought to the surface, they become personal property.

Ownership of property is the right to possess and use the property to the exclusion of others. Land cannot be without ownership. The rightful owners may be hard to determine, but ownership nevertheless exists. The extent of an owner's rights may vary. Absolute ownership is a superior status excluding participation by anyone else. The absolute owner is most frequently referred to as the fee owner and absolute ownership as fee ownership. There is a form of qualified ownership referring to a status establishing an equal right of participation in another person. For example, two parties are co-owners of a tract of land. Each party has certain rights to use and enjoy the land, but the rights of each party are qualified by the rights of the other party. Another form of ownership is limited ownership, which is a restricted right. The absolute owner who grants a 1-year grazing lease brings a form of limited ownership into being.

The absolute or fee owner is entitled to possession, which means the actual or physical occupancy of a thing. The party in possession of a thing is occasionally not the owner of that thing. Possession undoubtedly carries with it the intention to hold, but possession does not mean ownership.

The fee owner owns the surface of land and the minerals thereunder. The surface owner has no right to grant an oil and gas lease or mineral lease. However, the rights of mineral owners are often subject to the rights of

surface owners. The mineral owner has the right to grant mineral leases. A royalty owner has a right to receive royalty or a share of production as obtained but has no right to grant mineral leases or receive bonuses or rentals.

Ownership of Hydrocarbons in Place. Various ideas and theories have been suggested as to the nature of ownership of oil and gas in the reservoir prior to extraction. Two principal ideas have evolved: the absolute-ownership and the nonownership theories. In the absolute-ownership theory, hydrocarbons are considered a part of the land and absolute ownership of the land is absolute ownership of the oil and gas in place. This theory divests the absolute owner of the hydrocarbons in place when there is drainage across property lines. The nonownership theory requires the acceptance of oil and gas as fugitive minerals. Absolute ownership of the land will therefore carry with it only the exclusive right to drill on the land in an attempt to reduce the oil and gas to possession. Absolute ownership of the oil and gas is not attained until the oil and gas are reduced to actual possession.

Regardless of which theory of ownership each of the various states adheres to in its statutes, the courts are in agreement that oil and gas in place are minerals and a part of the land; when they are reduced to possession, they become personal property; a landowner has the right to drill a well on the property in an attempt to reduce the oil and gas to possession, and without liability for drainage from adjacent lands; these privileges and responsibilities can be transferred to others.

Rule of Capture

The theories of ownership provide for the migratory nature of oil and gas under certain conditions. The impossibility of determining liability for drainage where

*This author also wrote the original chapter on this topic in the 1962 edition.

landowners produce in a lawful manner from a well on their land is recognized. This freedom from liability for drainage is referred to as the "rule of capture." Since landowners cannot recover damages or enjoin the operator when their property is being drained by a well on adjacent lands, they must protect themselves as best they can. In short, they must drill, or have the lessee drill, a well on their own land as promptly as possible in order to prevent further drainage. This "offset drilling rule" is modified in these days of increased conservation legislation. Many states have statutes relating to well spacing, allocation of production, pooling, etc., which provide equitable relief for the landowners who are being drained by other means than the drilling of a well on their land, and which tend to prevent the drilling of unnecessary wells.

Mineral Severance

Severance of the minerals can occur in a number of ways. One of the most common ways is the conveyance of the land itself by a deed that provides for the reservation or exception of all or a part of the minerals to the grantor. Mineral severance is often accomplished by a deed conveying all or a part of the minerals themselves. A severance of oil and gas from the surface is recognized in all jurisdictions.

A lease or a conveyance using the term "minerals" will include oil and gas without otherwise describing them. A conveyance of a named mineral without the phrase "and other minerals" will convey only the mineral named. In some areas, "oil and gas" leases are obtained; in other areas, "oil, gas, and mineral" leases are obtained.

The owner of the mineral estate is entitled to the use of the surface as it may be necessary, subject to certain rights of the surface owner, for the exploration and recovery of the minerals. The foreclosure of a mortgage as to the surface estate is not effective as to the mineral estate, provided the execution of the mortgage is subsequent to the date of the mineral severance.

Adverse Possession. Adverse possession refers to the possession of real estate that is open, visible, continuous, and exclusive. The statutes of the various states establish the manner in which titles can be acquired by adverse possession. If such possession is continued for the time and in the manner prescribed by the statutes, the effect is to divest the owner of title and to vest in the adverse possessor a new title. If the minerals have not been severed, adverse possession of the surface is adverse possession of the minerals. Minerals severed from the surface prior to the commencement of adverse possession cannot be acquired by adverse possession. The years of occupancy, the construction and maintenance of fences, the construction and use of houses and outbuildings, the drilling of water wells, the grazing of cattle, the cutting of timber, the growing of crops, the payment of taxes, etc., are all important items to be considered by the title examiner in determining whether or not a basis exists for the establishment of an adverse title under the statutes of the state involved.

Partition. Partition is a division of real estate among co-owners whereby each acquires a separate tract. The ef-

fect of partition is to terminate the ownership of the undivided interests of the joint owners and to establish ownership in each co-owner as to the divided share. Partition is effected either voluntarily or involuntarily. The latter is called compulsory or judicial partition and consists of partition in kind or partition by sale and division of the proceeds. Partition in kind is, in general, the most equitable form of partition. Where such partition is impractical or unfair, partition by sale and division of the proceeds is resorted to.

A lessee who acquires an oil and gas lease from less than the entire group of cotenants is faced with certain problems, each of which has to be solved on its own merits under the applicable statutes. Partition of a tract subsequent to the granting of an oil and gas lease by the co-owners does not enlarge the obligations of the lessee. In such an instance, the lessee would not be required to drill an offset to prevent drainage in the event that the completed oil well is on one of the partitioned tracts.

Trespass. The landowner and his mineral lessee have several remedies for unauthorized entry and use of the surface and minerals. In determining the measure of damages for unauthorized intrusion it must first be determined whether the trespass was made in good faith or in bad faith. The measure of damages for unauthorized production in the case of good-faith trespassers is the value of the oil and gas at the surface less the reasonable costs of production; the measure of damages in the case of bad-faith trespassers is the value of the oil and gas at the surface.

Unauthorized penetration of the subsurface is a form of trespass. A lessee who commences a well on a tract of land and allows or causes the borehole to deviate from the vertical in such a manner so as to drill into the subsurface belonging to an owner who has not leased to the lessee is liable for trespass. In questions involving this type of trespass, a court order may be obtained for a well survey to determine whether or not a trespass has occurred. Should such a well produce, the measure of damages would be the value of the hydrocarbons removed. If the well results in a dry hole, the trespasser is liable to the landowner for damages for the destruction of the mineral value of the land.

Fee or absolute ownership carries with it the right of absolute control, including the right to grant oil and gas leases, to conduct exploratory operations on the land, to authorize others to so use the premises, etc. It therefore follows that a party who conducts exploratory operations without permission violates the rights of the landowner and is accordingly liable. In this type of trespass, damages may be recovered from the standpoint that such operation may have reduced or removed the marketability of an oil and gas lease on the land or reduced the leasing value of the land itself.

Correlative Rights. Despite the rule of capture, there has been much said and written, and some legislation, regarding correlative rights. Property owners overlying a common source of supply are restricted in their right to remove hydrocarbons by their duties to adjoining landowners. They are obligated not to injure the reservoir or dissipate the reservoir energy, and they cannot remove a disproportionate share of the hydrocarbons. In general,

owners may not use their land in such a manner as to injure the property of others. The principle of correlative rights is enforced by law in those states that have enacted comprehensive conservation legislation.

The Oil and Gas Lease

Background

A large number of printed lease forms are in use in the oil industry. The evolution of the oil-and-gas-lease contract has been a slow process. Present-day forms are quite lengthy when compared with the contracts made in the earlier years of the oil industry. The many refinements made since then have been based on the hard lessons learned through experience and on the many court decisions rendered as a result of the inevitable controversies which arose as the industry grew.

The courts have held, keeping in mind the fugitive nature of oil and gas, that the primary purpose of the oil and gas lease is development. Should the oil and gas lease not contain an express provision in this regard, the law will imply an obligation on the part of the lessee to explore and develop the leased premises.

An oil and gas lease is a conveyance or an interest or right. It is also a contract between the lessor and the lessee. Since an oil and gas lease conveys an interest in real estate, it must be in writing in accordance with the statute of frauds. A lease is sufficient if the names of the parties, the description of the property involved, and the terms of the agreement are set forth. It is not necessary that the lessee sign the lease to make it legally effective. Witnesses are not required in order to make the instrument effective between the parties. An acknowledgment is required only in connection with the recording of the instrument and does not affect the validity of the instrument between parties. Recording the lease is not necessary to the validity of the instrument between the parties, but is required to afford protection against bona fide purchasers.

The Lessor

A party owning a mineral interest and having the personal capacity to contract has the capacity to execute a valid oil and gas lease. Oil and gas leases from minors and insane persons are usually executed by guardians of such persons under the direction and approval of the court. The disabilities of minors may be removed in some states by judicial proceedings and leases obtained directly from such persons. Leases executed by minors are voidable at their election upon reaching majority. A lease executed by a person subsequently adjudged insane is voidable.

Landowners often leave a will devising certain real property to their children subject to a life estate or usufruct in the surviving widow, who is called the life tenant or usufructuary. The children are called the remaindermen or naked owners. Neither the life tenant nor the remainderman has the right to lease without the consent of the other. Both parties must join in the execution of an oil and gas lease for it to be valid. It is important that the rights of the lessors as to the bonus, delay rentals, and royalty payments be clearly set forth in the lease. Generally, the bonus and rental payments are payable to the life tenant, and royalty is payable to the remainderman.

A landowner can execute an oil and gas lease on lands that are subject to the qualified rights of others provided the lease does not interfere with such prior rights. The most common example is the landowner who grants a surface lease for grazing purposes and then at a subsequent date executes an oil and gas lease. The lessee in the oil and gas lease cannot be prevented from entering on the surface to exercise the rights granted in the lease, but at the same time the lessee is responsible to the tenant for damages to the extent that the tenant's rights are interfered with. A tenant's consent agreement is usually obtained prior to operations of any kind.

An administrator is one who is vested with the right of administration of an estate and is appointed by the court. An executor is a person appointed by a testator, or the party making a will, to execute his will. A trustee is a person holding property in trust for another party. Executors, administrators, and trustees have authority to execute oil and gas leases provided such specific authority is given by will, by the court, or by statutory provision. A power of attorney is an instrument authorizing one to act as the attorney or agent of the person granting it, and terminates upon the death of the grantor.

In the case of married persons, the husband may, in general, execute a lease without the joinder of his wife. Homestead statutes usually require that all instruments creating encumbrances upon the homestead be signed by both parties. The wife, in general, can execute a lease on her separate property. In community-property states the husband may or may not have the right to grant a lease on the community estate without joinder by his wife; however, most lessees will insist upon the joinder of the wife.

The law differs among the states as to whether or not a co-owner can execute a lease without the consent of the other cotenant. In most of the states, such a lease would be effective only as to the interest of the executing cotenant. Two or more lessees, each having leases on undivided interests in the same tract, are cotenants. Each is entitled to drill on any part of the leased premises but, if successful, must account to the other cotenant for his proportionate share of the production, less the cost of production.

Consideration, Date, Description, and Delivery

A valid oil and gas lease requires a consideration, a nominal cash payment or other consideration generally being sufficient. An undated lease takes effect upon execution and delivery. An exact description of the land to be leased is not necessary, provided the land can be identified with reasonable certainty. Delivery and acceptance of an oil and gas lease are required as with other conveyances: the intent of the lessor to make the instrument legally effective must be apparent.

The Granting Clause. This clause in an oil and gas lease is usually the first paragraph in the lease and is one of the most important paragraphs in the entire contract. The rights of the lessee are very broadly set forth. The remaining provisions of the contract modify or enlarge upon the provisions of this paragraph.

The granting of the lease is for the purpose of the development of the mineral estate. Accordingly, the lessee must have those exclusive rights that are necessary

to carry out the basic purpose of the lease. This includes the right to build pits and erect tanks and other equipment pertinent to the lessee's operations. The lessee has the right to construct, maintain, and use roads, pipelines, and/or canals on the leased premises. The lessee is not liable for operations on the leased premises unless the surface is used excessively, the operations are negligent, or any express provisions in the lease are violated. The lessee is required to restore the premises to their original condition, insofar as is practicable, when required by the lease. The lessee has the right to conduct exploratory operations on the leased premises and to conduct secondary-recovery operations and to dispose of salt water by reinjection into suitable formations.

The landowner is entitled to the use of the surface, less that required by the lessee, who has the responsibility of protecting this remaining surface for the benefit of the lessor. The lessee must exercise complete control over the surface storage of liquids and is responsible for damages in the event of leakage and injury to the adjoining surface.

The Habendum Clause. A simple form of this clause provides that "this lease shall be for a term of blank years from the date hereof, called primary term, and so long thereafter as oil or gas is produced." This clause fixes the ultimate duration of the lessee's interest. The lease may be terminated sooner, for example, by the failure of the lessee to pay delay rentals. The primary term will limit the life of the lease prior to the establishment of production from the leased premises. The primary term is one of the items that must be negotiated at the time of the purchase. The term most commonly used is either 3 or 5 years. It is usually difficult to acquire leases with terms longer than 5 years. In very active areas primary terms of 3 years and less are usual.

For the lease to be extended beyond its primary term, production must occur, subject to certain exceptions to be discussed subsequently. The fact that oil or gas may have been discovered on the leased premises will not in itself keep the lease in force unless specific provisions are made to the contrary. This is especially applicable to oil. In the case of gas, provision is frequently made in the lease to extend the lease past its primary term in the event the lessee is not able to market the gas for lack of transmission lines, lack of a gas market, etc. When such a provision appears in a lease, it is referred to as a shut-in gas clause. It usually provides for the payment of a sum of money on an annual basis in an amount that may be as high as the lessor would ordinarily receive as delay rentals.

The word "produced" in the habendum clause has been held to mean "produced in paying quantities." What constitutes production in paying quantities has been the subject of much dispute. In general, if a lease is past its primary term, and enough production is being obtained from the lease so that a profit is made, however small, in excess of the cost of operation, disregarding the drilling and completing costs, such lease is held by production in paying quantities.

While a lease may generally be maintained in force past its primary term only by production, there are other ways provided for in the lease to maintain the lease past the primary term. A lease can often be kept in force, in

the absence of production, through the date of expiration and after the primary term by the lessee's operations, which are conducted in a diligent manner looking toward the discovery and production of oil and gas. Most leases provide that the lease may be kept in force for an indefinite period of time in this manner provided that not more than 60 or perhaps 90 days elapse between the cessation of any such operations and the commencement of additional operations. Such additional operations might include reworking operations on any abandoned producer or deepening operations on a dry hole or possibly drilling operations for a new well at another location on the leased premises.

Drilling and Delay Rental Clause. A simplified drilling and delay rental clause might say that "the lease shall terminate on blank date unless on or before such date the lessee either commences operations for the drilling of a well on said land or pays to the lessor a rental of blank dollars per acre for all or that part of the land which lessee elects to continue to hold, which payment shall maintain lessee's rights in effect as to such land without drilling operations for 1 year from the above date." The lessee may continue to maintain such rights without drilling operations for successive 12-months periods by making similar payments to the lessor.

Early oil and gas leases usually provided for the commencement of a well. Changes were gradually made in the lease to allow the lessee to defer drilling operations by the payment of an annual sum called the delay rental. This alternative obligation to drill or pay a delay rental, when considered with the right of the lessee to surrender the lease at any time, is called an "or clause." Further changes were made. Wording was added to the lease to provide that, if no well was commenced before a certain time, usually 1 year from the date of the lease, the lease would terminate unless the lessee paid a delay rental. This further revised wording is known as the "unless clause."

Regardless of which clause is used, the lessee has the right either to commence a well within a specified time, pay a delay rental in lieu of commencing operations, or terminate the lease by the nonpayment of delay rentals. Almost all leases in use today are of the "unless" type.

Since the lessee is under no obligation either to pay delay rentals or commence operations for the drilling of a well, the practice has been to pay a substantial consideration, called the bonus, for the granting of the lease. The bonus may be any agreed-upon sum but is usually large when compared with the delay rental. The bonus is sufficient to keep the lease in force and effect until such time, usually 1 year, as a delay rental may be provided for. The bonus is subject to negotiation at the time of the purchase of the lease. The bonus may run from \$1 to many thousands of dollars per acre, depending on the size of the tract, the royalty, anticipated oil and gas reserves, the quality and quantity of geological and geophysical data available, etc.

Most leases provide for the commencement of "operations." The commencement of actual drilling is not necessary unless specifically provided for. Operations incident to the actual drilling are sufficient and include building roads, digging pits, building the derrick, etc. Such operations must be continuous, diligent, and in good faith.

The effect of the drilling of a dry hole during the primary term by the lessee may vary from one lease form to another. Most leases provide that, if a dry hole is completed on the leased premises within the primary term, the lease may be kept in force by the commencement of additional operations or by resuming the payment of delay rentals as provided for in the lease.

In the "unless" type of lease, there is no obligation to pay the delay rental and there is no liability for failure to pay. Unless otherwise specifically provided for in the lease, the entire amount of the delay rental must be paid. Most leases permit the lessee to surrender a portion of the leased premises and then pay delay rentals on the balance. Delay rentals in most states are not a matter for negotiation as is the bonus and are usually in the amount of \$1/acre/yr. Such is not the case in some areas, as in southern Louisiana. Here the delay rental is just as important as is the bonus as an item to be negotiated upon; it is the practice for rentals to be in an amount equal to at least one-third to one-half of the bonus consideration on a per-acre basis.

The lease provides that rentals may be made on or before the specified date, payable to the lessor or to the lessor's credit in a bank designated by the lessor. Most rentals are tendered by the lessee 3 to 6 weeks in advance of the due date to provide time for the lessee to receive a receipt from the lessor's depository bank evidencing deposit of the rentals to the lessor's credit. The lease also contains a proportionate-reduction clause or lesser-interest clause, which allows the lessee to reduce the amount of the delay rentals and royalty payments where the lessor does not own a full interest.

Royalty Clause. A simple royalty clause might provide that the royalties to be paid by the lessee are (1) on oil and liquid hydrocarbons, one-eighth of that produced and saved from the land; (2) on gas, one-eighth of the market value at the well of the gas used by the lessee in operations not connected with the land leased, the royalty on gas sold by the lessee to be one-eighth of the amount realized at the well from such sales; (3) one-eighth of the market value at the mouth of the well of gas used by the lessee in manufacturing gasoline.

The most common royalty is one-eighth, experience having shown this to be the most equitable fraction to be paid to the lessor in relatively unexplored areas. However, in known trends it is often difficult to purchase leases providing for a royalty of only one-eighth. Here again, the royalty is an item that must be negotiated in much the same manner as the bonus or delay rental. Royalties of one-sixth and more are now quite common in some areas.

The royalty interest created at the execution of the lease is payable to the lessor in the event of production. It does not refer to any additional royalties that may be created by the lessee out of the working interest and that are called overriding royalties. It does not refer to an advance royalty that can be deducted from any subsequently accruing royalties. It does not refer to a minimum royalty, which is a sum the lessee agrees to pay in the event of production regardless of whether or not it is equivalent to the lessor's share of gross production.

A failure to pay royalties does not in itself effect automatic termination of the lease. Failure to pay

royalties within a reasonable time could result in a forfeiture of the lease in a court action. Some delay, perhaps several months, in disbursing royalty is to be expected; title must be approved by the oil or gas purchaser and division orders circulated among those who will share in the production.

Oil royalties are payable to the lessor either in oil or to the lessor's credit in the pipeline, which is called payment in kind, or by payment in money based on the value of the royalty oil. Execution of a division order waives the lessor's right to receive royalty in kind. Royalty is computed as a share of the gross and not as a share of the net production, which means the royalty is not burdened with any production costs. However, the lessor is required to pay his proportionate share of the cost of transportation and gross production taxes.

Condensate or distillate is a liquid produced along with gas, but which originally was in the vapor phase in the reservoir. Casinghead gas is gas produced from an oil well. A gas well produces gas as distinguished from casinghead gas and may be defined in terms of gas/oil ratio by various regulatory bodies. The royalty payable on oil is also the royalty payable on condensate and other liquid hydrocarbons when separated on the leased premises. The royalties payable on gas are always payable in money and never in kind, and are subject to transportation costs. Royalty on gas is payable only on that gas which is sold or used off the leased premises. Royalty is not payable to the lessor on gas used by the lessee as a means of lifting the oil to the surface or that is injected into the reservoir for pressure-maintenance purposes.

A gasoline plant may be justified in areas where there are sufficient reserves of rich gas. A lessee will often enter into a contract with a processing plant whereby his gas wells are produced full-well stream to the plant for extraction of liquid hydrocarbons. The independently owned plant will retain a percentage of the value of the liquid hydrocarbons removed as a processing charge and credit the lessee with the value of the balance of the separated liquids as well as with all the residue gas. The lessee then disburses royalty to the lessor in accordance with the terms of the lease. If the lessee owns an interest in the plant, the lessee may be required to pay royalty on extracted liquids and residue gas less only the actual operating costs of the plant depending upon the terms of the lease.

The Pooling Clause. The pooling clause provides that the lessee, at its option, is given the right and power to pool or combine the land or mineral interest covered by the lease, or any portion thereof, with other land, lease or leases, and mineral interests in the immediate vicinity thereof, when in the lessee's judgment it is necessary or advisable to do so in order to develop or operate the leased premises properly to promote the conservation of oil and/or gas. The clause further states that "any unit or pool created for the production of oil shall not exceed 40 acres and that any unit for the production of gas shall not exceed blank acres." The number of acres inserted in the event of a gas well will vary from 160 to 640, depending on local practice.

The term "pooling" refers to the combining of small tracts for the purpose of forming a unit on which a well may be drilled. A lease form should be used that contains

an appropriate pooling clause. It may not be quite so important to obtain this right in certain areas where only oil is produced or in those states that provide for forced pooling and integration. The pooling right is related to development, and the owner of the working interest has the responsibility for such development.

The lessee must act in good faith in exercising the pooling privileges granted in the lease. When a lessee declares a unit and places the unit declaration of record in accordance with the lease, it is presumably done in the interest of proper development and conservation. Caution should be exercised in planning a unit to be declared so the unit will be in reasonable conformance to the subsurface and seismic data available. A lessee who declares a unit of an unusual shape for the obvious purpose of holding a lease past its expiration date, or that includes acreage most likely not productive, or that tends to disregard available geological control is probably not acting in good faith. Such a declared unit may be vulnerable to attack by the lessors.

When a lease contains a pooling clause, appropriate changes will appear elsewhere in the lease. The habendum clause may read, "this lease shall be for a term of blank years from the date hereof, called primary term, and so long thereafter as oil or gas is produced either on this land or on acreage pooled therewith, or with any part thereof." Operations for the drilling of a well or production from a well on a unit constitute operations or production from each of the tracts pooled.

Miscellaneous Clauses. Many miscellaneous clauses are found in leases for the benefit of the lessor or the lessee. The lessee is restricted in locating a well on the leased premises to the extent that no well may be drilled nearer than 200 ft to any house or barn. The lessee is required to lay pipelines at such a depth as not to interfere with plowing and cultivating operations. The lessee may be required to pay for all damages in connection with its operations on the land, although the damages are often restricted to timber and growing crops.

A paragraph is often found in leases that has as its purpose the inclusion of small strips of adjacent land owned by the lessor but not specifically described in the lease. The lessor usually intends to include such small parcels of land in the lease, but for various reasons a description of the strip may have been omitted. This paragraph is called the "Mother Hubbard clause." It is not intended that large tracts of land be subject to this clause but only strips or parcels of perhaps several acres in size. The lessee is given the right to use without cost gas, oil, and water produced on the leased premises for lessee's operations thereon. The lessee is given the right to remove machinery and fixtures from the leased premises, including casing, within a reasonable period of time after the lease has terminated.

The lease provides that the interests of the parties are assignable in whole or in part. No change in ownership of the land imposes any additional burden on the lessee until the lessee has been furnished with a certified copy of the recorded instrument evidencing the transfer. Since portions of many leases are eventually assigned, a clause is inserted to protect the lessee in the event of default in rental payments by the lessee's partial assignee. It provides that in the event of partial assignment a default in

the rental payment of the assignee shall not operate to defeat or affect the lease insofar as it covers that portion retained by the lessee.

The "warranty clause" provides that the lessor warrants and agrees to defend the title the land leased. If the covenant of general warranty is breached, the lessee can recover the consideration paid for the lease with interest and the expenses incurred in defending possession. The lessee is given the right to redeem for the lessor, by payment, any mortgages, taxes, or other liens on the leased premises and to apply to the repayment of the lessee any rentals and/or royalties accruing under the lease.

The Implied Covenant. It is important to keep in mind that the underlying purpose of the lease is to secure production. Most leases have very little to say about the manner in which wells will be drilled, or even if a well will be drilled at all. Little is ever said about the well density or the intervals at which development wells will be drilled. The lack of specific agreement between the lessor and lessee in these regards is intentional. Too much is unknown about the nature and characteristics of any reservoir present. The obligations of the lessee are the obligations of an ordinarily prudent operator under the same or similar circumstances, considering the lessor's interest as well as his own. The obligation to develop the leased premises as would a prudent operator arises only after discovery of oil or gas and continues for the life of the lease.

Assignments by the Landowner

Right to Transfer. Fee owners can dispose of their land in any way they see fit, either in whole or in part. They can convey the surface and reserve the minerals, or vice versa. They can sell all or a divided part or an undivided interest in the minerals. They can sell all or a part of their interest in the proceeds from the minerals. They can create a subordinate interest and transfer it to another party, as is done when a lease is granted.

Mineral Deeds and Interests. A mineral deed transfers the minerals or the right to obtain them as they exist in place. The owner of minerals has the right to go on the land, conduct exploratory operations, and produce oil and gas. If the minerals are subject to a lease at the time of the mineral conveyance, the mineral grantee may not exercise these rights until the lease terminates. The mineral owner has the right to execute a lease and to receive the bonus money therefrom. The mineral owner has the right to receive rentals and to share in the royalties if and when payable under any lease. Mineral interests are most often created by unqualified grants or reservations. However, many mineral conveyances are for a specified term of years, or for a specified term and so long thereafter as oil or gas is produced.

Royalty Deeds and Interests. Royalty is a share in production and, when applied to a lease, refers to the share of the oil and gas that is received by the lessor from production under the lease. This share is usually one-eighth of the whole, although it may be any other fraction agreed upon. Royalty also refers to an interest that is created by grant or reservation either before or after the

execution of a lease. The right to royalty is contingent on production and carries with it no right or interest in the minerals. The owner of a royalty interest receives no bonus and no delay rental payments. A royalty interest is an expense-free interest in the gross production and not in the net production. Royalties as well as minerals may be conveyed in fee or for a specified term of years, or for a specified term and as long thereafter as oil or gas is produced.

When referring to a conveyed royalty interest, it is customary to refer to the number of royalty acres conveyed, as well as to the fractional interest. If a landowner sold half of his one-eighth royalty in a tract of 80 acres, the royalty grantee is said to have purchased 40 royalty acres. If a royalty buyer purchased one-eighth of the same landowner's one-eighth royalty, the royalty purchaser would be entitled to one-sixty-fourth of all production and is said to own 10 royalty acres.

Assignments by the Lessee

Right to Transfer. The lessee is the owner of the lease, and the interest is usually seven-eighths of the production but may often be much less, depending on the amount of royalty. This interest is referred to as the working interest. A lessee may transfer his entire interest either in whole or part, or an undivided portion in the lease or a part thereof. The lessee has the right to convey overriding royalties, production payments, undivided interests, or an entire interest in a portion of the leased premises.

Assignments and Subleases. An assignment is a transfer of the assignor's entire interest in a lease either in its entirety or in a portion thereof. A sublease is a partial transfer in that the sublessor retains an interest in the lease in so far as it affects the property subleased. An instrument conveying the working interest but providing for the reservation of an overriding royalty is a sublease rather than an assignment.

Obligations undertaken by the lessee in the lease are called covenants. A contractual relationship exists between the lessor and the lessee, and there is said to be a privity of contract between the parties. The lessee has the right to assign the leasehold estate to a third party. The covenants contained in the lease are assumed by the third party and are said to be covenants running with the land. In the event of a true assignment, the lessee is usually relieved of his obligations to the lessor. In the event of a sublease, the lessee remains liable to the lessor because of the privity of contract between them.

Overriding Royalty. An overriding royalty interest is an interest carved out of the working interest and is not burdened with the cost of development or production. It is therefore a kind of royalty interest. An overriding royalty is usually created in a sublease, but may be created by grant. It in no way affects the royalty interest that is payable to the lessor. The overriding royalty owner generally cannot require the lessee to maintain the lease in force, to drill a well, or to develop the property, and shares in oil and gas only when, as, and if produced.

Production Payments. Oil payments, perhaps more correctly referred to as production payments, are related to overriding royalties in that they are usually carved out of the working interest and bear no cost of production. The overriding royalty differs from the production payment in that the former continues for the life of the lease and the latter terminates upon the payment of a specified sum of money from a stipulated percentage or fraction of the working interest. Production payments can be of practically any size and can be made payable out of any fraction or percentage of the working interest.

The production payment is occasionally used in negotiating a lease. A company may be willing to spend not more than \$100/acre as bonus for a lease but at the same time be willing to provide for a production payment of perhaps \$200/acre payable out of one-sixteenth of seven-eighths. A landowner can occasionally be shown the advantages of a production payment, with the result that a deal is made instead of lost.

The use of the production payment in the large-scale purchase of producing properties has become common. The task of how to purchase a producing property for a minimum cash outlay by the grantee with the grantor receiving the entire purchase price in cash and with the gain taxed at capital gains rates is often accomplished by an "ABC" transaction. A is the seller and the owner of the property. B is the purchaser of the property. C is the purchaser of the production payment and either has or can get the major part of the required cash. To illustrate, A owns a producing property that will sell for \$1,000,000. B wants to buy the property but has only \$200,000 for the purchase. A will convey the property to B for \$200,000, retaining a production payment of \$800,000 plus interest payable out of 85% of the production. A will then sell the production payment to C for \$800,000 cash. All parties to the transaction receive the maximum tax benefits allowed.

Unit Operations

Background

In recent years the objective has been to obtain the maximum ultimate recovery of oil and gas in place. In the early days of the industry a great number of unnecessary wells were drilled; only a fraction would have been required to obtain maximum efficient withdrawal. In time, limits were placed on the amount of production; well-spacing regulations came into existence; the establishment of drilling units and the pooling of small tracts of land followed. The advantages of cooperative development on a small scale became even more apparent when considered on the basis of the entire reservoir. Unit operation of a reservoir, whether for cooperative development, pressure maintenance, or secondary recovery, requires a knowledge of the hydrocarbons in place and an acceptance of the correlative rights of the owners; a fair distribution of the proceeds is best accomplished by contractual agreements among the royalty and working-interest owners.

The unit operation of an oil and gas reservoir is to be distinguished from pooling, which is the combination of small tracts to form a drilling unit or comply with spacing regulations. The term "unitization" is usually used interchangeably with unit operations. Unitization

therefore refers to the operation of all or a substantial part of the reservoir by a unit operator in accordance with the terms of a unitization contract. Unit operations may include two categories, depending on the manner in which they come into existence.

Voluntary Unit Operations. When the owners of the interests in a reservoir agree that all or a major portion of the reservoir is to be operated as a single unit regardless of property or lease lines, a voluntary unit operation comes into existence. The preparation of a unitization agreement acceptable to all the parties is a major undertaking. Two contracts are entered into, an operator's contract and a royalty owner's contract, sometimes called the unit contract. Many problems are involved regarding the operation of the reservoir and the drilling of additional wells that are best handled in a separate contract among the owners of the working interest. The royalty-unitization agreement must expressly provide for the consolidation of the interests of the lessors. Without such authority, lessors could demand that their tract be drilled to prevent drainage or be developed separately. The working out of a voluntary-unitization agreement requires a thorough knowledge of the conservation statutes. The voluntary-unitization agreement may provide that the contract will not become effective until approved by the appropriate regulatory body.

Compulsory Unit Operations. Compulsory unit operations come into being by order of a regulatory body in accordance with specific statutes. Early statutes provided that, if a certain percentage of the lessees in an area to be unitized petitioned the regulatory body to bestow jurisdiction to issue appropriate orders, it would do so. The laws of the states vary as to the percentage of ownership required. There must first be agreement among a majority of the lessees and royalty owners concerned regarding a unit plan. Here again a great deal of work and time are required. Numerous conferences are held among the working-interest owners and studies are made by various committees. Upon finalization of the plan, signatures are obtained from the working-interest and royalty-interest owners. A petition to the regulatory body is made and a hearing is held after proper notice has been given to all the interested parties. Upon issuance of the appropriate orders, accounting adjustments are made among the working-interest owners and the appointed unit operator assumes operations of the area.

Getting the Well Drilled

Lease Purchases. Oil and gas leases are purchased for a variety of reasons. Lease purchases are often of a trend nature, with no drillable prospect having been shown to exist. Such lease purchases could be in a sedimentary basin considered likely to contain accumulation of hydrocarbons, or as extensions to discovery wells. The owners of the leases might then plan to conduct seismic operations in an effort to isolate and define likely structures on large lease blocks or spreads of acreage. However, the owner of a geological idea or unleased prospect may have sufficient subsurface and/or seismic

data to justify the drilling of a well. In this instance, leases are acquired for the very definite purpose of drilling in the immediate future. Under such considerations, the amount of the rentals or the extent of the primary term becomes of secondary importance in negotiating the leases. A landman or lease broker will then be employed to review the records of the clerk of court to determine surface and mineral ownerships of all the tracts of land in the prospect including county roads, state and federal highways, rivers, school lands, canals, etc. Mineral leases will then be negotiated and acquired.

Capital to Drill the Well. Major oil companies have no real problem in raising the necessary capital to drill wells. Such funds are, to a large extent, available from earnings, and to a lesser extent, from borrowings. However, independents have been historically short of cash to drill wells. An "independent" is a small corporation or a partnership or perhaps an individual engaged in oil and gas exploration only. That is, an independent is not engaged in the transportation and refining of petroleum or in the marketing of petroleum products. Independents drill approximately 85% of all wells drilled in the U.S. and there are thousands of small companies and individuals engaged full time in oil and gas exploration.

In recent years, the limited partnership has been the primary source of venture capital for the independent. Investors buy units of a drilling fund and become limited partners. An experienced and successful independent becomes the general partner. Another significant source of venture capital for drilling wells has been the utility companies and end-users, such as the chemical industry. A typical independent may spend \$5 to \$15 million a year in drilling money, almost none of which belongs to the independent. The capital comes from investors and from persons who buy into drilling deals. Regardless of the source of the capital, the independent invariably promotes or lays off a part of his deal, usually on a third for a quarter basis. This means that the party being promoted or who buys into the deal will pay one-third of the cost of drilling the well for a one-quarter interest in the well. Variations of this type of promotion are endless; but by and large this type of promotion is standard between independents and investors as well.

Sources of Prospects. Major oil companies maintain large staffs of geologists, seismologists, paleontologists, and other supporting personnel engaged in development and exploration efforts. Major oil companies rarely participate in drilling on prospects not generated by them. On the other hand, most independents do not generate their own prospects but must buy them from geologists and others who generate geological prospects. The geologists, landmen, and others who can generate prospects and buy leases on them are then in a position, to a limited extent, to promote their prospect in dealing with an independent. Invariably, a nominal overriding royalty can be retained on the leases and occasionally a carried working interest to casing point. In this case it is difficult to obtain a carried working interest of as much as one-quarter because the independent taking the deal must

itself plan on laying off perhaps half of the deal and there must be some room left in the structuring of the deal to permit all concerned to realize some economic benefit.

Abstracts and Title Examination. Abstracts will be ordered on at least the proposed drillsite and offsetting tracts, and perhaps even on the entire prospect. The abstract will usually contain exact copies of all instruments of public record pertinent to the land from patent to date. Qualified oil and gas attorneys will review the abstracts and render a title opinion. There are usually numerous title deficiencies, most of which can be met by appropriate curative effort by the landman or title man. Supplemental title opinions will be obtained after the curative materials have been procured. Rarely can every requirement be met and the lessee may have to elect to waive such unmet remaining requirements and assume the business risk of proceeding with the drilling of the well.

Full-Interest Wells. When a lessee controls the entire acreage on all of the prospects it is fortunate indeed. The well can be drilled as the lessee pleases, being restricted only by appropriate regulations. Should the well result in being a producer the lessee will have control of the entire reservoir, assuming the lessee has more or less correctly anticipated the extent of the reservoir in the lease purchases. However, this situation is rarely found. Considerable work has yet to be done when a lessee is planning to drill a well and finds that all of the prospective acreage is not controlled.

Joint-Operating Agreements. Generally a lessee thinking of drilling a well will have at least some leases on the prospect. The remaining leases will be owned by one or more competitors, presumably people who are also interested in drilling wells and establishing production. Since the owners of the leases covering the prospect will all benefit in the event of production, it would seem equitable that each pay a proportionate part of a well or make a suitable contribution to the well.

However, it is not often that two or more lessees have the same data, or interpret the data in the same way. A lessee may elect to farm out its acreage, do nothing, or join in the drilling of a well. The other lessees will be contacted in an attempt to determine their interest in getting a well drilled. The other lessees may not have sufficient information to justify their joining in the drilling of a well. The party desiring to drill the well may find it desirable to make any information available to the adjacent lessees. This seismic or other control may represent a sizable investment, and the other lessees may be willing to pay for the data, exchange similar data of their own in another area, or negotiate almost any kind of agreement with the owner of the control. If all the lessees are eventually agreed that a joint well should be drilled, they will define a contract area that will be jointly owned. A joint-operating agreement will be entered into and the interests of the parties to the agreement determined on the basis of the surface acreage owned by each as compared with the total acres in the contract area. The joint-operating agreement will stipulate the interests of the participating parties, specify the operator, limit cer-

tain expenditures, establish liabilities, provide for the drilling of the first and subsequent wells, provide for nonconsent operations, etc. Certain operating costs are agreed on and an accounting procedure is attached to the joint-operating agreement.

The joint-operating agreement is a very useful tool in exploratory operations, particularly where the tracts of land are small or where it may be desirable to share the risk of an expensive exploratory well. Contract areas can be of practically any size but for exploratory purposes usually run from about 640 to several thousand acres in size. The joint-operating agreement is also used occasionally in development drilling. It finds frequent application in a unit or pool ordered by a regulatory body after a well has been completed as a producer.

Cash Contributions. A lessee may find it necessary to drill a well on a reduced-acreage basis with cash support from the adjacent lessees who might not be willing to farm out or enter into a joint operation. The most common type of cash contribution is the dry-hole contribution. It is usually a sum of money per foot drilled, determined by reservoir participation, discounted for lack of ownership in the well, etc. This type of contribution gets its name from the fact that no money is payable in the event the well is completed as a producer. The idea here is that the offset lessee is willing to make a cash contribution toward the drilling of a well that in all probability will be dry but which will at least partially evaluate the leases. In the unlikely event the well is completed as a producer it is thought that the rewards are sufficiently great for the owner of the well to make cash payment from the offset lessee unnecessary. A variation of the dry-hole contribution is the bottomhole contribution, which is payable upon reaching a specified depth regardless of whether or not the well is completed as a producer. Both types of cash contributions are used infrequently.

Farmouts. A transfer of the working interest with the obligation to drill a well is called a farmout. There are any number of ways in which a farmout can be negotiated. A farmout agreement provides for the drilling of a well, or the option to drill a well, at a mutually agreed location and to a mutually agreed depth on one of the leases owned by the party making the farmout. Upon completion of the well in accordance with the terms of the farmout agreement, the lessee will assign or sublease a portion of the leases and retain an interest, usually an overriding royalty. The amount of the overriding royalty will vary widely from area to area and will depend on a number of factors including the available geological and geophysical control, the amount of the working interest, the proximity of production, producing history in the area, lifting problems, suitable markets, size of the anticipated reservoir, the number of acres being farmed out, well costs, etc.

The operator that takes the farmout will be looking to the net revenue interest to recover costs. Gross income from the sale of production less royalty, overriding royalty, and any other burdens on the leases determines net revenue interest. Acceptable net revenue interests on farmouts vary widely: a net revenue interest in Oklahoma under a pooled section might be considered

unacceptable if less than 81.25%; in North Dakota in a wildcat well, 75%; in Louisiana in a low risk, close-in prospect, 68%.

A more complicated version of the farmout is found in the better producing areas. Such farmouts are often made on the basis of a portion of the working interest being retained by the party making the farmout. A typical arrangement might be the farmout of perhaps 2,000 acres on a 60/40 basis for a free well into the tanks to 12,000 ft. The party taking the farmout would agree to drill and complete a 12,000-ft test at the party's sole cost and risk and thereby earn an assignment of an undivided 60% interest in the 2,000-acre block. If the well is productive the party making the farmout owns 40% interest in the well and in the production, usually after the operator has recovered the costs to take full advantage of available tax deductions. The party taking the farmout will obtain payout from the proceeds of the sale of production from the earning well less any royalties and overriding royalties. Subsequent operations on the farmout block would be under the terms of a joint-operating agreement.

Variations of this type of deal are countless. The well could be a free well through the wellhead rather than into the tanks. This means the operator would pay for all completion costs through the well head but would share on a 60/40 basis in erecting tanks and treating equipment. Another variation is the free well to the sand. This means the operator would drill the well (at sole cost and risk) to the objective horizon, run an electrical log, and core and test as might be required to determine the possibility of production. If a decision is made to attempt a completion the operator will pay a negotiated fraction of the cost of running a production string of casing and setting subsurface production equipment, with the party making the farmout paying the remainder of the cost. Any interest may be negotiated; one-quarter and one-third interest deals are commonly made. Other variations might allow the operator to recover completion costs before the party making the farmout would be entitled to any share of the production. The party making the farmout might keep an overriding royalty during partial or complete payout and at the time of the payout would have the option to exchange the overriding royalty for a working interest.

Carried Interest. A carried-interest contract is an arrangement between co-owners of a working interest, whereby one agrees to advance all or some part of the development or operating costs on behalf of the others and to recover such advances from future production, if any, accruing to the other owners' shares of the working interest. The co-owner advancing such costs is referred to as the carrying party and the co-owners for whom costs are so advanced are referred to as the carried parties.

A carried interest usually comes into being in connection with a farmout. The carried-interest contract may apply not only to the first well but to subsequent wells. The party making the farmout may assign a portion of the working interest to an operator who will pay all the costs of drilling and equipping the first well, and possibly additional development wells. The grantee must look to the production, if any, attributable to the grantor's share of the working interest to recovery the gran-

tor's share of such costs. A carried interest is a share in the net and not the gross production.

Net-profits Interest. A net-profits interest is an interest in gross production measured by the net profits from the operation of an oil and gas property. A net-profits interest is similar to an overriding royalty in that it is created out of the working interest. The proceeds accruing to a net-profits interest are reducible by certain development and operating costs, which are specified in the net-profits contract. The net-profits interest is subject to such expenses to the extent of its share of the income. The owner of a net-profits interest is not required to pay out or advance money for development or operating costs, as in the case of the owner of a working interest, and is not liable for such costs. If no net profit is realized from the operation of the property the net-profits-interest owner receives no income but neither is the owner liable to the operator for a share of the loss. A net-profits interest can be regarded as a non-operating interest similar to an overriding royalty. The net-profits agreement finds its principal application in farmouts. Equitable as it may sound, this type of agreement is seldom used.

Lease Problems During Development

The lessor is often pleased and even overwhelmed by the discovery of hydrocarbons on the land and the sudden cash flow of royalty. Problems early in the development phase, such as the use of the surface for tank batteries, gathering lines, treating equipment, and roads are usually settled quickly. After a period of time, new problems arise of a subtle and sophisticated nature. As some lessors seek to maximize their royalty income, they turn to petroleum consultants and oil and gas attorneys for advice. From this effort come legal demands for additional development or release of undeveloped acreage. While development can occur both horizontally and vertically, lessor demands for development have generally been sustained by the courts in a horizontal sense only.

A more recent and more complex problem relates to the gas royalty clause and market value. The typical lease refers to the lessors' royalty as a fraction of market value. When a lessee discovers gas and enters into a long term contract for the sale of gas, the market value of gas and the contract price for gas are almost identical. However, the price of natural gas in recent years has risen dramatically. The lessee is sometimes contractually bound to a gas price with the purchaser and at the same time faces a demand from the lessor for gas prices at market value. The courts are not uniform from state to state on this issue. The U.S. Natural Gas Policy Act of 1978, with its price ceilings on categories of natural gas, may have been of some use in defending lessor suits for market value on royalty gas. Lessees now appear to be leaning to short-term gas contracts, provisions for frequent renegotiation of price, rewriting the gas royalty clause to provide for "price received" rather than market value, providing for in-kind royalty on gas, etc. Whether or not lessees will be successful in negotiating such gas contracts in periods of falling demand remains to be seen. Similarly, it can be expected that lessors and their attorneys will resist any changes in the lease form from the conventional wording on gas royalty. Resolution of this problem lies ahead.

Taxation*

The taxation of income related to oil and gas is a highly specialized field. The increasing complexity of tax laws and the very real effect that taxes have on the successful conduct of any business make it imperative that competent tax advice be sought out by any operator, however small his organization may be. The importance of tax planning can hardly be overestimated. Improper structuring of a drilling deal or a sale of a property from a tax standpoint can have the most serious of consequences. The larger organizations and major oil companies have tax departments comprised of specialists in the various subdivisions of taxation. Independents and small organizations must retain the services of tax consultants on a continuing basis.

Very briefly, all income less certain exclusions exempt from tax is gross income. Taxable income is gross income less deductions. Tax rates vary for individuals and corporations, as do long-term capital gains rates for individuals and corporations. Items of tax preference are deductions such as the excluded portion of capital gains, depletion, accelerated depreciation, and excess intangible drilling costs on productive property, all of which are subject to a minimum tax. Capital expenditures are not immediately deductible as are expenses, and must be recovered through depreciation or depletion. Some expenses, such as accelerated depreciation, are recaptured at sale, that is, become taxable at ordinary rates. The cost of tangible property used in business results in certain tax credits that are subtracted directly from the taxes due and are not a deduction.

Capital expenditures include the bonus costs of purchasing mineral leases, well and lease equipment, and most geological and geophysical exploration costs. Deductible expense items include overhead, lease rentals, abandoned leases, most intangible drilling costs, and geological and geophysical costs not resulting in lease acquisitions.

The enormous sums of money put into oil and gas exploration by private investors through limited partnerships deserve further comment. The private investor has taken advantage of the tax provisions in three principal areas: depletion, intangible drilling and development costs, and capital gains.

Depletion. A producing reservoir gradually suffers a reduction in the quantity and value of hydrocarbons in place. Depletion laws were enacted to provide for a return of capital because of mineral extraction. The taxpayer has a choice of two methods. Cost depletion provides for a reduction in basis as related to production and sale of minerals. Percentage depletion provides for a deduction of a percentage of the gross income from the property, which is limited to 50% of the net income from the property, and to 65% of net income from all sources. The U.S. Tax Reduction Act of 1975 effectively repealed percentage depletion, with certain exceptions. An exemption was allowed for independent producers and royalty owners as a percentage of qualified production, except as to transfers of producing property. For 1984

that percentage will be 15% of the first 1,000 BOPD produced, or 6 million cu ft/D gas.

Intangible Drilling and Development Costs. Taxpayers owning operating rights and incurring intangible costs may elect to expense or capitalize such costs. If the taxpayer elects to capitalize, the intangible drilling costs may be recovered through depreciation over 5 years, and are subject to an investment tax credit. Such capitalized costs do not represent a tax preference item. Since capitalization of such costs offers no real tax benefits, most taxpayers elect to expense such costs.

Intangible drilling costs may represent 80 to 90% of the cost of an exploratory well; the remaining portion representing tangible costs of equipment with salvage value. It is no surprise to note the enormous success of drilling funds through limited partnerships as such large deductions are made available to investors.

Capital Gains. A sale of a capital asset after a holding period set by law will subject the taxpayer to greatly reduced tax rates of a maximum of 20% of the profits of the sale. The sale of leases, either producing or non-producing, is subject to these favorable capital gains tax rates. The attraction of such favorable tax treatment in the event of future sales of properties has been a further inducement to investors in oil and gas exploration.

Offshore Leasing

Jurisdiction. Fifteenth and sixteenth century explorers claimed vast areas of waters, entire gulfs, seas, and oceans. However, these early claims, as a practical matter, were unenforceable. The extent of national sovereignty over the waters has not been resolved in international law. By presidential proclamation in 1945, the U.S. regards the natural resources of the Outer Continental Shelf (OCS) as a territory owned by the nation. The Submerged Lands Act of 1953 confirmed the jurisdiction and control of the U.S. over the natural resources of the seabed of the continental shelf seaward of the state boundaries.

Producing and Leasing History. The first commercial oil production in the Gulf of Mexico was discovered in 1947 on a Louisiana state lease. Drilling on federal lands under the OCS Lands Act began in 1954. Since 1956, the OCS (Atlantic, Pacific, Gulf of Mexico, and Alaska, comprising over more than 1 billion acres) has produced about 6 billion bbl of oil and about 55 Tcf gas. Leasing has proceeded at a snail's pace. For years, into the early 1970's, the abundance of oil and gas onshore and in world markets suppressed offshore leasing exploration with its high costs. As the search intensified, efforts to schedule lease sales met with great opposition from environmental groups. The time required for environmental assessment, state and local government comment, and so on, sometimes exceeded 3 years. The U.S. Dept. of Interior recently has moved to accelerate lease sales; almost the entire continental shelf will have been offered for lease at scheduled dates through 1987.

Leasing Procedure. The interior secretary prepares a proposed 5-year leasing program. In the preparation phase, the secretary invites and considers suggestions

*Written before the Tax Reform Act of 1986, which implements changes in alternative minimum tax, depletion, depreciation, investment tax credit, and deduction of losses.

from the governors of affected states, local government, industry, federal agencies, and all interested parties, including the general public. Time is provided for a response from the governors and others after preparation of a draft of a proposed program, and prior to publication in the *Federal Register*. Time is again provided for a response following publication and prior to submission to the president and congress for approval. The director of the Bureau of Land Management issues calls for nominations pursuant to an approved program, conferring with the governors where indicated. A list of tracts tentatively selected for leasing is drawn up. The director is free to make deletions or additions from the tentative selection of tracts. A selected tract will, in general, not exceed 5,760 acres. Upon approval by the secretary, the proposed notice of sale will be published in the *Federal Register*. The governors and local governments concerned again have an opportunity to comment. The secretary will make the final decision and will publish the notice of sale in the *Federal Register*. The sale itself will be held no sooner than 30 days after publication. Tracts are offered for lease by competitive sealed bidding. Leases are issued only to qualified bidders. Leases are issued for an initial period of 5 years, although longer times are provided for where unusually deep water or adverse conditions would discourage exploration and development. Annual rentals are due in advance to maintain the lease in the absence of production. Royalties bid are variable with one-eighth royalty being a minimum. Royalties on all leases in the Gulf of Mexico average about one-sixth.

After being awarded a lease, a lessee seeks to obtain the necessary permits. The lessee or operator will usually drill one or more test wells to determine whether hydrocarbons are present. If oil and/or gas is discovered, the operator, as a matter of common practice, will abandon the exploratory holes without attempting to complete

or produce from them. Exploratory wells are usually used to obtain information about potential oil and gas accumulation. Development or production wells are normally drilled from a production platform.

Economic Impact of Offshore Leasing. The interior secretary has stated that 85% of America's untapped oil wealth is on publicly owned lands, of which two-thirds is thought to be offshore. The economic implications for the future in exploring and developing such reserves are truly significant. The amount of capital required for such exploration and development is staggering. But consider the recent past: the OCS has produced about 6 billion bbl oil and 55 Tcf gas. There would appear to be little question about the ever-increasing significance of the leasing, exploration, and development of lands comprising the OCS.

Preface

The SPE Board in June 1982 endorsed revisions to "SPE Tentative Metric Standard" (Dec. 1977 *JPT*, Pages 1575-1611) and adopted it for implementation as this "SPE Metric Standard."

The following standard is the final product of 12 years' work by the Symbols and Metrication Committee. Members of the Metrication Subcommittee included John M. Campbell, chairman, John M. Campbell & Co.; Robert A. Campbell, Magnum Engineering Inc.; Robert E. Carlile, Texas Tech U.; J. Donald Clark, petroleum consultant; Hank Groeneveld, Mobil Oil Canada; Terry Pollard, retired, *ex-officio* member; and Howard B. Bradley, professional/technical training consultant.

With very few exceptions, the units shown are those

proposed and/or adopted by other groups involved in the metrication exercise, including those agencies charged with the responsibility (nationally and internationally) for establishing metric standards. These few exceptions, still to be decided, are summarized in the introduction to Part 2 of this report.

These standards include most of the units used commonly by SPE members. The subcommittee is aware that some will find the list incomplete for their area of specialty. Additions will continue to be made but too long a list can become cumbersome. The subcommittee believes that these standards provide a basis for metric practice beyond the units listed. So long as one maintains these standards a new unit can be "coined" that should prove acceptable.

Part 1: SI—The International System of Units*

Introduction

Worldwide scientific, engineering, industrial, and commercial groups are converting to SI metric units. Many in the U.S. are now active in such conversion, based on work accomplished by national¹ and international² authorities. Various U.S. associations, professional societies, and agencies are involved in this process, including, but not limited to, the American Soc. for Testing and Materials (ASTM),³ American Petroleum Inst. (API),^{4,5} American Natl. Standards Inst. (ANSI),^{3,6} American Soc. of Mechanical Engineers (ASME),⁷ and American Natl. Metric Council (ANMC).⁸ The Canadian Petroleum Assn. (CPA) and other Canadian groups have been especially active in conversion work.¹³ SPE intends to keep its worldwide membership informed on the conversion to and use of SI metric units.

The term "SI" is an abbreviation for *Le Système International d'Unités* or *The International System of Units*.

SI is not identical with any of the former cgs, mks, or mksA systems of metric units but is closely related to them and is an extension of and improvement over them. SI measurement symbols are identical in all languages. As in any other language, rules of spelling, punctuation, and pronunciation are essential to avoid errors in numerical work and to make the system easier to use and understand on a worldwide basis. These rules, together with decimal usage, units coherence, and a series of standard prefixes for multiples and submultiples of most SI units, provide a rational system with minimum difficulty of transition from English units or older systems of metric units. Refs. 1 through 4 of this paper are recommended to the reader wishing official information, development history, or more detail on SI; material from these and other references cited has been used freely in this report.

Appendix A provides definitions for some of the terms used.

SI Units and Unit Symbols³

The short-form designations of units (such as ft for feet, kg for kilograms, m for meters, mol for moles, etc.) have heretofore been called unit "abbreviations" in SPE terminology to avoid confusion with the term "symbols" applied to letter symbols used in mathematical equations. However, international and national standard practice is to call these unit designations "unit symbols"; the latter usage will be followed in this report.

SI Units

SI is based on seven well-defined "base units" that quantify seven *base quantities* that *by convention* are regarded as dimensionally independent. It is a matter of choice how many and which quantities are considered base quantities.⁹ SI has chosen the seven base quantities and base units listed in Table 1.1* as the basis of the International System. In addition, there are two "supplementary quantities" (Table 1.2).

Tables 1.1 and 1.2 show current practices for designating the dimensions of base and supplementary physical quantities, plus letter symbols for use in mathematical equations.

SI "derived units" are a third class, formed by combining, as needed, base units, supplementary units, and other derived units according to the algebraic relations linking the corresponding quantities. The symbols for derived units that do not have their own individual symbols are obtained by using the mathematical signs for multiplication and division, together with appropriate exponents (e.g., SI velocity, meter per second, m/s or $\text{m} \cdot \text{s}^{-1}$; SI angular velocity, radian per second, rad/s or $\text{rad} \cdot \text{s}^{-1}$).

Table 1.3 contains a number of SI derived units, including all the 19 approved units assigned special names and individual unit symbols.

Appendix B provides a more detailed explanation of the SI system of units, their definitions, and abbreviations.

*Prepared by T.A. Pollard for the subcommittee. Based on paper SPE 6212 presented by T.A. Pollard at the 1976 SPE Annual Technical Conference and Exhibition, New Orleans, Oct. 3-6.

*Table and figure numbers of the original SPE publication are used throughout this chapter.

SI Unit Prefixes⁸

The SI unit prefixes, multiplication factors, and SI prefix symbols are shown in Table 1.4. Some of the prefixes may seem strange at first, but there are enough familiar ones in the list to make it relatively easy for technical personnel to adjust to their use; kilo, mega, deci, centi, milli, and micro are known to most engineers and scientists.

One particular warning is required about the prefixes: in the SI system, k and M (kilo and mega) stand for 1000 and 1 000 000, respectively, whereas M and MM or m and mm have been used previously in the oil industry for designating thousands and millions of gas volumes. Note carefully, however, that there is no parallelism because SI prefixes are raised to the power of the unit employed, while the customary M and MM prefixes were not. Examples: km³ means cubic kilometers, *not* thousands of cubic meters; cm² means square centimeters, *not* one-hundredth of a square meter. The designation for 1000 cubic meters is 10³ m³ and for 1 million cubic meters is 10⁶ m³—*not* km³ and Mm³, respectively.

Appendix C gives examples of the vital importance of following the precise use of upper-case and lower-case letters for prefixes and for unit symbols.

Application of the Metric System

General

SI is the form of the metric system preferred for all applications. It is important that this modernized version be thoroughly understood and properly applied. This section, together with Appendix material, provides guidance and recommendations concerning style and usage of the SI form of the metric system.

Style and Usage

Take care to use unit symbols properly; the agreements in international and national standards provide uniform rules (summarized in Appendix C). It is essential that these rules be followed closely to provide maximum ease of communication and to avoid costly errors. Handling of unit names varies somewhat among different countries because of language differences, but using the rules in Appendix C should minimize most difficulties of communication.

Usage for Selected Quantities

Mass, Force, and Weight. The principal departure of SI from the gravimetric system of metric engineering units is the use of explicitly distinct units for mass and force. *In SI, kilogram is restricted to the unit of mass. The newton is the only SI unit of force*, defined as 1 (kg·m)/s², to be used wherever force is designated, including derived units that contain force—e.g., pressure or stress (N/m²=Pa), energy (N·m=J), and power [(N·m)/s=W].

There is confusion over the use of the term *weight* as a quantity to mean either *force* or *mass*. In science and technology, the term *weight of a body* usually means the force that, if applied to the body, would give it an acceleration equal to the local acceleration of free fall (*g*, when referring to the earth's surface). This acceleration varies in time and space; *weight*, if used to mean force, varies also. The term *force of gravity* (mass times acceleration of gravity) is more accurate than *weight* for this meaning.

In commercial and everyday use, on the other hand, the term *weight* nearly always means *mass*. Thus, when

TABLE 1.1 — SI BASE QUANTITIES AND UNITS*

Base Quantity or "Dimension"	SI Unit	SI Unit Symbol ("Abbreviation"), Use Roman (Upright) Type	SPE Letter Symbol for Mathematical Equations, Use Italic (Sloping) Type
length	meter	m	<i>L</i>
mass	kilogram	kg	<i>m</i>
time**	second	s	<i>t</i>
electric current**	ampere	A	<i>I</i>
thermodynamic temperature	kelvin	K	<i>T</i>
amount of substance	mole†	mol	<i>n</i>
luminous intensity	candela	cd	

*The seven base units, two supplementary units and other terms are defined in Appendixes A and B, Part 1.

**SPE heretofore has arbitrarily used charge *q*, the product of electric current and time, as a basic dimension. In unit symbols this would be A·s; in SPE mathematical symbols, *q*.

†When the mole is used, the elementary entities must be specified; they may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles. In petroleum work, the terms "kilogram mole," "pound mole," etc., often are shortened erroneously to "mole."

TABLE 1.2 — SI SUPPLEMENTARY UNITS*

Supplementary Quantity or "Dimension"	SI Unit	SI Unit Symbol ("Abbreviation"), Use Roman (Upright) Type	SPE Letter Symbol for Mathematical Equations, Use Italic (Sloping) Type
plane angle**	radian	rad	<i>θ</i>
solid angle**	steradian	sr	<i>Ω</i>

*The seven base units, two supplementary units, and other terms are defined in Appendixes A and B, Part 1.

**ISO specifies these two angles as dimensionless with respect to the seven base quantities.

TABLE 1.3 — SOME COMMON SI DERIVED UNITS

Quantity	Unit	SI Unit Symbol ("Abbreviation"), Use Roman Type	Formula, Use Roman Type
absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	...	m/s ²
activity (of radionuclides)	becquerel	Bq	1/s
angular acceleration	radian per second squared	...	rad/s ²
angular velocity	radian per second	...	rad/s
area	square meter	...	m ²
Celsius temperature	degree Celsius	°C	K
density	kilogram per cubic meter	...	kg/m ³
dose equivalent	sievert	Sv	J/kg
electric capacitance	farad	F	A·s/V (= C/V)
electric charge	coulomb	C	A·s
electrical conductance	siemens	S	A/V
electric field strength	volt per meter	...	V/m
electric inductance	henry	H	V·s/A (= Wb/A)
electric potential	volt	V	W/A
electric resistance	ohm	Ω	V/A
electromotive force	volt	V	W/A
energy	joule	J	N·m
entropy	joule per kelvin	...	J/K
force	newton	N	kg·m/s ²
frequency	hertz	Hz	1/s
illuminance	lux	lx	lm/m ²
luminance	candela per square meter	...	cd/m ²
luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	...	A/m
magnetic flux	weber	Wb	V·s
magnetic flux density	tesla	T	Wb/m ²
potential difference	volt	V	W/A
power	watt	W	J/s
pressure	pascal	Pa	N/m ²
quantity of electricity	coulomb	C	A·s
quantity of heat	joule	J	N·m
radiant flux	watt	W	J/s
radiant intensity	watt per steradian	...	W/sr
specific heat	joule per kilogram kelvin	...	J/(kg·K)
stress	pascal	Pa	N/m ²
thermal conductivity	watt per meter kelvin	...	W/(m·K)
velocity	meter per second	...	m/s
viscosity, dynamic	pascal second	...	Pa·s
viscosity, kinematic	square meter per second	...	m ² /s
voltage*	volt	V	W/A
volume*	cubic meter	...	m ³
wave number	1 per meter	...	1/m
work	joule	J	N·m

*In 1964, the General Conference on Weights and Measures adopted liter as a special name for the cubic decimeter but discouraged the use of liter for volume measurement of extreme precision (see Appendix B).

TABLE 1.4 — SI UNIT PREFIXES

Multiplication Factor	SI Prefix	SI Prefix Symbol, Use Roman Type	Pronunciation (U.S.)*	Meaning (U.S.)	Meaning In Other Countries
1 000 000 000 000 000 000 = 10 ¹⁸	exa**	E	ex' a (a as in a bout)	one quintillion times†	trillion
1 000 000 000 000 000 = 10 ¹⁵	peta**	P	as in p etal	one quadrillion times†	thousand billion
1 000 000 000 000 = 10 ¹²	tera	T	as in terra ce	one trillion times†	billion
1 000 000 000 = 10 ⁹	giga	G	jig' a (a as in a bout)	one billion times†	milliard
1 000 000 = 10 ⁶	mega	M	as in mega phone	one million times	
1 000 = 10 ³	kilo	k	as in kilo watt	one thousand times	
100 = 10 ²	hecto‡	h	heck' toe	one hundred times	
10 = 10	deka‡	da	deck' a (a as in a bout)	ten times	
0.1 = 10 ⁻¹	deci‡	d	as in deci mal	one tenth of	
0.01 = 10 ⁻²	centi‡	c	as in senti ment	one hundredth of	
0.001 = 10 ⁻³	milli	m	as in mili tary	one thousandth of	
0.000 001 = 10 ⁻⁶	micro	μ	as in micro phone	one millionth of	
0.000 000 001 = 10 ⁻⁹	nano	n	nan' oh (an as in an t)	one billionth of†	milliardth
0.000 000 000 001 = 10 ⁻¹²	pico	p	peek' oh	one trillionth of†	billionth
0.000 000 000 000 001 = 10 ⁻¹⁵	femto	f	fem' toe (fem as in fem inine)	one quadrillionth of†	thousand billionth
0.000 000 000 000 000 001 = 10 ⁻¹⁸	atto	a	as in anato my	one quintillionth of†	trillionth

*The first syllable of every prefix is accented to assure that the prefix will retain its identity. Therefore, the preferred pronunciation of kilometer places the accent on the first syllable, not the second.

**Approved by the 15th General Conference of Weights and Measures (CGPM), May-June 1975.

†These terms should be avoided in technical writing because the denominations above 1 million are different in most other countries, as indicated in the last column.

‡While hecto, deka, deci, and centi are SI prefixes, their use generally should be avoided except for the SI unit multiples for area, volume, moment, and nontechnical use of centimeter, as for body and clothing measurement.

one speaks of a person's weight, the quantity referred to is mass. Because of the dual use, the term weight should be avoided in technical practice except under circumstances in which its meaning is completely clear. When the term is used, it is important to know whether *mass* or *force* is intended and to use SI units properly as described above by using kilograms for mass and newtons for force.

Gravity is involved in determining mass with a balance or scale. When a standard mass is used to balance the measured mass, the effect of gravity on the two masses is canceled except for the indirect effect of air or fluid buoyancy. On a spring scale, mass is measured indirectly since the instrument responds to the force of gravity. Such scales may be calibrated in mass units if the variation in acceleration of gravity and buoyancy corrections are not significant in their use.

The use of the same name for units of force and mass causes confusion. When non-SI units are being converted to SI units, distinction should be made between *force* and *mass*—e.g., use lbf to denote force in gravimetric engineering units, and use lbm for mass.

Use of the metric ton, also called *tonne* (1.0 Mg), is common.

Linear Dimensions. Ref. 3 provides discussions of length units applied to linear dimensions and tolerances of materials and equipment, primarily of interest to engineers in that field.

Temperature. The SI temperature unit is the kelvin (not “degree Kelvin”); it is the preferred unit to express thermodynamic temperature. Degrees Celsius ($^{\circ}\text{C}$) is an SI derived unit used to express temperature and temperature intervals. The Celsius scale (formerly called centigrade) is related directly to the kelvin scale as follows: the temperature interval $1^{\circ}\text{C}=1\text{ K}$, exactly. Celsius temperature ($T_{^{\circ}\text{C}}$) is related to thermodynamic temperature (T_{K}) as follows: $T_{^{\circ}\text{C}}=T_{\text{K}}-T_0$ exactly, where $T_0=273.15\text{ K}$ by definition. Note that the SI unit symbol for the kelvin is K without the degree mark, whereas the older temperature units are known as degrees Fahrenheit, degrees Rankine, and degrees Celsius, with degree marks shown on the unit symbol ($^{\circ}\text{F}$, $^{\circ}\text{R}$, $^{\circ}\text{C}$).

Time. The SI unit for time is the second, and this is preferred, but use of the minute, hour, day, and year is permissible.

Angles. The SI unit for plane angle is the radian. The use of the arc degree and its decimal submultiples is permissible when the radian is not a convenient unit. Use of the minute and second is discouraged except possibly for cartography. Solid angles should be expressed in steradians.

Volume. The SI unit of volume is the cubic meter. This unit, or one of its regularly formed multiples, is preferred for all applications. The special name *liter* has been approved for the cubic decimeter (see Appendix B), but use of the liter is restricted to the measurement of liquids and gases.

Energy. The SI unit of energy, the joule, together with its multiples, is preferred for all applications. The kilowatt-hour is used widely as a measure of electric energy, but this unit should not be introduced into any new areas; eventually it should be replaced by the megajoule.

Torque and Bending Moment. The vector product of force and moment arm is expressed in newton meters ($\text{N}\cdot\text{m}$) by SPE as a convention when expressing torque energies.

Pressure and Stress. The SI unit for pressure and stress is the pascal (newton per square meter); with proper SI prefixes it is applicable to all such measurements. Use of the old metric gravitational units—kilogram-force per square centimeter, kilogram-force per square millimeter, torr, etc.—is to be discontinued. Use of the bar is discouraged by the standards organizations.

It has been recommended internationally that pressure units themselves should not be modified to indicate whether the pressure is “absolute” (above zero) or “gauge” (above atmospheric pressure). If the context leaves any doubt as to which is meant, the word “pressure” must be qualified appropriately: “...at a gauge pressure of 13 kPa,” or “...at an absolute pressure of 13 kPa,” etc.

Units and Names To Be Avoided or Abandoned

Tables 1.1 through 1.3 include all SI units identified by formal names, with their individual unit symbols. Virtually all other *named* metric units formerly in use (as well as nonmetric units) are to be avoided or abandoned. There is a long list of such units (e.g., dyne, stokes, “esu,” gauss, gilbert, abampere, statvolt, angstrom, fermi, micron, mho, candle, calorie, atmosphere, mm Hg, and metric horsepower). The reasons for abandoning the non-SI units are discussed in Appendix B. Two of the principal reasons are the relative simplicity and the coherence of the SI units.

Rules for Conversion and Rounding³

Conversion

Table 1.7, Appendix D, contains general conversion factors that give exact values or seven-digit accuracy for implementing these rules except where the nature of the dimension makes this impractical.

The conversion of quantities should be handled with careful regard to the implied correspondence between the accuracy of the data and the given number of digits. In all conversions, the number of significant digits retained should be such that accuracy is neither sacrificed nor exaggerated.

Proper conversion procedure is to multiply the specified quantity by the conversion factor exactly as given in Table 1.7 and then round to the appropriate number of significant digits. For example, to convert 11.4 ft to meters: $11.4 \times 0.3048 = 3.47472$, which rounds to 3.47 m.

Accuracy and Rounding

Do not round either the conversion factor or the quantity before performing the multiplication; this reduces ac-

curacy. Proper conversion procedure includes rounding the *converted* quantity to the proper number of significant digits commensurate with its intended precision. The practical aspects of measuring must be considered when using SI equivalents. If a scale divided into sixteenths of an inch was suitable for making the original measurements, a metric scale having divisions of 1 mm is obviously suitable for measuring in SI units, and the equivalents should not be reported closer than the nearest 1 mm. Similarly, a gauge or caliper graduated in divisions of 0.02 mm is comparable to one graduated in divisions of 0.001 in. Analogous situations exist for mass, force, and other measurements. A technique to determine the proper number of significant digits in rounding converted values is described here for general use.

General Conversion. This approach depends on first establishing the intended precision or accuracy of the quantity as a necessary guide to the number of digits to retain. The precision should relate to the number of digits in the original, but in many cases that is not a reliable indicator. A figure of 1.1875 may be a very accurate decimalization of a noncritical $1\frac{3}{8}$ that should have been expressed as 1.19. On the other hand, the value 2 may mean "about 2" or it may mean a very accurate value of 2, which should then have been written as 2.0000. It is therefore necessary to determine the intended precision of a quantity before converting. *This estimate of intended precision should never be smaller than the accuracy of measurement but usually should be smaller than one-tenth the tolerance if one exists.* After the precision of the dimension is estimated, the converted dimension should be rounded to a minimum number of significant digits (see section on Significant Digits) such that a unit of the last place is equal to or smaller than the converted precision.

Examples

1. A stirring rod 6 in. long: In this case, precision is estimated to be about $\frac{1}{2}$ in. ($\pm \frac{1}{4}$ in.). Converted, $\frac{1}{2}$ in. is 12.7 mm. The converted 6-in. dimension of 152.4 mm should be rounded to the nearest 10 mm, or 150 mm.

2. 50,000-psi tensile strength: In this case, precision is estimated to be about ± 200 psi (± 1.4 MPa) based on an accuracy of $\pm 0.25\%$ for the tension tester and other factors. Therefore, the converted dimension, 344.7379 MPa, should be rounded to the nearest whole unit, 345 MPa.

3. Test pressure 200 ± 15 psi: Since one-tenth of the tolerance is ± 1.5 psi (10.34 kPa), the converted dimension should be rounded to the nearest 10 kPa. Thus, 1378.9514 ± 103.421 kPa becomes 1380 ± 100 kPa.

Special Cases. Converted values should be rounded to the minimum number of significant digits that will maintain the required accuracy. In certain cases, deviation from this practice to use convenient or whole numbers may be feasible. In that case, the word "approximate" must be used following the conversion—e.g., $1\frac{1}{8}$ in. = 47.625 mm exact, 47.6 mm normal rounding, 47.5 mm (approximate) rounded to preferred or convenient half-millimeter, 48 mm (approximate) rounded to whole number.

A quantity stated as a limit, such as "not more than"

or "maximum," must be handled so that the stated limit is not violated. For example, a specimen "at least 4 in. wide" requires a width of at least 101.6 mm, or (rounded) at least 102 mm.

Significant Digits. Any digit that is necessary to define the specific value or quantity is said to be significant. For example, a distance measured to the nearest 1 m may have been recorded as 157 m; this number has three significant digits. If the measurement had been made to the nearest 0.1 m, the distance may have been 157.4 m—four significant digits. In each case, the value of the right-hand digit was determined by measuring the value of an additional digit and then rounding to the desired degree of accuracy. In other words, 157.4 was rounded to 157; in the second case, the measurement may have been 157.36, rounded to 157.4.

Importance of Zeros. Zeros may be used either to indicate a specific value, as does any other digit, or to indicate the magnitude of a number. The 1970 U.S. population figure rounded to thousands was 203 185 000. The six left-hand digits of this number are significant; each *measures* a value. The three right-hand digits are zeros that merely indicate the *magnitude* of the number rounded to the nearest thousand. To illustrate further, each of the following estimates and measurements is of different magnitude, but each is specified to have only one significant digit:

1 000
100
10
0.01
0.001
0.000 1.

It is also important to note that, for the first three numbers, the identification of significant digits is possible only through knowledge of the circumstances. For example, the number 1000 may have been rounded from about 965, or it may have been rounded from 999.7, in which case all three zeros are significant.

Data of Varying Precision. Occasionally, data required for an investigation must be drawn from a variety of sources where they have been recorded with varying degrees of refinement. Specific rules must be observed when such data are to be *added, subtracted, multiplied, or divided*.

The rule for addition and subtraction is that the *answer* shall contain no significant digits farther to the right than occurs in the least precise number. Consider the addition of three numbers drawn from three sources, the first of which reported data in millions, the second in thousands, and the third in units:

163 000 000
217 885 000
96 432 768
477 317 768

This total indicates a precision that is not valid. The numbers should *first* be rounded to *one significant digit*

farther to the right than that of the least precise number, and the sum taken as follows.

$$\begin{array}{r} 163\,000\,000 \\ 217\,900\,000 \\ \hline 96\,400\,000 \\ 477\,300\,000 \end{array}$$

Then, the total is rounded to 477 000 000 as called for by the rule. Note that if the second of the figures to be added had been 217 985 000, the rounding before addition would have produced 218 000 000, in which case the zero following 218 would have been a significant digit.

The rule for multiplication and division is that the *product* or *quotient* shall contain no more significant digits than are contained in the number with the *fewest significant digits* used in the multiplication or division. The difference between this rule and the rule for addition and subtraction should be noted; for addition and subtraction, the rule merely requires rounding digits to the right of the last significant digit in the least precise number. The following illustration highlights this difference.

Multiplication:	$113.2 \times 1.43 = 161.876$ rounded to 162.
Division:	$113.2 \div 1.43 = 79.16$ rounded to 79.2
Addition:	$113.2 + 1.43 = 114.63$ rounded to 114.6
Subtraction:	$113.2 - 1.43 = 111.77$ rounded to 111.8.

The above product and quotient are limited to three significant digits because 1.43 contains only three significant digits. In contrast, the rounded answers in the addition and subtraction examples contain four significant digits.

Numbers used in the illustration are all estimates or measurements. *Numbers that are exact counts (and conversion factors that are exact) are treated as though they consist of an infinite number of significant digits.* Stated more simply, when a *count* is used in computation with a measurement, the number of significant digits in the answer is the same as the number of significant digits in the measurement. If a count of 40 is multiplied by a measurement of 10.2, the product is 408. However, if 40 were an estimate accurate only to the nearest 10 and, hence, contained one significant digit, the product would be 400.

Rounding Values¹⁰

When a figure is to be rounded to fewer digits than the total number available, the procedure should be as follows.

When the First Digit Discarded is	The Last Digit Retained is
less than 5	unchanged
more than 5	increased by 1
5 followed only by zeros*	unchanged if even, increased by 1 if odd

*Unless a number of rounded values are to appear in a given problem, most roundings conform to the first two procedures — i.e., rounding upward when the first digit discarded is 5 or higher.

Examples:

4.463 25 if rounded to three places would be 4.463.
8.376 52 if rounded to three places would be 8.377.
4.365 00 if rounded to two places would be 4.36.
4.355 00 if rounded to two places would be 4.36.

Conversion of Linear Dimensions of Interchangeable Parts

Detailed discussions of this subject are provided by ASTM,³ API,⁴ and ASME⁷ publications and are recommended to the interested reader.

Other Units

Temperature. General guidance for converting tolerances from degrees Fahrenheit to kelvins or degrees Celsius is given in Table 1.5. Normally, temperatures expressed in a whole number of degrees Fahrenheit should be converted to the nearest 0.5 K (or 0.5°C). As with other quantities, the number of significant digits to retain will depend on implied accuracy of the original dimension; e.g.,*

$100 \pm 5^\circ\text{F}$ (tolerance); implied accuracy, estimated total 2°F (nearest 1°C) $37.7778 \pm 2.7778^\circ\text{C}$ rounds to $38 \pm 3^\circ\text{C}$.

$1,000 \pm 50^\circ\text{F}$ (tolerance); implied accuracy, estimated total 20°F (nearest 10°C) $537.7778 \pm 27.7778^\circ\text{C}$ rounds to $540 \pm 30^\circ\text{C}$.

Pressure or Stress. Pressure or stress values may be converted by the same principle used for other quantities. Values with an uncertainty of more than 2% may be converted without rounding by the approximate factor:

$$1 \text{ psi} = 7 \text{ kPa.}$$

For conversion factors see Table 1.7.

Special Length Unit—the Vara. Table 1.8, Appendix E, provides conversion factors and explanatory notes on the problems of converting the several kinds of vara units to meters.

Special Terms and Quantities Involving Mass and Amount of Substance

The Intl. Union of Pure and Applied Chemistry, the Intl. Union of Pure and Applied Physics, and the Intl.

TABLE 1.5 — CONVERSION OF TEMPERATURE TOLERANCE REQUIREMENTS

Tolerance (°F)	Tolerance (K or °C)
± 1	± 0.5
± 2	± 1
± 5	± 3
± 10	± 5.5
± 15	± 8.5
± 20	± 11
± 25	± 14

Organization for Standardization provide clarifying usages for some of the terms involving the base quantities "mass" and "amount of substance." Two of these require modifying the terminology appearing previously in SPE's Symbols Standards.

Table 1.6 shows the old and the revised usages.

Mental Guides for Using Metric Units

Table 1.9, Appendix F, is offered as a "memory jogger" or guide to help locate the "metric ballpark" relative to customary units. Table 1.9 is *not* a conversion table. For accurate conversions, refer to Table 1.7, or to Tables 2.2 and 2.3 for petroleum-industry units, and round off the converted values to practical precision as described earlier.

Terminology

To ensure consistently reliable conversion and rounding practices, a clear understanding of the related nontechnical terms is prerequisite. Accordingly, certain terms used in this standard are defined as follows.

Accuracy (as distinguished from precision). The degree of conformity of a measured or calculated value to some recognized standard or specified value. This concept involves the systematic error of an operation, which is seldom negligible.

Approximate. A value that is nearly but not exactly correct or accurate.

Coherence. A characteristic of a coherent system of units, as described in Appendix B, such that the product or quotient of any two unit quantities is the unit of the

*For information on any of these references, contact the Book Order Dept. at SPE headquarters.

TABLE 1.6 — SPECIAL TERMS AND QUANTITIES INVOLVING MASS AND AMOUNT OF SUBSTANCE

Old Usage		Standardized Usage	
Term	Dimensions (ISO Symbols, See Table 1.1)	Term	SI Unit Symbol
atomic weight (SPE Symbols Standard)	M	mass of atom	kg
atomic weight (elsewhere)	*	relative atomic mass	*
equivalent	—	mole	mol
mass of molecule	M	molecular mass	kg
molar	—	molar (means, "divided by amount of substance")	1/mol
molarity	—	concentration	mol/m ³
molecular weight (SPE Symbols Standard)	M	molar mass	kg/mol
molecular weight (elsewhere)	*	relative molecular mass	*
normal — obsolete			

*Dimensionless

resulting quantity. The SI base units, supplementary units, and derived units form a coherent set.

Deviation. Variation from a specified dimension or design requirement, usually defining upper and lower limits (see also **Tolerance**).

Digit. One of the 10 Arabic numerals (0 to 9).

Dimension(s). Two meanings: (1) A group of fundamental (physical) quantities, arbitrarily selected, in terms of which all other quantities can be measured or identified.⁹ Dimensions identify the physical nature of, or the basic components making up, a physical quantity. They are the bases for the formation of useful dimensionless groups and dimensionless numbers and for the powerful tool of dimensional analysis. The dimensions for the arbitrarily selected base units of the SI are length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity. SI has two supplementary quantities considered dimensionless—plane angle and solid angle. (2) A geometric element in a design, such as length and angle, or the magnitude of such a quantity.

Figure (numerical). An arithmetic value expressed by one or more digits or a fraction.

Nominal Value. A value assigned for the purpose of convenient designation; a value existing in name only.

Precision (as distinguished from accuracy). The degree of mutual agreement between individual measurements (repeatability and reproducibility).

Quantity. A concept used for qualitative and quantitative descriptions of a physical phenomenon.⁹

Significant Digit. Any digit that is necessary to define a value or quantity (see text discussion).

Tolerance. The total range of variation (usually bilateral) permitted for a size, position, or other required quantity; the upper and lower limits between which a dimension must be held.

U.S. Customary Units. Units based on the foot and the pound, commonly used in the U.S. and defined by the Natl. Bureau of Standards.¹¹ Some of these units have the same name as similar units in the U.K. (British, English, or U.K. units) but are not necessarily equal to them.

APPENDIX B³

SI Units

Advantages of SI Units

SI is a rationalized selection of units from the metric system that individually are not new. They include a unit of force (the newton), which was introduced in place of the kilogram-force to indicate by its name that it is a unit of force and not of mass. SI is a coherent system with seven base units for which names, symbols, and precise definitions have been established. Many derived units are defined in terms of the base units, with symbols

assigned to each; in some cases, special names and unit symbols are given—e.g., the newton (N).

One Unit per Quantity. The great advantage of SI is that there is one, and only one, unit for each physical quantity—the meter for length (L), kilogram (instead of gram) for mass (m), second for time (t), etc. From these elemental units, units for all other mechanical quantities are derived. These derived units are defined by simple equations among the quantities, such as $v=dL/dt$ (velocity), $a=dv/dt$ (acceleration), $F=ma$ (force), $W=FL$ (work or energy), and $P=W/t$ (power). Some of these units have only generic names, such as meter per second for velocity; others have special names and symbols, such as newton (N) for force, joule (J) for work or energy, and watt (W) for power. *The SI units for force, energy, and power are the same regardless of whether the process is mechanical, electrical, chemical, or nuclear.* A force of 1 N applied for a distance of 1 m can produce 1 J of heat, which is identical with what 1 W of electric power can produce in 1 second.

Unique Unit Symbols. Corresponding to the SI advantages of a unique unit for each physical quantity are the advantages resulting from the use of a unique and well-defined set of symbols. Such symbols eliminate the confusion that can arise from current practices in different disciplines, such as the use of “b” for both the *bar* (a unit of pressure) and *barn* (a unit of area).

Decimal Relation. Another advantage of SI is its retention of the decimal relation between multiples and sub-multiples of the base units for each physical quantity. Prefixes are established for designating multiple and sub-multiple units from “exa” (10^{18}) down to “atto” (10^{-18}) for convenience in writing and speaking.

Coherence. Another major advantage of SI is its coherence. This system of units has been chosen in such a way that the equations between numerical values, including the numerical factors, have the same form as the corresponding equations between the quantities: this constitutes a “coherent” system. Equations between units of a coherent unit system contain as numerical factors only the number 1. In a coherent system, the product or quotient of any two unit quantities is the unit of the resulting quantity. For example, in any coherent system, unit area results when unit length is multiplied by unit length ($1\text{ m} \times 1\text{ m} = 1\text{ m}^2$), unit force when unit mass* is multiplied by unit acceleration ($1\text{ kg} \times 1\text{ m/s}^2 = 1\text{ N}$), unit work when unit force is multiplied by unit length ($1\text{ N} \times 1\text{ m} = 1\text{ J}$), and unit power when unit work is divided by unit time ($1\text{ J} \div 1\text{ second} = 1\text{ W}$). Thus, in a coherent system in which the meter is the unit of length, the square meter is the unit of area, but the are** and hectare are not coherent. Much worse disparities occur in systems of “customary units” (both nonmetric and older metric) that require many numerical adjustment factors in equations.

Base Units. Whatever the system of units, whether it be coherent or noncoherent, particular samples of some

*Note that the kilogram (not the gram) is the coherent SI unit of mass.

**The are is an old metric unit.

physical quantities must be selected arbitrarily as units of those quantities. The remaining units are defined by appropriate experiments related to the theoretical interrelations of all the quantities. For convenience of analysis, units pertaining to *certain base quantities are by convention regarded as dimensionally independent; these units are called base units* (Table 1.1), and all others (derived units) can be expressed algebraically in terms of the base units. In SI, the unit of mass, the kilogram, is defined as the mass of a prototype kilogram preserved by the Intl. Bureau of Weights and Measures (BIPM) in Paris. All other base units are defined in terms of reproducible phenomena—e.g., the wave lengths and frequencies of specified atomic transitions.

Non-SI Metric Units

Various other units are associated with SI but are not a part thereof. They are related to units of the system by powers of 10 and are used in specialized branches of physics. An example is the bar, a unit of pressure, approximately equivalent to 1 atm and exactly equal to 100 kPa. The bar is used extensively by meteorologists. Another such unit is the gal, equal exactly to an acceleration of 0.01 m/s^2 . It is used in geodetic work. These, however, are not coherent units—i.e., equations involving both these units and SI units cannot be written without a factor of proportionality even though that factor may be a simple power of 10.

Originally (1795), the liter was intended to be identical to the cubic decimeter. The Third General Conference on Weights and Measures (CGPM) in 1901 defined the liter as the volume occupied by the mass of 1 kilogram of pure water at its maximum density under normal atmospheric pressure. Careful determinations subsequently established the liter so defined as equivalent to $1.000\,028 \text{ dm}^3$. In 1964, the CGPM withdrew this definition of the liter and declared that "liter" was a special name for the cubic decimeter. Thus, its use is permitted in SI but is discouraged because it creates two units for the same quantity and its use in precision measurements might conflict with measurements recorded under the old definition.

SI Base Unit Definitions

Authorized translations of the original French definitions of the seven base and two supplementary units of SI follow³ (parenthetical items added).

"Meter (m)—The meter is the length equal to $1\,650\,763.73$ wavelengths in vacuum of the radiation corresponding to the transition between the levels $2p_{10}$ and $5d_5$ of the krypton-86 atom." (Adopted by 11th CGPM 1960.)

"Kilogram (kg)—The kilogram is the unit of mass (and is the coherent SI unit); it is equal to the mass of the international prototype of the kilogram." (Adopted by First and Third CGPM 1889 and 1901.)

"Second (s)—The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.*" (Adopted by 13th CGPM 1967.)

"Ampere (A)—The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section,

and placed one meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length." (Adopted by Ninth CGPM 1948.)

"Kelvin (K)—The kelvin, unit of thermodynamic temperature, is the fraction $1/273.15$ of the thermodynamic temperature of the triple point of water."³ (Adopted by 13th CGPM 1967.)

"Mole (mol)—The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilograms of carbon-12." (Adopted by 14th CGPM 1971.)

"Note—When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles."

"Candela (cd)—The candela is the luminous intensity in a given direction of a source that emits monochromatic radiation of frequency $540 (E + 12)$ hertz (Hz) and that has a radiant intensity in that direction of $1/683$ watt per steradian."

"Radian (rad)—The radian is the plane angle between two radii of a circle which cut off on the circumference an arc equal in length to the radius."

"Steradian (sr)—The steradian is the solid angle which, having its vertex at the center of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere."

Definitions of SI Derived Units Having Special Names³

Physical Quantity	Unit and Definition
Absorbed dose	The <i>gray</i> (Gy) is the absorbed dose when the energy per unit mass imparted to matter by ionizing radiation is 1 J/kg .
Activity	The <i>becquerel</i> (Bq) is the activity of a radionuclide decaying at the rate of one spontaneous nuclear transition per second.
Celsius temperature	The <i>degree Celsius</i> ($^{\circ}\text{C}$) is equal to the kelvin and is used in place of the kelvin for expressing Celsius temperature (symbol $T_{^{\circ}\text{C}}$) defined by $T_{^{\circ}\text{C}} = T_K - T_0$, where T_K is the thermodynamic temperature and $T_0 = 273.15 \text{ K}$ by definition.
Dose equivalent	The <i>sievert</i> is the dose equivalent when the absorbed dose of ionizing radiation multiplied by the dimensionless factors Q (quality factor) and N (product of any other multiplying factors) stipulated by the Intl. Commission on Radiological Protection is 1 J/kg .
Electric capacitance	The <i>farad</i> (F) is the capacitance of a capacitor between the plates of which there appears a difference of potential of 1 V when it is charged by a quantity of electricity equal to 1 C .

* This definition supersedes the ephemeris second as the unit of time

Electric conductance	The <i>siemens</i> (S) is the electric conductance of a conductor in which a current of 1 A is produced by an electric potential difference of 1 V.
Electric inductance	The <i>henry</i> (H) is the inductance of a closed circuit in which an electromotive force of 1 V is produced when the electric current in the circuit varies uniformly at a rate of 1 A/s.
Electric potential difference, electromotive force	The <i>volt</i> (V) is the difference of electric potential between two points of a conductor carrying a constant current of 1 A when the power dissipated between these points is equal to 1 W.
Electric resistance	The <i>ohm</i> (Ω) is the electric resistance between two points of a conductor when a constant difference of potential of 1 V, applied between these two points, produces in this conductor a current of 1 A, this conductor not being the source of any electromotive force.
Energy	The <i>joule</i> (J) is the work done when the point of application of a force of 1 N is displaced a distance of 1 m in the direction of the force.
Force	The <i>newton</i> (N) is that force that, when applied to a body having a mass of 1 kg, gives it an acceleration of 1 m/s ² .
Frequency	The <i>hertz</i> (Hz) is the frequency of a periodic phenomenon of which the period is 1 second.
Illuminance	The <i>lux</i> (lx) is the illuminance produced by a luminous flux of 1 lm uniformly distributed over a surface of 1 m ² .
Luminous flux	The <i>lumen</i> (lm) is the luminous flux emitted in a solid angle of 1 sr by a point source having a uniform intensity of 1 cd.
Magnetic flux	The <i>weber</i> (Wb) is the magnetic flux that, linking a circuit of one turn, produces in it an electromotive force of 1 V as it is reduced to zero at a uniform rate in 1 s.
Magnetic flux density magnetic induction	The <i>tesla</i> (T) is the magnetic flux density of 1 Wb/m ² . In an alternative approach to defining the magnetic field quantities the <i>tesla</i> may also be defined as the magnetic flux density that produces on a 1-m length of wire carrying a current of 1 A, oriented normal to the flux density, a force of 1 N, magnetic flux density being defined as an axial vector quantity such that

the force exerted on an element of current is equal to the vector product of this element and the magnetic flux density.

Power The *watt* (W) is the power that represents a rate of energy transfer of 1 J/s.

Pressure or stress The *pascal* (Pa) is the pressure or stress of 1 N/m².

Electric charge, quantity of electricity *Electric charge* is the time integral of electric current; its unit, the *coulomb* (C), is equal to 1 A·s.

No other SI derived units have been assigned special names at this time.

APPENDIX C^{3,8*}

Style Guide for Metric Usage

Rules for Writing Metric Quantities

Capitals. Units—Unit names, including prefixes, are not capitalized except at the beginning of a sentence or in titles. Note that for “degree Celsius” the word “degree” is lower case; the modifier “Celsius” is always capitalized. The “degree centigrade” is now obsolete.

Symbols—The short forms for metric units are called unit symbols. They are lower case except that the first letter is upper case when the unit is named for a person. (An exception to this rule in the U.S. is the symbol L for liter.)

Examples:	Unit Name	Unit Symbol
	meter**	m
	gram	g
	newton	N
	pascal	Pa

Printed unit symbols should have Roman (upright) letters, because italic (sloping or slanted) letters are reserved for quantity symbols, such as *m* for mass and *L* for length.

Prefix Symbols—All prefix names, their symbols, and pronunciation are listed in Table 1.4. Notice that the top five are upper case and all the rest lower case.

The importance of following the precise use of upper-case and lower-case letters is shown by the following examples of prefixes and units.

G for giga; g for gram.

K for kelvin; k for kilo.

M for mega; m for milli.

N for newton; n for nano.

T for tera; t for tonne (metric ton).

Information Processing—Limited Character Sets—Prefixes and unit symbols retain their prescribed forms regardless of the surrounding typography, except for systems with limited character sets. ISO has provided a standard¹² for such systems; this standard is recommended.

Plurals and Fractions. Names of SI units form their plurals in the usual manner, except for lux, hertz, and siemens.

* Ref. 8 is primary source.

** The spellings “metre” and “litre” are preferred by ISO but “meter” and “liter” are official U.S. government spellings.

Values less than one take the singular form of the unit name; for example, 0.5 kilogram or $\frac{1}{2}$ kilogram. While decimal notation (0.5, 0.35, 6.87) is generally preferred, the most simple fractions are acceptable, such as those where the denominator is 2, 3, 4, or 5.

Symbols of units are the same in singular and plural—e.g., 1 m and 100 m.

Periods. A period is *not* used after a symbol, except at the end of a sentence. Examples: "A current of 15 mA is found..." "The field measured 350×125 m."

The Decimal Marker. ISO specifies the comma as the decimal marker⁹; in English-language documents a dot on the line is acceptable. In numbers less than one, a zero should be written before the decimal sign (to prevent the possibility that a faint decimal sign will be overlooked). Example: The oral expression "point seven five" is written 0.75 or 0,75.

Grouping of Numbers. Separate digits into groups of three, counting from the decimal marker. A comma should not be used between the groups of three⁹; instead, a space is left to avoid confusion, since the comma is the ISO standard for the decimal marker.

In a four-digit number, the space is not required unless the four-digit number is in a column with numbers of five digits or more:

For	4,720,525	write	4 720 525
For	0.52875	write	0.528 75
For	6,875	write	6875 or 6 875
For	0.6875	write	0.6875 or 0.687 5

Spacing. In symbols or names for units having prefixes, no space is left between letters making up the symbol or the name. Examples are kA, kiloampere; and mg, milligram.

When a symbol follows a number to which it refers, a space must be left between the number and the symbol, except when the symbol (such as °) appears in the superscript position. Examples: 455 kHz, 22 mg, 20 mm, 10^6 N, 30 K, 20°C.

When a quantity is used as an adjective, a hyphen should be used between the number and the symbol (except °C). Examples: It is a 35-mm film; the film width is 35 mm. I bought a 6-kg turkey; the turkey weighs 6 kg.

Leave a space on each side of signs for multiplication, division, addition, and subtraction, except within a compound symbol. Examples: 4 cm \times 3 m (not 4 cm \times 3 m); kg/m³; N·m.

Powers. For unit *names*, use the modifier *squared* or *cubed* after the unit name (except for area and volume)—e.g., meter per second squared. For area or volume, place a modifier before the unit name, including derived units:—e.g., cubic meter and watt per square meter.

For unit *symbols*, write the symbol for the unit followed by the power superscript—e.g., 14 m² and 26 cm³.

Compound Units. For a unit name (not a symbol) derived as a quotient (e.g., for kilometers per hour), it is preferable not to use a slash (/) as a substitute for "per" except where space is limited and a symbol might not be understood. Avoid other mixtures of words and symbols. Examples: Use meter per second, not m/s. Use only one "per" in any combination of units—e.g., meter per second squared, not meter per second per second.

For a unit symbol derived as a quotient do not, for example, write k.p.h. or kph for km/h because the first two are understood only in the English language, whereas km/h is used in all languages. The symbol km/h also can be written with a negative exponent—e.g., km·h⁻¹.

Never use more than one slash (/) in any combination of symbols unless parentheses are used to avoid ambiguity; examples are m/s², not m/s/s; W/(m·K), not W/m/K.

For a unit *name* derived as a product, a space or a hyphen is recommended but never a "product dot" (a period raised to a centered position)—e.g., write newton meter or newton-meter, not newton·meter. In the case of the watt hour, the space may be omitted—watt-hour.

For a unit *symbol* derived as a product, use a product dot—e.g., N·m. For computer printouts, automatic typewriter work, etc., a dot on the line may be used. Do not use the product dot as a multiplier symbol for calculations—e.g., use 6.2×5 , not $6.2 \cdot 5$.

Do not mix nonmetric units with metric units, except those for time, plane angle, or rotation—e.g., use kg/m³, not kg/ft³ or kg/gal.

A quantity that constitutes a ratio of two like quantities should be expressed as a fraction (either common or decimal) or as a percentage—e.g., the slope is 1/100 or 0.01 or 1%, not 10 mm/m or 10 m/km.

SI Prefix Usage. General—SI prefixes should be used to indicate orders of magnitude, thus eliminating non-significant digits and leading zeros in decimal fractions and providing a convenient alternative to the powers-of-10 notation preferred in computation. For example, 12 300 m (in computations) becomes 12.3 km (in non-computation situations); $0.0123 \mu\text{A}$ (12.3×10^{-9} A for computations) becomes 12.3 nA (in noncomputation situations).

Selection—When expressing a quantity by a numerical value and a unit, prefixes should be chosen so that the numerical value lies between 0.1 and 1000. Generally, prefixes representing steps of 1000 are recommended (avoiding hecto, deka, deci, and centi). However, some situations may justify deviation from the above:

1. In expressing units raised to powers (such as area, volume and moment) the prefixes hecto, deka, deci, and centi may be required—e.g., cubic centimeter for volume and cm⁴ for moment.

2. In tables of values of the same quantity, or in a discussion of such values within a given context, it generally is preferable to use the same unit multiple throughout.

3. For certain quantities in particular applications, one certain multiple is used customarily; an example is the millimeter in mechanical engineering drawings, even when the values lie far outside the range of 0.1 to 1000 mm.

Powers of Units—An exponent attached to a symbol

containing a prefix indicates that *the multiple or sub-multiple of the unit* (the unit with its prefix) *is raised to the power expressed by the exponent*. For example,

$$\begin{array}{lll} 1 \text{ cm}^3 & = (10^{-2} \text{ m})^3 & = 10^{-6} \text{ m}^3 \\ 1 \text{ ns}^{-1} & = (10^{-9} \text{ s})^{-1} & = 10^9 \text{ s}^{-1} \\ 1 \text{ mm}^2/\text{s} & = (10^{-3} \text{ m})^2/\text{s} & = 10^{-5} \text{ m}^2/\text{s} \end{array}$$

Double Prefixes—Double or multiple prefixes should not be used. For example,

use GW (gigawatt), not kMW;
use pm (picometer), not $\mu\mu\text{m}$;
use Gg (gigagram), not Mkg;
use 13.58 m, not 13 m 580 mm.

Prefix Mixtures—Do not use a mixture of prefixes unless the difference in size is extreme. For example, use 40 mm wide and 1500 mm long, not 40 mm wide and 1.5 m long; however, 1500 m of 2-mm-diameter wire is acceptable.

Compound Units—It is *preferable* that prefixes not be used in the denominators of complex units, except for kilogram (kg) which is a base unit. However, there are cases where the use of such prefixes is necessary to obtain a numerical value of convenient size. Examples of some of these rare exceptions are shown in the tables contained in these standards.

Prefixes may be applied to the numerator of a compound unit; thus, megagram per cubic meter (Mg/m^3), but *not* kilogram per cubic decimeter (kg/dm^3) *nor* gram per cubic centimeter (g/cm^3). Values required outside the range of the prefixes should be expressed by powers of 10 applied to the base unit.

Unit of Mass—Among the base units of SI, the kilogram is the only one whose name, for historical reasons, contains a prefix; it is also the coherent SI unit for mass (See Appendices A and B for discussions of coherence.) However, names of decimal multiples and submultiples of the unit of mass are formed by attaching prefixes to the word “gram.”

Prefixes Alone—Do not use a prefix without a unit—e.g., use kilogram, not kilo.

Calculations—Errors in calculations can be minimized if, instead of using prefixes, the *base* and the *coherent* derived SI units are used, expressing numerical values in powers-of-10 notation—e.g., $1 \text{ MJ} = 10^6 \text{ J}$.

Spelling of Vowel Pairs. There are three cases where the final vowel in a prefix is omitted: megohm, kilohm, and hectare. In all other cases, both vowels are retained and both are pronounced. No space or hyphen should be used.

Complicated Expressions. To avoid ambiguity in complicated expressions, symbols are preferred over words.

Attachment. Attachment of letters to a unit symbol for giving information about the nature of the quantity is incorrect: MWe for “megawatts electrical (power),” kPag for “kilopascals gauge (pressure),” Paa for “pascals absolute (pressure),” and Vac for “volts ac” are not acceptable. If the context is in doubt on any units used, supplementary descriptive phrases should be added to making the meanings clear.

Equations. When customary units appear in equations, the SI equivalents should be omitted. Instead of inserting the latter in parentheses, as in the case of text or small tables, the equations should be restated using SI unit symbols, or a sentence, paragraph, or note should be added stating the factor to be used to convert the calculated result in customary units to the preferred SI units.

Pronunciation of Metric Terms

The pronunciation of most of the unit names is well known and uniformly described in U.S. dictionaries, but four have been pronounced in various ways. The following pronunciations are recommended:

candela	— Accent on the second syllable and pronounce it like <i>dell</i> .
joule	— Pronounce it to rhyme with <i>pool</i> .
pascal	— The preferred pronunciation rhymes with <i>rascal</i> . An acceptable second choice puts the accent on the second syllable.
siemens	— Pronounce it like <i>seamen</i> 's.

For pronunciation of unit prefixes, see Table 1.4.

Typewriting Recommendations

Superscripts. The question arises of how numerical superscripts should be typed on a machine with a conventional keyboard. With an ordinary keyboard, numerals and the minus sign can be raised to the superscript position by rolling the platen half a space before typing the numeral, using care to avoid interference with the text in the line above.

Special Characters. For technical work, it is useful to have Greek letters available on the typewriter. If all SI symbols for units are to be typed properly, a key with the upright Greek lower-case μ (pronounced “mew,” not “moo”) is necessary, since this is the symbol for micro, meaning one millionth. The symbol can be approximated on a conventional machine by using a lower-case u and adding the tail by hand (μ). A third choice is to spell out the unit name in full.

For units of electricity, the Greek upper-case omega (Ω) for ohm also will be useful; when it is not available, the word “ohm” can be spelled out.

It is fortunate that, except for the more extensive use of the Greek μ for micro and Ω for ohm, the change to SI units causes no additional difficulty in manuscript preparation.

The Letter for Liter. On most U.S. typewriters, there is little difference between the lower-case “el” (“l”) and the numerical “one” (“1”). The European symbol for liter is a simple upright bar; the Canadians¹³ used a script *ℓ* but now have adopted the upright capital L; AN-SI now recommends the upright capital L.

Typewriter Modification. Where frequently used, the following symbols could be included on typewriters: superscripts ² and ³ for squared and cubed; Greek μ for micro; ° for degree; · for a product dot (not a period) for symbols derived as a product; and Greek Ω for ohm.

A special type-ball that contains all the superscripts, μ , Ω , and other characters used in technical reports is available for some typewriters. Some machines have replaceable character keys.

Longhand. To assure legibility of the symbols m, n, and μ , it is recommended that these three symbols be written to resemble printing. For example, write nm, not $n\mu$. The symbol μ should have a long distinct tail and should have the upright form (not sloping or italic).

Shorthand. Stenographers will find that the SI symbols generally are quicker to write than the shorthand forms for the unit names.

APPENDIX D

General Conversion Factors*

General

Table 1.7 is intended to serve two purposes:

1. To express the definitions of general units of measure as exact numerical multiples of coherent "metric" units. Relationships that are exact in terms of the fundamental SI unit are followed by an asterisk. Relationships that are not followed by an asterisk either are the result of physical measurements or are only approximate.

2. To provide multiplying factors for converting expressions of measurements given by numbers and general or miscellaneous units to corresponding new numbers and metric units.

Notation

Conversion factors are presented for ready adaptation to computer readout and electronic data transmission. The factors are written as a number equal to or greater than one and less than 10, with six or fewer decimal places (i.e., seven or fewer total digits). Each number is followed by the letter E (for exponent), a plus or minus symbol, and two digits that indicate the power of 10 by which the number must be multiplied to obtain the correct value. For example,

$$3.523\ 907\ (E-02) \text{ is } 3.523\ 907 \times 10^{-2}$$

or

$$0.035\ 239\ 07.$$

Similarly,

$$3.386\ 389\ (E+03) \text{ is } 3.386\ 389 \times 10^3$$

or

$$3\ 386.389.$$

An asterisk (*) after the numbers shown indicates that the conversion factor is exact and that all subsequent digits (for rounding purposes) are zero. All other conversion factors have been rounded to the figures given in accordance with procedures outlined in the preceding text.

Where fewer than six decimal places are shown, more precision is not warranted.

The following is a further example of the use of Table 1.7.

To Convert From	To	Multiply By
pound-force per square foot	Pa	4.788 026 E+01
pound-force per square inch	Pa	6.894 757 E+03
inch	m	2.540* E-02

These conversions mean that

1 lbf/ft² becomes 47.880 26 Pa,
 1 lbf/in.² becomes 6894.757 Pa or
 6.894 757 kPa, and
 1 inch becomes 0.0254 m (exactly).

The unit symbol for pound-force sometimes is written lbf and sometimes lb_f or lb_f; the form lbf is recommended.

Organization

The conversion factors generally are listed alphabetically by units having specific names and compound units derived from these specific units. A number of units starting with the pound symbol (lb) are located in the "p" section of the list.

Conversion factors classified by physical quantities are listed in Refs. 3 and 4.

The conversion factors for other compound units can be generated easily from numbers given in the alphabetical list by substitution of converted units. Two examples follow.

1. Find the conversion factor for productivity index, (B/D)/psi to (m³/d)/Pa. Convert 1 B/D to 1.589 873 (E-01) m³/d and 1 psi to 6.894 757 (E+03) Pa. Then, substitute

$$\begin{aligned} & [1.589\ 873\ (E-01)]/[6.894\ 757\ (E+03)] \\ & = 2.305\ 916\ (E-05)\ (m^3/d)/Pa. \end{aligned}$$

2. Find the conversion factor for tonf·mile/ft to MJ/m. Convert 1 tonf to 8.896 444 (E+03) N; 1 mile to 1.609 344* (E+03) m; and 1 ft to 3.048* (E-01) m. Then, substitute

$$\begin{aligned} & [8.896\ 444\ (E+03)] [1.609\ 344\ (E+03)] \\ & \div [3.048\ (E-01)] \\ & = 4.697\ 322\ (E+07)\ (N \cdot m)/m \text{ or } J/m \\ & = 4.697\ 322\ (E+01)\ MJ/m. \end{aligned}$$

When conversion factors for complex compound units are being calculated from Table 1.7, numerical uncertainties may be present in the seventh (or lesser last "significant") digit of the answer because of roundings already taken for the last digit of tabulated values. Mechtly¹⁵ provides conversion factors of more than seven digits for certain quantities.

*Based on ASTM Pub. E380-82 (Ref. 3), values of conversion factors tabulated herewith are identical with those in E380-82; generally similar material is found in Ref. 4. Conversion values in earlier editions of E 380 (for example, E 380-74) are based on Ref. 15, which has available some factors with more than seven digits.

Btu (thermochemical)/(lbm-°F) (heat capacity)	joule per kilogram kelvin [J/(kg·K)]	4.184 000	E + 03

⁽¹⁾Since 1893 the U.S. basis of length measurement has been derived from metric standards. In 1959 a small refinement was made in the definition of the yard to resolve discrepancies both in this country and abroad, which changed its length from 3600/3937 m to 0.9144 m exactly. This resulted in the new value being shorter by two parts in a million. At the same time it was decided that any data in feet derived from and published as a result of geodetic surveys within the U.S. would remain with the old standard (1 ft = 1200/3937 m) until further decision. This foot is named the U.S. survey foot. As a result, all U.S. land measurements in U.S. customary units will relate to the meter by the old standard. All the conversion factors in these tables for units referenced to this footnote are based on the U.S. survey foot, rather than the international foot. Conversion factors for the land measure given below may be determined from the following relationships:

1 league = 3 miles (exactly)
 1 rod = 16 1/2 ft (exactly)
 1 chain = 66 ft (exactly)
 1 section = 1 sq mile
 1 township = 36 sq miles

⁽²⁾This value was adopted in 1956. Some of the older International Tables use the value 1.055 04 E + 03. The exact conversion factor is 1.055 055 852 62* E + 03.

perm (°C) ⁽⁶⁾	kilogram per pascal second meter ² [kg/(Pa·s·m ²)]	5.721 35 E − 11

⁽⁵⁾In 1964 the General Conference on Weights and Measures adopted the name liter as a special name for the cubic decimeter. Before this decision the liter differed slightly (previous value, 1.000 028 dm³) and in expression of precision volume measurement this fact must be kept in mind.

⁽⁶⁾Not the same as reservoir "perm."

APPENDIX F

Part 2: Discussion of Metric Unit Standards*

Introduction

The standards and conventions shown in Part 1 are part of the SPE tentative standards. Table 2.1 presents nomenclature for Tables 2.2 and 2.3. Table 2.2 is a modified form of a table in API 2564 reflecting SPE recommendations. Table 2.3 shows a few units commonly used in the petroleum industry that are not shown in Table 1.7 and 2.2. The columns in these tables are based on the following.

Quantity and SI Unit. The quantity and the base or derived SI unit that describes that quantity.

Customary Unit. The unit most commonly used in expressing the quantity in English units.

SPE Preferred. The base or derived SI unit plus the approved prefix, if any, that probably will be used most

commonly to achieve convenient unit size. Any approved prefix may be used in combination with an approved SI unit without violation of these standards except where otherwise noted.

Other Allowable. A small, selected list of non SI units that are approved *temporarily* for the convenience of the English-metric transition. Use of the allowable units may be discouraged but is not prohibited. Any traditional, non-SI unit not shown is prohibited under these standards.

Conversion Factor. For certain commonly used units, a conversion factor is shown. The primary purpose in these tables is to show how the *preferred metric unit* compares in size with the *traditional unit*. An effort has been made to keep the unit sizes comparable to minimize transition difficulties.

*Prepared by John M. Campbell for the subcommittee.

A detailed summary of general conversion factors is included as Table 1.7 in Part 1 of this report.

The notation for conversion factors in Tables 2.2 and 2.3 is explained in the introduction to Table 1.7.

Fig. 2.1 shows graphically how SI units are related in a very coherent manner. Although it may not be readily apparent, this internal coherence is a primary reason for adoption of the metric system of units.

The SPE Metrication Subcommittee is endeavoring to provide SPE members with all information needed on the International System of Units and to provide tentative standards (compatible with SI coherence, decimal, and other principles) for the application of the SI system to SPE fields of interest. The tentative SPE standards are intended to reflect reasonable input from many sources, and we solicit your positive input with the assurance that all ideas will receive careful consideration.

Review of Selected Units

Certain of the quantities and units shown in Tables 2.2 and 2.3 may require clarification of usage (see also the notes preceding Tables 2.2 and 2.3).

Time

Although second(s) is the base time unit, any unit of time may be used — minute (min), hour (h), day (d), and year

(a). Note that (a) is used as the abbreviation for year (annum) instead of (yr). The use of the minute as a time unit is discouraged because of abbreviation problems. It should be used only when another time unit is absolutely inappropriate.

Date and Time Designation

The Subcommittee proposes to recommend a standard date and time designation to the American Natl. Standards Inst., as shown below. This form already has been introduced in Canada.

76 — 10 — 03 — 16 : 24 : 14
year month day hour minute second
(76-10-03-16:24:14)

The sequence is orderly and easy to remember; only needed portions of the sequence would be used — most documents would use the first three. No recommendation has been made for distinguishing the century, such as 1976 vs. 1876 vs. 2076.

Area

The hectare (ha) is allowable but its use should be confined to large areas that describe the areal extent of a por-

TABLE 2.1—NOMENCLATURE FOR TABLES 2.2 AND 2.3

Unit Symbol	Name	Quantity	Type of Unit
A	ampere	electric current	base SI unit
a	annum (year)	time	allowable (not official SI) unit
Bq	becquerel	activity (of radionuclides)	derived SI unit = 1/s
bar	bar	pressure	allowable (not official SI) unit, = 10^5 Pa
C	coulomb	quantity of electricity	derived SI unit, = 1 A·s
cd	candela	luminous intensity	base SI unit
°C	degree Celsius	temperature	derived SI unit = 1.0 K
°	degree	plane angle	allowable (not official SI) unit
d	day	time	allowable (not official SI) unit, = 24 hours
F	farad	electric capacitance	derived SI unit, = 1 A·s/V
Gy	gray	absorbed dose	derived SI unit, = J/kg
g	gram	mass	allowable (not official SI) unit, = 10^{-3} kg
H	henry	inductance	derived SI unit, = 1 V·s/A
h	hour	time	allowable (not official SI) unit, = 3.6×10^3 s
Hz	hertz	frequency	derived SI unit, = 1 cycle/s
ha	hectare	area	allowable (not official SI) unit, = 10^4 m ²
J	joule	work, energy	derived SI unit, = 1 N·m
K	kelvin	temperature	base SI unit
kg	kilogram	mass	base SI unit
kn	knot	velocity	allowable (not official SI) unit, = $5.144\,444 \times 10^{-1}$ m/s = 1.852 km/h
L	liter	volume	allowable (not official SI) unit, = 1 dm ³
lm	lumen	luminous flux	derived SI unit, = 1 cd·sr
lx	lux	illuminance	derived SI unit, = 1 lm/m ²
m	meter	length	base SI unit
min	minute	time	allowable (not official SI) unit
'	minute	plane angle	Allowable cartography (not official SI) unit
N	newton	force	derived SI unit, = 1 kg·m/s ²
naut. mile	U.S. nautical mile	length	allowable (not official SI) unit, = 1.852×10^3 m
Ω	ohm	electric resistance	derived SI unit, = 1 V/A
Pa	pascal	pressure	derived SI unit, = 1 N/m ²
rad	radian	plane angle	supplementary SI unit
S	siemens	electrical conductance	derived SI unit, = 1 A/V
s	second	time	base SI unit
"	second	plane angle	allowable cartography (not official SI) unit
sr	steradian	solid angle	supplementary SI unit
T	tesla	magnetic flux density	derived SI unit, = 1 Wb/m ²
t	tonne	mass	allowable (not official SI) unit, = 10^3 kg = 1 Mg
V	volt	electric potential	derived SI unit, = 1 W/A
W	watt	power	derived SI unit, = 1 J/s
Wb	weber	magnetic flux	derived SI unit, = 1 V·s

tion of the earth's crust (normally replacing the acre or section).

Volume

The liter is an allowable unit for small volumes only. It should be used for volumes not exceeding 100 L. Above this volume (or volume rate), cubic meters should be used. The only two prefixes allowed with the liter are "milli" and "micro."

In the U.S., the "-er" ending for meter and liter is official. The official symbol for the liter is "L." In other countries the symbol may be written as "ℓ" and spelled out with the "-re" ending (metre, litre). Since SPE is international, it is expected that members will use local conventions.

Notice that "API barrel" or simply "barrel" disappears as an allowable volume term.

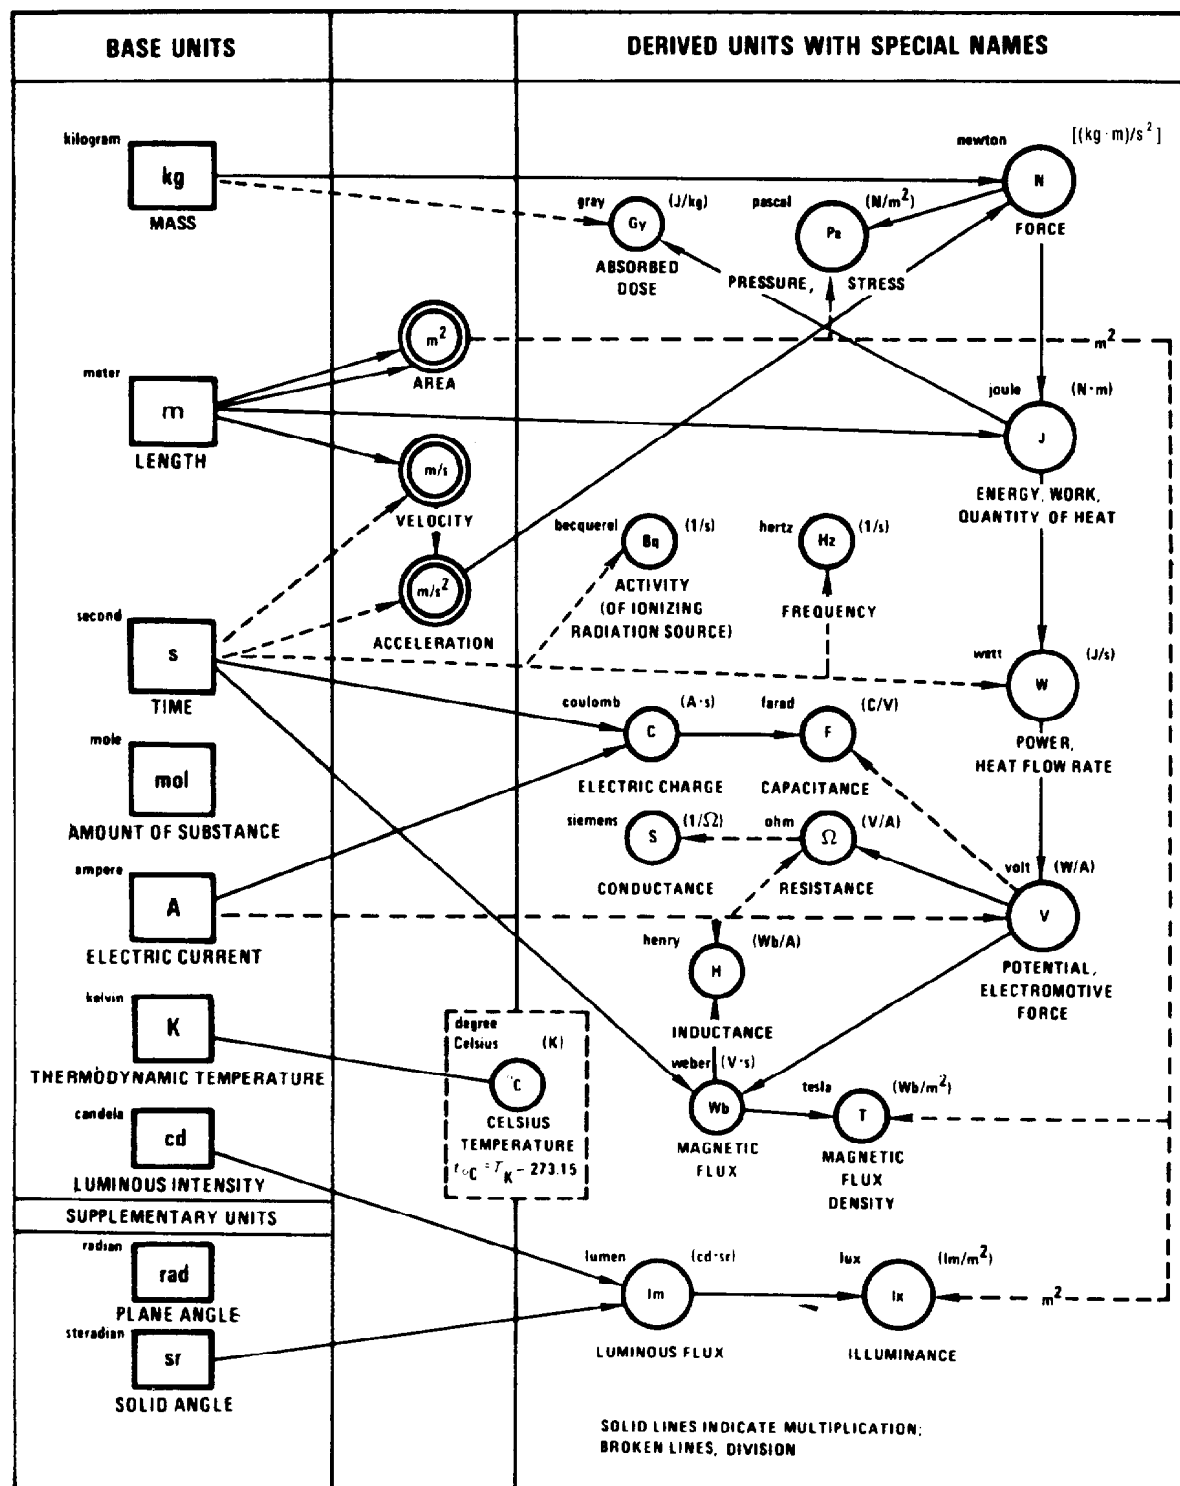

Fig. 2.1—Graphic relationships of SI units with names.

Force

Any force term will use the newton (N). Derived units involving force also require the newton. The expression of force using a mass term (like the kilogram) is absolutely forbidden under these standards.

Mass

The kilogram is the base unit, but the gram, alone or with any approved prefix, is an acceptable SI unit.

For large mass quantities the metric ton (t) may be used. Some call this "tonne." However, this spelling sometimes has been used historically to denote a regular short ton (2,000 lbm). A metric ton is also a megagram (Mg). The terms metric ton or Mg are preferred in text references.

Energy and Work

The joule (J) is the fundamental energy unit; kilojoules (kJ) or megajoules (MJ) will be used most commonly. The calorie (large or small) is no longer an acceptable unit under these standards. The kilowatthour is acceptable for a transition period but eventually should be replaced by the megajoule.

Power

The term horsepower disappears as an allowable unit. The kilowatt (kW) or megawatt (MW) will be the multiples of the fundamental watt unit used most commonly.

Pressure

The fundamental pressure unit is the pascal (Pa) but the kilopascal (kPa) is the most convenient unit. The bar (100 kPa) is an allowable unit. The pressure term kg/cm^2 is not allowable under these standards.

Viscosity

The terms poise, centipoise, stokes, and centistokes are no longer used under these standards. They are replaced by the metric units shown in Table 2.2.

Temperature

Although it is permissible to use $^{\circ}\text{C}$ in text references, it is recommended that "K" be used in graphical and tabular summaries of data.

Density

The fundamental SI unit for density is kg/m^3 . Use of this unit is encouraged. However, a unit like kg/L is permissible.

The traditional term "specific gravity" will not be used. It will be replaced by the term "relative density." API gravity disappears as a measure of relative density.

Relative Atomic Mass and Molecular Mass

The traditional terms "atomic weight" and "molecular weight" are replaced in the SI system of units by "relative atomic mass" and "relative molecular mass," respectively. See Table 1.6.

Unit Standards Under Discussion

There are some quantities for which the unit standards have not been clarified to the satisfaction of all parties and some controversy remains. These primary quantities are summarized below.

Permeability

The SPE-preferred permeability unit is the square micrometer (μm^2). One darcy (the traditional unit) equals $0.986\,923\,\mu\text{m}^2$.

The fundamental SI unit of permeability (in square meters) is defined as follows: "a permeability of one meter squared will permit a flow of $1\,\text{m}^3/\text{s}$ of fluid of $1\,\text{Pa}\cdot\text{s}$ viscosity through an area of $1\,\text{m}^2$ under a pressure gradient of $1\,\text{Pa/m}$."

The traditional terms of "darcy" and "millidarcy" have been approved as preferred units of permeability. Note 11 of Table 2.2 shows the relationships between traditional and SI units and points out that the units of the darcy and the square micrometer can be considered equivalent when high accuracy is not needed or implied.

Standard Temperature

Some reference temperature is necessary to show certain properties of materials, such as density, volume, viscosity, and energy level. Historically, the petroleum industry almost universally has used 60°F [15.56°C] as this reference temperature, and metric systems have used 0°C , 20°C , and 25°C most commonly, depending on the data and the area of specialty.

API has opted for 15°C because it is close to 60°F . ASME has used 20°C in some of its metric guides. The bulk of continental European data used for gas and oil correlations is at 0°C , although 15°C is used sometimes.

The SPE Subcommittee feels that the choice between 0°C and 15°C is arbitrary. Tentatively, a standard of 15°C has been adopted simply to conform to API standards. It may be desirable to have a flexible temperature standard for various applications.

Standard Pressure

To date, some groups have opted for a pressure reference of 101.325 kPa, which is the equivalent of 1 std atm. The Subcommittee considers this an unacceptable number. Its adoption possesses some short-term convenience advantages but condemns future generations to continual odd-number conversions to reflect the change of pressure on properties. It also violates the powers-of-10 aspect of the SI system, one of its primary advantages.

The current SPE standard is 100 kPa and should be used until further notice. It is our hope that reason will prevail and others will adopt this standard.

Gauge and Absolute Pressure

There is no provision for differentiating between gauge and absolute pressure, and actions by international bodies prohibit showing the difference by an addendum to the unit symbol. The Subcommittee recommends that gauge and absolute be shown using parentheses following p :

$$p=643\,\text{kPa}, \quad p(g)=543\,\text{kPa}$$

[p is found from $p(g)$ by adding actual barometric pressure. (100 kPa is suitable for most engineering calculations.)]

In custody transfer the standard pressure will be specified by contract. Unless there is a special reason not to do so, the standard pressure will be 100 kPa to preserve the "multiples of ten" principle of the metric system.

Standard pressure normally is defined and used as an absolute pressure. So, $p_{sc} = 100$ kPa is proper notation. Absolute pressure is implied if no (g) is added to denote gauge pressure specifically.

Standard Volumes

Cubic meters at standard reference conditions must be equated to a term with the standard "sc" subscript. For example, for a gas production rate of 1 200 000 m³/d, write

$$q_{gsc} = 1.2 \times 10^6 \text{ m}^3/\text{d} \text{ or } 1.2 \text{ (E+06) m}^3/\text{d} \\ \text{read as "1.2 million cubic meters per day."}$$

If the rate is 1200 cubic meters per day, write

$$q_{gsc} = 1.2 \times 10^3 \text{ m}^3/\text{d}.$$

For gas in place, one could write

$$G_{sc} = 11.0 \times 10^{12} \text{ m}^3.$$

Notes for Table 2.2

1. The cubem (cubic mile) is used in the measurement of very large volumes, such as the content of a sedimentary basin.
2. In surveying, navigation, etc., angles no doubt will continue to be measured with instruments that read out in degrees, minutes, and seconds and need not be converted into radians. But for calculations involving rotational energy, radians are preferred.
3. The unit of a million years is used in geochronology. The mega-annum is the preferred SI unit, but many prefer simply to use mathematical notation (i.e., $\times 10^6$).
4. This conversion factor is for an ideal gas.
5. Subsurface pressures can be measured in megapascals or as freshwater heads in meters. If the latter approach is adopted, the hydrostatic gradient becomes dimensionless.
6. Quantities listed under "Facility Throughput, Capacity" are to be used only for characterizing the size or capacity of a plant or piece of equipment. Quantities listed under "Flow Rate" are for use in design calculations.
7. This conversion factor is based on a density of 1.0 kg/dm³.
8. Seismic velocities will be expressed in km/s.
9. The interval transit time unit is used in sonic logging work.

10. See discussion of "Energy, Torque, and Bending Moment," Part 1.

11. The permeability conversions shown in Table 2.2 are for the traditional definitions of darcy and millidarcy.

In SI units, the square micrometer is the preferred unit of permeability in fluid flow through a porous medium, having the dimensions of viscosity times volume flow rate per unit area divided by pressure gradient, which simplifies to dimensions of length squared. (The *fundamental* SI unit is the square meter, defined by leaving out the factor of 10^{-12} in the equation below).

A permeability of 1 μm^2 will permit a flow of 1 m³/s of fluid of 1 Pa·s viscosity through an area of 1 m² under a pressure gradient of 10^{12} Pa/m (neglecting gravity effects):

$$1 \mu\text{m}^2 = 10^{-12} \text{ Pa} \cdot \text{s} [\text{m}^3/(\text{s} \cdot \text{m}^2)]/(\text{m}/\text{Pa}) \\ = 10^{-12} \text{ Pa} \cdot \text{s}(\text{m}/\text{s})/(\text{m}/\text{Pa}) \\ = 10^{-12} \text{ m}^2.$$

The range of values in petroleum work is best served by units of $10^{-3} \mu\text{m}^2$. The traditional millidarcy (md) is an informal name for $10^{-3} \mu\text{m}^2$, which may be used where high accuracy is not implied.

For virtually all engineering purposes, the familiar darcy and millidarcy units may be taken to be equal to 1 μm^2 and $10^{-3} \mu\text{m}^2$, respectively.

12. The ohm-meter is used in borehole geophysical devices.

13. As noted in Sec. 1, the mole is an amount of substance expressible in elementary entities as atoms, molecules, ions, electrons, and other particles or specified groups of such particles. Because the expression "kilogram mole" is inconsistent with other SI practices, we have used the abbreviation "kmol" to designate an amount of substance which contains as many kilograms (groups of molecules) as there are atoms in 0.012 kg of carbon 12 multiplied by the relative molecular mass of the substance involved. In effect, the "k" prefix is merely a convenient way to identify the type of entity and facilitate conversion from the traditional pound mole without violating SI conventions.

Notes for Table 2.3

1. The standard cubic foot (scf) and barrel (bbl) referred to are measured at 60°F and 14.696 psia; the cubic meter is measured at 15°C and 100 kPa (1 bar).
2. The kPa is the preferred SPE unit for pressure. But many are using the bar as a pressure measurement. The bar should be considered as a nonapproved name (or equivalent) for 100 kPa.
3. See discussion of "Torque and Bending Moment," Part 1.

Symbols in Alphabetical Order

Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Quantity	Dimensions
English				
A	S	ARA	area	L^2
A	F	HWF	Helmholtz function (work function)	mL^2/t^2
A		AMP	amplitude	various
A		AWT	atomic weight	m
A	S	ARA	cross section (area)	L^2
A_c		AMPC	amplitude, compressional wave	various
A_r		AMPR	amplitude, relative	various
A_s		AMPS	amplitude, shear wave	various
a		ACT	activity	
a	F_a	AIR	air requirement	various
a		DEC	decline factor, nominal	
a	L_a, L_1	DLW	distance between like wells (injection or production) in a row	L
a_E	F_{aE}	AIREX	air requirement, unit, in laboratory experimental run, volumes of air per unit mass of pack	L^3/m
a_R	F_{aR}	AIRR	air requirement, unit, in reservoir, volumes of air per unit bulk volume of reservoir rock	
B	C	COR	correction term or correction factor (either additive or multiplicative)	
B	F	FVF	formation volume factor, volume at reservoir conditions divided by volume at standard conditions	
B_g	F_g	FVFG	formation volume factor, gas	
B_{gb}	F_{gb}	FVFGB	bubblepoint formation volume factor, gas	
B_{gb}	F_{gb}	FVFGB	formation volume factor at bubblepoint conditions, gas	
B_o	F_o	FVFO	formation volume factor, oil	
B_{ob}	F_{ob}	FVFOB	bubblepoint formation volume factor, oil	
B_{ob}	F_{ob}	FVFOB	formation volume factor at bubblepoint conditions, oil	
B_t	F_t	FVFT	formation volume factor, total (two-phase)	
B_w	F_w	FVFW	formation volume factor, water	
b	w	WTH	breadth, width, or (primarily in fracturing) thickness	L
b	Y	ICP	intercept	various
b	f, F	RVF	reciprocal formation volume factor, volume at standard conditions divided by volume at reservoir conditions (shrinkage factor)	
b	w	WTH	width, breadth, or (primarily in fracturing) thickness	L
b_g	f_g, F_g	RVFG	reciprocal gas formation volume factor	
b_{gb}	f_{gb}, F_{gb}	RVFGB	reciprocal gas formation volume factor at bubblepoint conditions	
b_o	f_o, F_o	RVFO	reciprocal oil formation volume factor (shrinkage factor)	
C		ECQ	capacitance	q^2t^2/mL^2

Dimensions: L=length, m=mass, q=electrical charge, t=time, T=temperature, and M=money.

Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Quantity	Dimensions
C	C_i	INVT	capital investments, summation of all	M

C	n_C	NMBC	components, number of	
C	c, n	CNC	concentration	various
C	σ	ECN	conductivity (electrical logging)	tq^2/mL^3
C	K	CND	conductivity, other than electrical (with subscripts)	various
C	c, n	CNC	salinity	various
C	c	HSP	specific heat (always with phase or system subscripts)	L^2/t^2T
C		WDC	water-drive constant	L^4t^2/m
C_{C_1}	c_{C_1}	CNCC1	concentration, methane (concentration of other paraffin hydrocarbons would be indicated similarly, C_{C_2} , C_{C_3} , etc.)	various
C_L	c_L, n_L	CNTL	content, condensate or natural gas liquids	various
C_L		WDCL	water-drive constant, linear aquifer	L^4t^2/m
C_{O_2}	c_{O_2}	CNCO2	concentration, oxygen (concentration of other elements or compounds would be indicated similarly, C_{CO_2} , C_{N_2} , etc.)	various
C_a	σ_a	ECNA	conductivity, apparent	tq^2/mL^3
C_{fD}		CNDFQ	conductivity, fracture, dimensionless	
C_i		INVI	capital investment, initial	M
C_k		INVK	capital investment, subsequent, in year k	M
C_m	c_m, n_m	CNCFU	fuel concentration, unit (see symbol m)	various
C_{uk}		INVUK	unamortized investment over year k	
C_{wg}	c_{wg}, n_{wg}	CNTWG	content, wet-gas	various
c	k, κ	CMP	compressibility	Lt^2/m
c_f	k_f, κ_f	CMPF	compressibility, formation or rock	Lt^2/m
c_g	k_g, κ_g	CMPG	compressibility, gas	Lt^2/m
c_o	k_o, κ_o	CMPO	compressibility, oil	Lt^2/m
c_{pr}	k_{pr}, κ_{pr}	CMPPRD	compressibility, pseudo reduced	
c_w	k_w, κ_w	CMPW	compressibility, water	Lt^2/m
D		DLV	deliverability (gas well)	L^3/t
D	y, H	DPH	depth	L
D	μ, δ	DFN	diffusion coefficient	L^2/t
D		DSC	discount factor, general	
D_c		DSCC	discount factor, constant-income	
D_{sp}		DSCSP	discount factor, single-payment [$1/(1+i)^k$; or e^{-jk} , $j = \ln(1+i)$]	
D_{spc}		DSCSPC	discount factor, single-payment (constant annual rate) [$e^{-jk}(e^j - 1)/j$]	
d		DECE	decline factor, effective	
d	D	DIA	diameter	L
d	L_d, L_2	DUW	distance between adjacent rows of injection and production wells	L
\bar{d}_p	\bar{D}_p	DIAAVP	diameter, mean particle	L
d_h	d_H, D_h	DIAH	diameter, hole	L
d_i	d_I, D_i	DIAI	diameter, invaded zone (electrically equivalent)	L
E	η, e	EFF	efficiency	
E	V	EMF	electromotive force	mL^2/t^2q

Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Quantity	Dimensions
E	U	ENG	energy	mL^2/t^2
E	Y	ELMY	modulus of elasticity (Young's modulus)	m/Lt^2
E_A	η_A, e_A	EFFA	efficiency, areal (used in describing results of model studies only): area swept in a model divided by total model reservoir area (see E_P)	
E_D	η_D, e_D	EFFD	efficiency, displacement: volume of hydrocarbons (oil or gas) displaced from individual pores or small groups of pores divided by the volume of hydrocarbon in the same pores just prior to	
E_{Db}	η_{Db}, e_{Db}	EFFDB	efficiency, displacement, from burned portion of in-situ combustion pattern	
E_{Du}	η_{Du}, e_{Du}	EFFDU	efficiency, displacement, from unburned portion of in-situ combustion pattern	
E_I	η_I, e_I	EFFI	efficiency, invasion (vertical): hydrocarbon pore space invaded (affected, contacted) by the injection fluid or heat front divided by the hydrocarbon pore space enclosed in all layers behind the injected fluid or heat front	
E_π			Euler's number	
E_P	η_P, e_P	EFFP	efficiency, pattern sweep (developed from areal efficiency by proper weighting for variations in net pay thickness, porosity, and hydrocarbon saturation): hydrocarbon pore space enclosed behind the injected fluid or heat front divided by total hydrocarbon pore space of the reservoir or project	
E_R	η_R, e_R	EFFR	efficiency, overall reservoir recovery: volume of hydrocarbons recovered divided by volume of hydrocarbons in place at start of project ($E_R = E_P E_I E_D = E_V E_D$)	
E_{SP}	Φ_{SP}	EMFSP	SP (measured SP) (Self Potential)	$\text{mL}^2/\text{t}^2\text{q}$
E_{SSP}	Φ_{SSP}	EMFSSP	SSP (static SP)	$\text{mL}^2/\text{t}^2\text{q}$
E_V	η_V, e_V	EFFV	efficiency, volumetric: product of pattern sweep and invasion efficiencies	
E_{Vb}	η_{Vb}, e_{Vb}	EFFVB	efficiency, volumetric, for burned portion only, in-situ combustion pattern	
E_c	Φ_c	EMFC	electrochemical component of the SP	$\text{mL}^2/\text{t}^2\text{q}$
E_k	Φ_k	EMFK	electrokinetic component of the SP	$\text{mL}^2/\text{t}^2\text{q}$
E_k		ENGK	kinetic energy	mL^2/t^2
E_{pSP}	Φ_{SP}	EMFP	pseudo-SP	mL^2/qt^2
$-Ei(-x)$			exponential integral, $\int_x^\infty \frac{e^{-t}}{t} dt$, x positive	
$Ei(x)$			exponential integral, modified $\lim_{\epsilon \rightarrow 0} \left[\int_{-\infty}^{-\epsilon} \frac{e^t}{t} dt + \int_{\epsilon}^\infty \frac{e^t}{t} dt \right]$, x positive	
e	i	ENC	encroachment or influx rate	L^3/t

e_w	i_w	ENCW	encroachment or influx rate, water	L^3/t
e^z	$exp\ z$	EXP	exponential function	
F		DGF	degrees of freedom	
F		FAC	factor in general, including ratios (always with identifying subscripts)	various
F	f	FLU	fluid (generalized)	various
F	Q	FCE	force, mechanical	mL/t^2
F		FAC	ratio or factor in general (always with identifying subscripts)	various
F_B		FACB	factor, turbulence	
F_R		FACHR	formation resistivity factor—equals R_o/R_w (a numerical subscript to F indicates the value R_w)	
F_{WV}	γ	WGTS	specific weight	mL^2/t^2
F_{aF}		FACAFU	air/fuel ratio	various
F_s	F_d	DMRS	damage ratio or condition ratio (conditions relative to formation conditions unaffected by well operations)	
F_{wF}		FACWFO	water/fuel ratio	various
F_{wo}		FACWO	water/oil ratio, producing, instantaneous	
F_{wop}		FACWOP	water/oil ratio, cumulative	
f	F	FRC	fraction (such as the fraction of a flow stream consisting of a particular phase)	
f	ν	FQN	frequency	$1/t$
f		FACF	friction factor	
f		FUG	fugacity	m/Lt^2
$f_{\phi sh}$	ϕ_{igfsh}	FIGSH	fraction of intergranular space ("porosity") occupied by all shales	
$f_{\phi shd}$	ϕ_{imfshd}	FIMSHD	fraction of intermatrix space ("porosity") occupied by nonstructural dispersed shale	
$f_{\phi w}$	ϕ_{igfw}	FIGW	fraction of intergranular space ("porosity") occupied by water	
f_L	F_L, f_L script l	FRCL	fraction liquid	
f_L	F_L, f_L script l	MFRTL	mole fraction liquid, $L/(L+V)$	
f_{Pk}		PRAPK	profit, annual, over year k , fraction of unamortized investment	
f_V	f_{Vb}, V_{bf}	FRCVB	fraction of bulk (total) volume	
f_g	F_g	FRCG	fraction gas	
f_g	F_g	MFRTV	mole fraction gas, $V/(L+V)$	
f_s	Q, x	QLTS	quality (usually of steam)	
G	F	GFE	free energy (Gibbs function)	mL^2/t^2
G	g	GASTI	gas in place in reservoir, total initial	L^3
G	g	GAS	gas(any gas, including air) always with identifying subscripts	various
G	f_G	GMF	geometrical factor (multiplier) (electrical logging)	
G	E_s	ELMS	shear modulus	m/Lt^2

Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Quantity	Dimensions
G_{Fi}	g_{Fi}	GASFI	free-gas volume, initial reservoir ($=mNB_{oi}$)	L^3
G_{Fp}	g_{Fp}	GASFP	free gas produced, cumulative	L^3
G_L	g_L	NGLTi	condensate liquids in place in reservoir, initial	L^3
G_{Lp}	g_{Lp}	NGLP	condensate liquids produced, cumulative	L^3
G_{an}	f_{Gan}	GMFAN	factor, geometrical (multiplier), annulus (electrical logging)	
G_{an}	f_{Gan}	GMFAN	geometrical factor (multiplier), annulus (electrical logging)	
G_e	g_e	GASE	gas influx (encroachment), cumulative	L^3
G_i	g_i	GASI	gas injected, cumulative	L^3
G_i	f_{Gi}	GMFI	geometrical factor (multiplier), invaded zoned (electrical logging)	
G_m	f_{Gm}	GMFM	geometrical factor (multiplier), mud (electrical logging)	
G_p	g_p	GASP	gas produced, cumulative	L^3
G_p	f_{Gp}	GMFP	geometrical factor (multiplier), pseudo (electrical logging)	
G_{pE}	g_{pE}	GASPEX	gas produced from experimental tube run	L^3
G_{pa}	g_{pa}	GASPUL	gas recovery, ultimate	L^3
G_t	f_{Gt}	GMFT	geometrical factor, (multiplier), true (noninvaded zone) (electrical logging)	
G_{wgp}	g_{wgp}	GASWGP	wet gas produced, cumulative	L^3
G_{xo}	f_{Gxo}	GMFXO	geometrical factor (multiplier), flushed zone (electrical logging)	
g		GRV	acceleration of gravity	L/t^2
g	γ	GRD	gradient	various
g_G	g_g	GRDGT	gradient, geothermal	T/L
g_T	g_h	GRDT	gradient, temperature	T/L
g_c		GRVC	conversion factor in Newton's Second Law of Motion	
H	I	HEN	enthalpy (always with phase or system subscripts)	mL^2/t^2
H_s	I_s	HENS	enthalpy (net) of steam or enthalpy above reservoir temperature	mL^2/t^2
h	d, e	THK	bed thickness, individual	L
h	i	HENS	enthalpy, specific	L^2/t^2
h	h_h, h_T	HTCC	heat-transfer coefficient, convective	m/t^3T
h	d, e	ZHT	height (other than elevation)	L
h		HPC	hyperbolic decline constant (from equation) $q = q_i / \left[1 + \frac{a_i t}{h} \right]^h$	
h	d, e	THK	thickness (general and individual bed)	L
h_{mc}	d_{mc}, e_{mc}	THKMC	thickness, mud cake	L
h_n	d_n, e_n	THKN	thickness, net pay	L
h_t	d_t, e_t	THKT	thickness, gross pay (total)	L

overall reservoir recovery efficiency: volume of hydrocarbons recovered divided by volume of hydrocarbons in place at start of project ($E_R = E_P E_S E_O = E_V E_D$)	E_R	η_R, e_R	EFFR	
oxygen concentration (concentration of other elements or compounds would be indicated as C_{CO_2} , C_{N_2} , etc.)	C_{O_2}	c_{O_2}	CNCO2	various
oxygen utilization	e_{O_2}	E_{O_2}	UTLO2	
particle diameter, mean	\bar{d}_p	\bar{D}_p	DIAAVP	L
path length, length, or distance	L	$s, l \text{ script } l$	LTH	L
pattern sweep efficiency (developed from areal efficiency by proper weighting for variations in net pay thickness, porosity, and hydrocarbon saturation: hydrocarbon pore space enclosed behind the injected-fluid or heat front divided by total hydrocarbon pore space of the reservoir or project)	E_p	η_p, e_p	EFFP	
pay thickness, gross (total)	h_t	d_t, e_t	THKT	L
pay thickness, net	h_n	d_n, e_n	THKN	L
period	T	Θ	PER	t
permeability, absolute (fluid flow)	k	K	PRM	L^2
permeability, effective, to gas	k_g	K_g	PRMG	L^2
permeability, effective, to oil	k_o	K_o	PRMO	L^2
permeability, effective, to water	k_w	K_w	PRMW	L^2
permeability, magnetic	μ	m	PRMM	mL/q^2
permeability ratio, gas/oil	k_g/k_o	K_g/K_o	PRMGQ	
permeability ratio, water/oil	k_w/k_o	K_w/K_o	PRMWO	
permeability, relative, to gas	k_{rg}	K_{rg}	PRMRG	
permeability, relative, to oil	k_{ro}	K_{ro}	PRMRO	
permeability, relative, to water	k_{rw}	K_{rw}	PRMRW	
phases, number of	P		NMBP	
Poisson's ratio	μ	ν, σ	PSN	
pore volume $V_b - V_s$	V_p	ν_p	VOLP	L^3
pore volume, dimensionless	V_{pD}	ν_{pD}	VOLPQ	
pore volumes of injected fluid, cumulative	Q_i	q_i	FLUIQ	
porosity $(V_b - V_s)/V_b$	ϕ	f, ϵ	POR	
porosity, apparent	ϕ_a	f_a, ϵ_a	PORA	
porosity, effective (V_{pe}/V_b)	ϕ_e	f_e, ϵ_e	PORE	
porosity exponent (cementation) (in an empirical relation between F_R and ϕ)	m		MXP	
porosity, hydrocarbon-filled, fraction or percent of rock bulk volume occupied by hydrocarbons	ϕ_h	f_h, ϵ_h	PORH	
porosity index	I_ϕ	i_ϕ	PRX	
porosity index, primary	$I_{\phi 1}$	$i_{\phi 1}$	PRXP	
porosity index, secondary	$I_{\phi 2}$	$i_{\phi 2}$	PRXSE	
porosity, noneffective (V_{pne}/V_b)	ϕ_{ne}	f_{ne}, ϵ_{ne}	PORNE	

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
"porosity" (space), intergranular ($V_b - V_{gr} / V_b$)	ϕ_{ig}	f_{ig}, ϵ_{ig}	PORIG	
"porosity" (space), intermatrix ($V_b - V_{ma} / V_b$)	ϕ_{im}	f_{im}, ϵ_{im}	PORIM	
porosity of experimental pack	ϕ_E	f_E, ϵ_E	POREX	
porosity of reservoir or formation	ϕ_R	f_R, ϵ_R	PORR	
porosity, total	ϕ_t	f_t, ϵ_t	PORT	
potential or potential function	Φ	f	POT	various
potential difference (electric)	V	U	VLT	mL ² /qt ²

temperature, reduced	T_r	θ_r	TEMRD	T
temperature, reservoir	T_R	θ_R	TEMR	T
temperature, standard conditions	T_{sc}	θ_{sc}	TEMSC	T
tension, surface (interfacial)	σ	γ, γ	SFT	m/t^2

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
tensor of x	\bar{x}			
thermal conductivity (always with additional phase or system subscripts)	k_h	λ	HCN	mL/t ³ T
thermal cubic expansion coefficient	β	b	HEC	1/T
thermal or heat diffusivity	α	a, η_h	HTD	L ² /t
thickness (general and individual bed)	h	d, e	THK	L
thickness, gross pay (total)	h_i	d_i, e_i	THKT	L
thickness, mudcake	h_{mc}	d_{mc}, e_{mc}	THKMC	L
thickness, pay, gross (total)	h_i	d_i, e_i	THKT	L
thickness, net pay	h_n	d_n, e_n	THKN	L
time	t	τ	TIM	t
time after well is opened to production (pressure drawdown)	Δt_{wf}	$\delta \tau_{wf}$	DELTIMWF	t
time after well is shut in (pressure buildup)	Δt_{ws}	$\Delta \tau_{ws}$	DELTIMWS	t
time constant	τ	τ_c	TIMC	t
time, decay (mean life) (1/ λ)	τ_d	t_d	TIMD	t
time, delay	t_d	τ_d	TIMD	t
time difference (time period or interval, fixed length)	Δt	$\Delta \tau$	DELTIM	t
time, dimensionless	t_D	τ_D	TIMQ	
time, dimensionless at condition m	t_{Dm}	τ_{Dm}	TIMMQ	
time for stabilization of a well	t_s	τ_s	TIMS	t
time, interval transit	$t_{script} t$	Δt	TAC	t/L
time, interval transit, apparent	$t_a \text{ script } t$	Δt_a	TACA	t/L
time, interval transit, fluid	$t_f \text{ script } t$	Δt_f	TACF	t/L
time, interval transit, matrix	$t_{ma} \text{ script } t$	Δt_{ma}	TACMA	t/L
time, interval transit, shale	$t_{sh} \text{ script } t$	Δt_{sh}	TACSH	t/L
time, neutron decay (neutron mean life)	t_{dN}		TIMDN	t
time, payout (payoff, payback)	t_p	τ_p, t_{po}	TIMPO	t
time period or interval, fixed length	Δt	$\Delta \tau$	DELTIM	t
time well was on production before shut-in, equivalent (pseudotime)	t_p	τ_p	TIMP	t
tortuosity	τ		TOR	
tortuosity, electric	τ_e		TORE	
tortuosity, hydraulic	τ_H		TORHL	
total (combined) liquid saturation	S_L	ρ_L, s_L	SATL	
total entropy	s		HER	L ² /t ² T
total mobility of all fluids in a particular region of the reservoir; e.g., ($\lambda_o + \lambda_g + \lambda_w$)	λ_t	Λ	MOBT	L ³ t/m
total mobility ratio [(λ_t) _{swept} /(λ_t) _{unswept}]; "swept" and "unswept" refer to invaded and uninvaded regions behind and ahead of leading edge of a displacement front	M_t	$F_{\lambda t}$	MBRT	
total (gross) pay thickness	h_i	d_i, e_i	THKT	L
total gross revenue ("value")	V	R, V_t, R_t	GRRT	M
total initial gas in place in reservoir	G	g	GASTI	L ³
total moles	n	n_t, N_t	NMBM	
total porosity	ϕ_t	f_t, ϵ_t	PORT	
total (two-phase) formation volume factor	B_t	F_t	FVFT	

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
transfer coefficient, convective heat	h	h_h, h_T	HTCC	m/t ³ T
transfer coefficient, heat, overall	U	U_T, U_θ	HTCU	m/t ³ T
transfer coefficient, heat, radiation	I	I_T, I_θ	HTCI	m/t ³ T
transit time, interval	$t \text{ script } t$	Δt	TAC	t/L
transit time, apparent, interval	$t_a \text{ script } t$	Δt_a	TACA	t/L
transit time, fluid interval	$t_f \text{ script } t$	Δt_f	TACF	t/L
transit time, matrix interval	$t_{ma} \text{ script } t$	Δt_{ma}	TACMA	t/L
transit time, shale interval	$t_{sh} \text{ script } t$	Δt_{sh}	TACSH	t/L
transform, Laplace of $y \int_0^\infty y(t) e^{-st} dt$	$\mathcal{L}(y) \text{ script } L$			
transform, Laplace, variable	s			
transmissivity, transmissibility	T	T	TRM	various
true density	ρ_t	D_t	DENT	m/L ³
true formation resistivity	R_t	ρ_t, r_t	REST	mL ³ /tq ²
true geometrical factor (multiplier) (noninvaded zone) (electrical logging)	G_t	f_{Gt}	GMFT	
tubing pressure, flowing	p_{tf}	P_{tf}	PRSTF	m/Lt ²
tubing pressure, static	p_{ts}	P_{ts}	PRSTS	m/Lt ²
turbulence factor	F_B		FACB	
two-phase or total formation volume factor	B_t	F_t	FVFT	
ultimate gas recovery	G_{pa}	g_{pa}	GASPUL	L ³
unamortized investment over year k	C_{uk}		INVUK	
undiscounted cash flow	P			M
unburned reservoir rock, volume of	V_{Ru}	v_{Ru}	VOLRU	L ³
unit air requirement in laboratory experimental run, volumes of air per unit mass of pack	a_E	F_{aE}	AIREX	L ³ /m
unit air requirement in reservoir, volumes of air per unit bulk volume of reservoir rock	a_R	F_{aR}	AIRR	
unit fuel concentration (see symbol m)	C_m	c_m, n_m	CNCFU	various
universal gas constant (per mole)	R		RRR	mL ² /t ² T
utilization, oxygen	e_{O_2}	E_{O_2}	UTLO2	
valence	z		VAL	
vapor phase, mole fraction of component	y		MFRV	
vapor phase, moles of	V		MOLV	
vaporization, latent heat of	L_v	λ_v	HLTV	L ² /t ²
variance of a random variable	σ^2		VAR	
variance of a random variable, estimated	s^2		VARES	
vector of x	\vec{x}			
velocity	v	V, u	VEL	L/t
velocity, acoustic	v	V, u	VAC	L/t
velocity, acoustic apparent (measured)	v_a	V_a, u_a	VACA	L/t
velocity, acoustic fluid	v_f	V_f, u_f	VACF	L/t
velocity, matrix acoustic	v_{ma}	V_{ma}, u_{ma}	VACMA	L/t
velocity, shale acoustic	v_{sh}	V_{sh}, u_{sh}	VACSH	L/t
velocity (rate) of burning-zone advance	v_b	V_b, u_b	VELB	L/t
vertical (invasion) efficiency: hydrocarbon pore space invaded (affected, contacted) by the injected-fluid or heat front divided by the	E_I	η_I, e_I	EFFI	

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
hydrocarbon pore space enclosed in all layers behind the injected-fluid or heat front				
viscosity, air	μ_a	η_a	VISA	m/Lt
viscosity at mean pressure	$\mu_{\bar{p}}$	$\eta_{\bar{p}}$	VISPAV	m/Lt
viscosity, dynamic	μ	η	VIS	m/Lt
viscosity, gas	μ_g	η_g	VISG	m/Lt
viscosity, gas, at 1 atm	μ_{ga}	η_{ga}	VISGA	m/Lt
viscosity, kinematic	ν	N	VSK	L ² /t
viscosity, oil	μ_o	η_o	VISO	m/Lt
viscosity, water	μ_w	η_w	VISW	m/Lt
volume	V	v	VOL	L ³
volume at bubblepoint pressure	V_{bp}	v_{bp}	VOLBP	L ³
volume, bulk	V_b	v_b	VOLB	L ³
volume, bulk, of pack burned in experimental run	V_{bE}	v_{bE}	VOLBEX	L ³
volume, effective pore	V_e	V_{pe}, v_e	VOLG	L ³
volume fraction or ratio (as needed, use same subscripted symbols as for "volumes"; note that bulk volume fraction is unity and pore volume fractions are ϕ)	V	f_V, F_V	VLF	various
volume, free-gas, initial reservoir ($=mNb_{oi}$)	G_{Fi}	g_{Fi}	GASFI	L ³
volume, grain (volume of all formation solids except shales)	V_{gr}	v_{gr}	VOLGR	L ³
volume, intergranular (volume between grains; consists of fluids and all shales) ($V_b - V_{gr}$)	V_{ig}	v_{ig}	VOLIG	L ³
volume, intermatrix (consists of fluids and dispersed shale) ($V_b - V_{ma}$)	V_{im}	v_{im}	VOLIM	L ³
volume, matrix (framework) (volume of all formation solids except dispersed shale)	V_{ma}	v_{ma}	VOLMA	
volume, noneffective pore ($V_p - V_e$)	V_{ne}	V_{pne}, v_{ne}	VOLNE	L ³
volume of reservoir rock burned	V_{Rb}		VOLRB	L ³
volume of reservoir rock unburned	V_{Ru}		VOLRU	L ³
volume per mole (molal volume)	V_M		VOLM	L ³
volume, pore ($V_b - V_s$)	V_p	v_p	VOLP	L ³
volume, pore, dimensionless	V_{pD}	v_{pD}	VOLPQ	
volume, shale, dispersed	V_{shd}	v_{shd}	VOLSHD	L ³
volume, shale, laminated	V_{shl} <i>script l</i>	v_{shl} <i>script l</i>	VSHLAM	L ³
volume, shale, structural	V_{shs}	v_{shs}	VOLSHS	L ³
volume, shale(s) (volume of all shales: structural and dispersed)	V_{sh}	v_{sh}	VOLSH	L ³
volume, solid(s) (volume of all formation solids)	V_s	v_s	VOLS	L ³
volume, specific	v	v_s	SPV	L ³ /m
volumetric efficiency for burned portion only, in-situ combustion pattern	E_{Vb}	η_{Vb}, e_{Vb}	EFFVB	
volumetric efficiency: product of pattern sweep and invasion efficiencies	E_V	η_V, e_V	EFFV	

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
volumetric flow rate	q	Q	RTE	L^3/t
volumetric flow rate downhole	q_{dh}	q_{wf}, q_{DH}, Q_{dh}	RTEDH	L^3/t
volumetric flow rate, surface conditions	q_{sc}	q_{σ}, Q_{sc}	RTESC	L^3/t
volumetric heat capacity	M		HSPV	m/Lt^2T
volumetric velocity (flow rate or flux, per unit area)	u	ψ	VELV	L/t
water (always with identifying subscripts)	W	w	WTR	various
water compressibility	c_w	k_w, κ_w	CMPW	Lt^2/m
water density	ρ_w rho	D_w	DENW	m/L^3
water displaced from burned volume, volume per unit volume of burned reservoir rock	δ_{wb}	F_{wb}	DPRWB	
waterdrive constant	C		WDC	L^4t^2/m
waterdrive constant, linear aquifer	C_L		WDCL	L^4t^2/m
water, effective permeability to	k_w	K_w	PRMW	L^2
water formation volume factor	B_w	F_w	FVFW	
water/fuel ratio	F_{wF}		FACWFU	various
water, gas solubility in	R_{sw}		GWRS	
water in place in reservoir, initial	W	w	WTRTI	L^3
water influx (encroachment), cumulative	W_e	w_e	WTRE	L^3
water influx (encroachment) during an interval	ΔW_e	Δw_e	DELWTRE	L^3
water influx (encroachment) rate	e_w	i_w	ENCW	L^3/t
water injected, cumulative	W_i	w_i	WTRI	L^3
water injected during an interval	ΔW_i	Δw_i	DELWTRI	L^3
water injection rate	i_w		INJW	L^3/t
water mobility	λ_w		MOBW	L^3t/m
water/oil permeability ratio	k_w/k_o	K_w/K_o	PRMWO	
water/oil ratio, cumulative	F_{wop}		FACWOP	
water/oil ratio, producing, instantaneous	F_{wo}		FACWO	
water produced, cumulative	W_p	w_p	WTRP	L^3
water produced during an interval	ΔW_p	Δw_p	DELWTRP	L^3
water production rate	q_w	Q_w	RTEW	L^3/t
water production rate, dimensionless	q_{wD}	Q_{wD}	RTEWQ	
water, relative permeability to	k_{rw}	K_{rw}	PRMRW	
water resistivity	R_w	ρ_w, r_w	RESW	mL^3/tq^2
water saturation	S_w	ρ_w, s_w	SATW	
water saturation, critical	S_{wc}	ρ_{wc}, s_{wc}	SATWC	
water saturation, initial	S_{wi}	ρ_{wi}, s_{wi}	SATWI	
water saturation (interstitial) in oil band	S_{wo}	S_{wb}	SATWO	
water saturation in gas cap, interstitial	S_{wg}	ρ_{wg}, s_{wg}	SATWG	
water saturation, interstitial, connate, or irreducible	S_{iw}	ρ_{iw}, s_{iw}	SATIW	
water saturation, residual	S_{wr}	ρ_{wr}, s_{wr}	SATWR	
water specific gravity	γ_w	s_w, F_{ws}	SPGW	
water viscosity	μ_w	η_w	VISW	m/Lt
wave length ($1/\sigma$)	λ		WVL	L
wave number ($1/\lambda$)	σ	$\tilde{\nu}$	WVN	$1/L$
weight (gravitational)	W	w, G	WGT	m/Lt^2
weight-weighted average density of produced liquid	$\bar{\rho}_L$ rho	\bar{D}_L	DENAVL	m/L^3
weight, atomic	A		AWT	m

Quantity	Letter Symbol	Reserve SPE Letter Symbol	Computer Letter Symbol	Dimensions
weight, molecular	M		MWT	m
well radius	r_w	R_w	RADW	L
well radius of damage or stimulation (skin)	r_s	R_s	RADS	L
well stabilization time	t_s	τ_s	TIMS	t
wellbore radius, effective or apparent (includes effects of well damage or stimulation)	r_{wa}	R_{wa}	RADWA	L
wet-gas content	C_{wg}	c_{wg}, n_{wg}	CNTWG	various
wet gas produced, cumulative	G_{wgp}	g_{wgp}	GASWGP	L ³
width, breadth, or thickness (primarily in fracturing)	b	w	WTH	L
work	W	w	WRK	mL ² /t ²
Young's modulus (modulus of elasticity)	E	Y	ELMY	m/Lt ²
zone diameter, invaded, electrically equivalent	d_i	d_I, D_i	DIAI	L
zone resistivity, invaded	R_i	ρ_i, r_i	RESI	mL ³ /tq ²

<i>NL</i>	<i>nl script l</i>	NL	neutron lifetime log, TDT
<i>PV</i>	<i>pv</i>	PV	discounted value, present worth, or present value
<i>Pk</i>		PK	profit—unamortized investment
<i>p</i>		P	particle (usually with diameter, d_p)
<i>P</i>		P	pattern (usually with pattern efficiency, E_p)
<i>p</i>	<i>po</i>	PO	payout, payoff, or payback
<i>p</i>	<i>P</i>	P	pore (usually with volume, V_p)
\bar{p}		PAV	pressure, mean or average
<i>p</i>	<i>P</i>	P	produced
<i>p</i>		P	produced, cumulative
<i>p</i>	<i>P</i>	P	production period (usually with time, t_p)
<i>p</i>		P	pseudo
<i>pD</i>		PQ	pore value, dimensionless (usually with volume, V_{pD})
<i>pD</i>		PQ	pseudodimensionless
<i>pE</i>		PEX	produced in experiment
<i>pSP</i>		PSP	pseudo-SP
<i>pc</i>		PC	pseudocritical
<i>pj</i>		PJ	produced component j (usually with moles, n_{pj})
<i>pr</i>		PRD	pseudoreduced
<i>R</i>			rate
<i>R</i>			ratio
<i>R</i>		R	recovery (usually with recovery efficiency, E_R)
<i>R</i>	<i>r</i>	R	reservoir
<i>R</i>		R	resistivity
<i>R</i>		R	resistivity log
<i>Rb</i>	<i>r, \rho</i>	RB	reservoir rock, burned
<i>Ru</i>		RU	reservoir rock, unburned
<i>Re</i>			Reynolds (used with Reynolds number only, N_{Re})
<i>r</i>	<i>R</i>	R	radius, radial, or radial distance
<i>r</i>	<i>R</i>	R	rate of return
<i>r</i>		RD	reduced
<i>r</i>	<i>b, \rho</i>	R	reference
<i>r</i>	<i>R</i>	R	relative

Letter Subscript	Reserve SPE Subscript	Computer Letter Subscript	Subscript Definition
r	R	R	residual
\bar{S}	$\bar{s}, \bar{\rho}$	SAV	saturation, mean or average
S	SW	SW	sidewall
\bar{S}	s, σ	S	storage or storage capacity
\bar{S}	$\bar{s}, \bar{\rho}$	SAV	average or mean saturation
SN	sn	SN	neutron log, sidewall
SP	sp	SP	SP
SSP		SSP	SSP
SV	sv	SV	sonic, velocity or acoustic log
SWN	swn	SWN	sidewall neutron log
s	d	S	damage or damaged (includes "skin" conditions)
s		S	formation, surrounding
s		S	gas/oil ratio, solution
s	$S\sigma$	S	segregation (usually with segregation rate, q_s)
s	τ	S	shear
s	τ	S	shear wave
s	S	S	skin (stimulation or damage)
s	σ	S	slip or slippage
s	σ	S	solid (usually with volume or density)
s		S	solution (usually with gas/oil ratios)
s		L	spacing
s		S	specific (usually with J and I)
s	S	S	stabilization (usually with time)
s	S	S	steam or steam zone
s	S	S	stimulation (includes "skin" conditions)
s	σ	S	surface
s		S	surrounding formation
s	S, σ	S	swept or swept region
s	σ	S	system
sE		SEX	solids in experiment
sb		SB	solution at bubblepoint conditions (usually with gas/oil ratio, R_{sb})
sc		SC	scattered, scattering
sc	σ	SC	standard conditions
sd	sa	SD	sand
sh	sha	SH	shale
si		SI	solution, initial (usually with gas/oil ratio, R_{si})
sl	slt	SL	silt
sp		SP	separator conditions
sp		SP	single payment
ss	sst	SS	sandstone
st		ST	stock-tank conditions
st	s	ST	structural
sw		SW	solution in water (usually with gas solubility in water, R_{sw})
gyp		GY	gypsum
T	h, θ	T	temperature
T	t, h	T	temperature log
T	t	T	tool, sonde
T	t	T	transmissibility
TV	tv	TV	televviewer log, borehole

Letter Subscript	Reserve SPE Subscript	Computer Letter Subscript	Subscript Definition
t	T	T	gross (total)
t	T	T	total, total system
t	τ	T	treatment or treating
t	tr	T	true (electrical logging) (opposed to apparent)
t	tg	T	tubing or tubinghead
tD		TQ	time, dimensionless
tf		TF	tubing flowing (usually with pressure)
ti		TI	total initial in place in reservoir
ts		TS	tubing, static (usually with pressure)
u	U	U	unamortized
u		U	unburned
u	U	U	unit
u	U	U	unswept or unswept region
u	U	U	upper
ul	a	UL	ultimate
V	v	V	vertical
V	v	V	volume or volumetric
VD	vd	VD	microseismogram log, signature log, variable density log
Vb		VB	volumetric or burned portion of in-situ combustion pattern (usually with efficiency, E_{Vb})
v	V	V	vaporization, vapor, or vapor phase
v	V	V	velocity
v	W	W	water
W	w	W	weight
w		W	well conditions
w	W	W	wetting
wD		WQ	water, dimensionless
wF		WFU	water/fuel
wa		WA	wellbore, apparent (usually with wellbore radius, r_{wa})
wb		WB	water from burned volume (usually with displacement ratio, δ_{wb})
wf		WF	bottomhole, flowing (usually with pressure or time)
wf	f	WF	well, flowing conditions (usually with time)
wg		WG	water in gas cap (usually with saturation, S_{wg})
wg		WG	wet gas (usually with composition or content, C_{wg})
wgp		WGP	wet gas produced
wh	th	WH	wellhead
wo		WO	water/oil (usually with instantaneous producing water/oil ratio, F_{wo})
wop		WOP	water/oil, produced (cumulative) (usually with cumulative water/oil ratio, F_{wop})
ws		WS	static bottomhole (usually with pressure or time)
ws	s	WS	well, static, or shut-in conditions (usually with time)
xo		XO	flushed zone
Y		Y	Young's modulus, refers to
z		Z	conductive liquids in invaded zone
z			zone, conductive invaded

Subject Index

A

- Abandonment pressure, 39-8, 39-10, 39-11, 39-14, 39-16, 39-23, 40-8, 40-10, 40-16, 40-24, 40-33, 40-34
- Abandonment time, 41-21 to 41-23, 41-27
- ABC transaction, 41-8, 57-7
- Abrasion-resistant coatings, 11-6
- Abrasive jet cleaning, 56-1
- Abrasive well fluids, 6-34
- Absolute open flow, 33-6 to 33-10, 34-33, 34-35
- Absolute ownership,
 - control, 57-2
 - definition, 57-1
 - theory, 57-1
- Absolute permeability, effect of temperature on, 46-37, 46-38
- Absolute pipe roughness, 15-4, 34-2, 34-24, 34-27
- Absolute viscosity, definition, 22-13
- Absolute zero, definition, 20-1
- Absorbed dose, unit and definition, 58-10, 58-23, 58-36
- Absorption, 26-11, 39-27
- Absorptive interactions, 50-9
- Abstract of API manual, 17-3 to 17-8
- Abstracts examination, 57-9
- Acceleration head, 6-50, 6-51
- Accelerometer, 53-4
- Accessory equipment for liquid hydrocarbon metering systems, 17-4
- Accounting method of valuation, 41-16, 41-17, 41-19, 41-22 to 41-24
- Accumulator, 18-13 to 18-15, 18-50, 18-51
- Accuracy and rounding of numbers, 58-5, 58-6
- Accuracy, of bubblepoint pressure
 - correlations, 22-8, 22-9
 - of Organick-Golding correlation, 21-15
 - vs. precision, 58-8, 58-9
- Acentric factor, 20-13
- Acetic acid (HAc), as sequestering agent, 54-7
 - in acidizing, 54-3, 54-8, 54-10
- Acetylene water system, 25-24
- Acid,
 - concentration, effect on limestone dissolved, 54-2
 - emulsions, 54-8
 - major types for acidizing, 54-1
 - primary requirements for acidizing, 54-1
 - solubility test, 54-11
 - solution of limestone in, 54-2
 - strength, estimated in field, 54-3
 - treatment design, 54-9 to 54-11
- Acid additives,
 - alcohols, 54-8
 - corrosion inhibitors, 54-6
 - gelling and fluid-loss agents, 54-8
 - iron-control agents, 54-7, 54-8
 - liquefied gases, 54-8
 - retarded acids, 54-8
 - sequestering agents, 54-7
 - silicate-control agent, 54-7
 - surfactants, 54-6, 54-7
 - thickeners, 54-8
- Acid concentration, effect on acid reaction rate, 54-5
- Acid fracturing, 54-8, 54-9
- Acid gases removal, 14-21, 14-22
- Acid-in-oil emulsion, 54-8
- Acid inhibitor, 54-10
- Acid number, 47-19, 47-23
- Acid penetration of matrix, 54-10
- Acid reaction rates, factors affecting,
 - acid concentration, 54-5
 - area/volume ratio, 54-5
 - flow velocity, 54-5
 - formation composition, 54-6
 - pressure and temperature, 54-4, 54-5
- Acid solubility, 54-6
- Acid solubility tests, 54-9
- Acid-soluble scales, 54-6, 56-2
- Acid solvent, 56-2
- Acid strength, 54-2
- Acid-swallowable synthetic polymers, 54-10
- Acid-thickening additives, 54-8
- Acid treatment design,
 - fracture acidizing—carbonate formations, 54-11
 - matrix acidizing—carbonate formations, 54-10, 54-11
 - matrix acidizing—sandstone formations, 54-11
- Acids used in acidizing, 54-1 to 54-4
- Acidizing,
 - acid reaction rates, 54-4 to 54-6
 - additives, 54-6 to 54-8
 - critical wells, 54-11, 54-12
 - general principles, 54-1 to 54-4
 - general references, 54-12 to 54-14
 - introduction, 54-1
 - laboratory testing, 54-9
 - references, 54-12
 - solutions, 54-3
 - summary, 54-12
 - techniques, 54-8, 54-9
 - treatment design, 54-9 to 54-11
 - well treatment, 6-3, 35-4, 56-3
- Acme thread profiles, 2-1, 2-38
- Acoustic array logging, 51-25
- Acoustic array sonde, 51-27, 51-28
- Acoustic backup system, 18-15, 18-16
- Acoustic beacons, 18-21
- Acoustic energy, 51-1, 51-11, 51-20, 51-24, 51-41
- Acoustic impedance, 51-46, 51-47
- Acoustic intensity, 51-3
- Acoustic log correlation, 51-30
- Acoustic log vs. core analysis porosity, 51-32
- Acoustic logging,
 - acoustic wave propagation in rocks, 51-4 to 51-11
 - acoustic wave propagation methods, 51-11 to 51-14
 - applications, 51-28
 - conclusions, 51-47, 51-48
 - elasticity, 51-1 to 51-4
 - introduction, 51-1
 - methods of recording acoustic data, 51-14 to 51-28
 - nomenclature, 51-48
 - references, 51-50 to 51-52
 - theory of elastic wave propagation in rocks, 51-49, 51-50
- Acoustic logs, 41-8, 51-30 to 51-33, 51-37, 51-38
- Acoustic positioning beacons, 18-10
- Acoustic properties of rock, 51-4, 51-5
- Acoustic signal transmission system, 18-3
- Acoustic telemetry, 53-1
- Acoustic transit (travel) time, 51-16 to 51-33, 51-35, 51-39, 51-40, 51-45, 51-47, 53-1
- Acoustic velocities, 34-45, 34-46, 51-29, 51-31, 51-43
- Acoustic velocity log, 51-5
- Acoustic wave propagation in rock,
 - acoustic properties, 51-4, 51-5, 51-43
 - borehole modeling, 51-25

 - temperature, 51-7
 - texture, 51-8 to 51-11
 - understanding of, 51-48
- Acoustic wave propagation logging, 51-27
- Acoustic wave propagation methods,
 - in fluid-filled borehole, 51-12
 - introduction to, 51-11
 - reflection, 51-2
 - transmission, 51-2
- Acoustic wave propagation properties, 51-1
- Acoustic wave train analysis, 27-1
- Acoustic waveform, 51-12, 51-14, 51-18, 51-24, 51-26, 51-27, 51-40 to 51-43, 51-45, 51-47, 51-48
- Acoustic waves,
 - characteristics, 51-3
 - compressional, 51-2
 - information contained in, 51-18
 - shear, 51-2
 - transit time of, 51-29, 51-30
- Acoustical survey, 5-40, 49-1
- Acoustical well sounder, 30-7
- Acoustics, units and conversions, 58-36
- Acquisition and acquisition costs, 41-13, 41-15
- Acre-feet diagram, 40-4
- Acrylamide polymer, 44-39
- Activated aluminas, 14-21
- Activation energy, 46-12
- Activation gamma ray, 50-3
- Activity coefficient of water, 25-3
- Activity coefficient plot, 25-4
- Activity of radionuclide, unit and definition, 58-10, 58-23
- Actuator ratio, 3-27
- Actuator specifications, 3-27
- Ad valorem taxes, 39-27, 41-1, 41-4, 41-7, 41-9, 41-12
- Adapter, 3-9, 3-39
- Adapter flange, 3-8, 3-9, 3-13
- Adaptive implicit formulation, 48-14
- Adiabatic horsepower, 34-42, 34-44, 34-45
- Adjustable choke, 5-54, 14-3
- Adjustment factors, critical flow prover, 33-13 to 33-15
- Administration and supervision costs, 41-12
- Administrator of an estate, definition, 57-3
- Adsorption approach, statistical mechanics for, 25-5
- Adsorption cycle, 14-10
- Adsorption dehydration unit, 14-20
- Adsorption ion exchange, 48-5
- Adsorption rate of an emulsion, 19-5
- Adsorption reaction, Darcy's law, 26-11

- Advanced Ocean Drilling Program, 18-15
- Advantages, of batch-type meters, 32-10, 32-11
- of gas lift, 5-1, 5-2
- of positive-displacement meters, 32-11, 32-12
- of SI units, 58-9
- Adverse mobility ratio waterfloods, 48-11
- Adverse possession, 57-2
- Aeolian dune sandstones, 36-4
- Aerobic bacteria, 24-16, 24-17
- After breakthrough performance, 44-20 to 44-25

 Boiling point,
 cubic average, 21-12, 21-15
 definition of types of, 21-11, 21-12
 mean average, 21-11, 21-15
 molal average, 21-6, 21-11, 21-13 to 21-15, 21-17
 molar distribution of SCN groups, 39-11
 of hydrocarbons, 19-7
 of six refrigerants, 14-10
 volumetric average, 21-11, 21-12
 vs. K-value, 39-12
 Boise sandstone, 51-8, 51-9
 Boll-weevil casing hanger, 3-6
 Boll-weevil tubing hanger, 3-9
 Bolted steel tanks, 11-1 to 11-3, 11-6, 11-9, 11-11
 Bonding conditions, cement, 51-40 to 51-42
 Bonus, oil and gas lease, 57-4, 57-7
 Booster application, ESP, 7-2, 7-3
 Booster pump, 15-17, 44-47
 Borehole acoustic measurements, 51-28, 51-29, 51-44, 51-45, 51-47, 51-48
 Borehole-compensated (BHC) acoustic log, 51-15
 Borehole-compensated device, 50-15
 Borehole-compensated sonde, 51-15
 Borehole-compensated sonic log, 49-15, 51-16, 51-17, 51-24, 51-26, 51-30, 51-32, 51-37
 Borehole-compensated sonic tool, 49-32
 Borehole-compensated sonic travel time, 51-22
 Borehole-compensated transit time, 51-21
 Borehole configuration, 53-16, 53-17
 Borehole corrections, IL, 49-18
 Borehole, fluid-filled, acoustic wave propagation in, 51-12 to 51-14
 Borehole geometry, 51-19, 51-28
 Borehole geometry log, 53-17
 Borehole geophysical devices, 58-25
 Borehole measurement of transit times, 51-26
 Borehole reflection method, 51-46
 Borehole size effects, 51-19
 Borehole televiewer, 51-27 to 51-29, 51-41, 51-46, 53-17
 Borehole televiewer log, 51-46 to 51-48
 Boron, 24-4, 24-5, 24-12, 50-6, 50-11, 50-12, 50-14, 50-32, 50-36
 Borosilicate glass, 24-4
 Boscan field, Venezuela, 6-24, 10-18
 Bottle tests, 19-10, 19-15
 Bottom discharge application, ESP, 7-2, 7-3
 Bottom gas lift valve, selecting, 5-26
 Bottom intake application, ESP, 7-2, 7-3
 Bottom-seating holddown, 8-3
 Bottom-seating stationary-barrel rod pumps, 8-8
 Bottom-unloading gas lift valve, 5-51
 Bottomhole assembly (BHA), 6-3 to 6-6, 6-31, 6-39
 Bottomhole bumper spring, 5-52, 5-53
 Bottomhole collar lock, 5-52
 Bottomhole GOR, 37-23, 37-24
 Bottomhole pressure (BHP):
 gas wells, 34-3 to 34-27
 gas-condensate wells, 34-27, 34-28
 gas injection wells, 34-28 to 34-30
 liquid injection wells, 34-28
 Bottomhole pressure buildup analysis, 40-27
 Bottomhole pressure calculations,
 by Cullender-Smith method, 34-25, 34-26
 by Sukkar-Cornell method, 34-9 to 34-24
 flowing gas wells, 34-23, 34-24
 gas-condensate wells, 34-27
 static gas well, 34-8, 34-9
 Bottomhole pressure gauge, 31-1
 Bottomhole pressure instruments, 30-1 to 30-6, 30-15
 Bottomhole pressure, steamflood, 46-17
 Bottomhole pressures, 30-1 to 30-15
 Bottomhole test adapter, 3-13
 Bottomhole valve temperature, 5-46
 Bottom-water, 24-2
 Bottomwater drive, 40-15, 41-10, 48-4
 Bounded reservoirs, shape factors, 35-5
 Bounding additive, 46-19
 Bourdon tube, 13-38, 13-56, 16-4, 16-7, 30-1, 30-2, 30-4, 30-6, 30-7, 31-1
 Box and pin entrance threads, extreme-line casing joint, 2-64, 2-69, 2-70
 Box and pin subcoupling, 9-4
 Boyle's law, 20-1, 20-2, 26-6, 26-7, 27-1, 30-8
 Boyle's-law-type porosimeter, 26-4, 26-6
 Bradford field, Pennsylvania, 24-1, 24-2, 44-1, 44-4, 47-22
 Brake horsepower, 10-9, 10-17, 10-19
 Brazil, 12-2, 12-21, 46-3, 46-4, 58-20
 Brea field, California, 46-16, 46-18, 46-24, 46-25
 Brea-Olinda field, California, 46-15, 47-22
 Breakdown pressures, 44-3, 44-46, 56-1
 Breakthrough of free gas, 40-10
 Breakthrough of gas, 40-14
 Breakthrough of inert gas, 39-17
 Breakthrough of polymer, 44-40
 Breakthrough of water, 40-18, 40-19, 44-4, 44-7, 44-9, 44-11, 44-12, 44-14, 44-15, 44-34
 Breakthrough sweep efficiency, 44-15, 44-16, 44-25
 Breast mooring system, 18-2
 Breathing losses in tanks, 11-12, 11-13
 Breccia, 29-8
 Bridge plugs, 55-9
 Bridging in flow channels, 54-11
 Brightness of emulsions, 19-5
 Brine displacement of product method of solution mining, 11-13, 11-14
 Brine/oil ratios, 47-14
 Brine salinity, 47-3 to 47-5, 47-10, 47-11, 47-13, 47-21
 Brinnell hardness, 2-2, 2-37, 9-5
 British Commonwealth countries, 1-69
 British imperial gallon, 1-69, 1-70
 British system of weights and measures, 1-69, 1-70
 Bromide, 19-10, 24-9, 24-12, 24-18, 24-20
 Bromine, 24-5, 24-20, 24-21
 Brownscombe-Collins method of water-drive predictions, 38-9
 Bubble flow, 34-36 to 34-39
 Bubble Reynolds number, 34-38, 34-39
 Bubble rise coefficient, 34-38, 34-39
 Bubble rise velocity, 34-38, 34-39
 Bubble size range of foams, 47-8
 Bubblepoint curve, 20-2
 Bubblepoint equation, constants for, 22-8
 Bubblepoint liquid, definition, 22-21
 Bubblepoint of a system, definition, 22-20
 Bubblepoint of crude, 6-21
 Bubblepoint pressure, 6-39, 22-1, 22-5 to 22-9, 22-11, 22-12, 22-21, 23-3, 23-11, 24-12, 24-14, 24-15, 34-31, 34-33, 34-34, 35-2, 37-1, 37-3, 37-5, 37-6, 37-8 to 37-10, 37-15, 37-22, 39-6, 40-6, 40-7, 40-10 to 40-13, 40-19, 44-5
 Bubblepoint pressure correlations,
 accuracy, 22-8
 empirical, 21-9, 21-10
 Lasater, 22-5 to 22-7
 Standing, 22-5
 Vasquez and Beggs, 22-7, 22-8
 Bubblepoint pressure factor, 22-7
 Bubblepoint viscosity, 22-16
 Buckley-Leverett calculations, 48-1
 Buckley-Leverett equation, 28-3
 Buckley-Leverett frontal-drive method, 40-13
 Buckling,
 of ice, 18-39
 of pipe, 18-37
 of tubing string, 4-9, 4-10
 Buildup curve, 30-9 to 30-13, 30-15
 Buildup test, 35-4, 35-14 to 35-16, 35-19
 Bulk density, 50-1 to 50-4, 50-7, 50-8, 50-17, 50-26 to 50-28, 50-30, 50-33, 51-14, 51-37
 Bulk modulus, 6-55, 51-1, 51-2, 51-4, 51-14, 51-43, 51-44, 51-49
 Bulk pore compressibilities, 51-43
 Bulk volume (BV), 26-1 to 26-7, 26-22, 27-1, 37-11
 Bumper subs, 18-13, 18-14, 18-18
 Bundle of capillary tubes model, 28-12
 Buoyancy effect, 2-2, 13-51, 18-2, 18-15 to 18-17, 18-24, 18-25, 18-29, 18-37, 18-49, 24-2
 Buoyancy, effect on water-drive recovery, 40-20
 Buoyancy method of gravity measurements, 52-19, 52-20
 Burbank unit, Oklahoma, 44-41

Bureau of Land Management, 57-12
 Buried bar with shale drape, 53-12, 53-13
 Burners for emulsion-treating equipment, 19-28
 Butane as IC engine fuel, 10-16
 Butterfly charts, 49-28
 Butterfly diagram, 24-19
 Butterfly valve, 13-58
 Buttress-thread casing and coupling, 2-1, 2-5, 2-7, 2-9, 2-11, 2-13, 2-15, 2-17, 2-19, 2-29 to 2-31, 2-57 to 2-61, 2-63, 2-64
 Buttress thread profile, 2-38
 Bypass valve, 13-59

 Partial penetration, 35-4
 Partial pressure maintenance, 42-3, 43-9 to 43-17
 Partial pressure of gas, 20-4
 Partial water drive, 39-24
 Partial water-drive reservoir, 40-6
 Partially scaled models, high-pressure, 46-13 physical types, 46-11, 46-12 vacuum, 46-13
 Particle reactions, 50-5, 50-6
 Particle-size distribution, 26-2, 44-45
 Partition, 57-2
 Past performance analysis, gas pressure maintenance, 43-9
 Pattern effects on waterflooding, 44-29
 Pattern efficiency, 44-15, 44-18, 45-6, 45-8 to 45-10
 Pattern ($h\phi S$ -weighted) efficiency, 39-15, 39-17, 39-18, 39-20 to 39-23, 39-26
 Pattern floods, 46-1
 Pattern injection, 43-2
 Pattern selection, thermal recovery, 46-17
 Pattern types in firefloods and steamfloods, 46-18
 Payout, 41-3, 41-35, 41-36
 Payout schedule, 41-31
 Peace River field, 46-34
 Peak crank torque, 9-2, 9-3
 Peak polished-rod load, 9-2
 Peak torque, 10-26
 Pendular rings, 26-24
 Penetration of acid, 54-8
 Peng-Robinson equation, 20-8, 23-13
 Penn State arrangement, 28-5
 Pennsylvania, 18-1, 21-2, 24-1, 24-2, 24-6, 24-7, 44-1, 44-4, 47-22
 Pennsylvania Oil Producers, 17-1
 Penultimate layer, 36-4
 Percent factor, assigned spacing design line, 5-33
 Percent-load design method, 5-42
 Percent-load intermittent-gas-lift installation designs, 5-44
 Percent-load production pressure, 5-48
 Percent-tubing-load installation design, 5-48
 Percentage depletion, 57-11
 Percentage-depletion allowance, 41-5, 41-13, 41-14
 Percentage factor, gas lift, 5-32
 Percentage-time controller, 16-4
 Percentage timer, 10-28
 Percussion-sampling techniques, 27-9
 Percussion sidewall core data, 27-9
 Perforated-interval completion, 5-51
 Perforating gun, 53-26
 Perforating operations, 51-40
 Perforating pipe, 56-1
 Perforation ball sealers, 54-10
 Perforation cleaning methods, backflow, 56-5 backsurging, 56-5 HCl preflush, 56-5 matrix acid stimulation, 56-5 matrix treatment with acid, 56-5 overflush, 56-5 perforation washing, 56-5 underbalance, 56-5
 Perforation, sand control, 56-4, 56-5
 Perforation tunnels, 56-1, 56-4, 56-5, 56-8
 Perforation washing, 56-5
 Perforations, locating, 53-26
 Performance calculations, reciprocating pumps, 6-28 to 6-30
 Performance characteristics, jet pumps, 6-34

Performance coefficient, of backpressure equation, 33-5 to 33-10, 33-12
 of refrigerants, 14-11
 Performance curves, abandonment contour vs. cumulative oil, 40-34 cumulative gas vs. cumulative oil, 40-32, 40-33 improved recovery reserves, 40-34 material balance method for nonassociated gas reservoirs, 40-33, 40-34 of jet pump, 6-35, 6-36, 6-38, 6-41 to 6-43, 6-46, 6-47 of tubing and choke, 34-5 oil percentage in total fluid vs. cumulative oil, 40-32 water/oil contact (WOC), 40-34
 Performance evaluation of rigs, 18-7, 18-8
 Performance factors for motors, cyclic load, 10-25 efficiency, 10-25 power, 10-25 service, 10-25, 10-26 slip, 10-23, 10-24 speed variation, 10-24, 10-25 temperature rise, 10-26 torque, 10-25
 Performance indicators, common to both steamfloods and firefloods, changes in oil property, 46-15 oil recovery, 46-14, 46-15 sweep efficiency, 46-14 pertaining to firefloods only, air/oil ratio (AOR), 46-17 air requirements, 46-16 fuel content, 46-16 pertaining to steamfloods only, steam/oil ratio (SOR), 46-15
 Performance of solution-gas-drive reservoirs, 37-1, 37-2
 Performance predictions, models, 37-19 of micellar-polymer flooding, 47-17 of oil and gas reservoirs, 36-9, 36-10 of solution-gas drive, 37-14 to 39-18 of volatile oil reservoir, 37-22 to 37-26
 Performance profiles, 5-20, 5-21
 Performance properties, of casing, 2-1, 2-4 to 2-19, 2-32 of pipe, 2-46, 2-54 to 2-56 of tubing, 2-38 to 2-43
 Performance technique for reserve estimation, 40-1
 Performance-time predictions, 43-9, 43-10
 Performax plate pack, 19-13
 Periodic inspection of separators, 12-40
 Periodic production tests, 12-17
 Peripheral flood, 44-2, 44-13, 44-17, 44-36
 Permafrost, 18-38, 18-39, 18-41 to 18-43
 Permafrost cement, 18-41
 Permafrost problem, 3-27
 Permanent packers, 4-1 to 4-6, 4-8
 Permeability-block method, 40-19, 40-20, 40-24, 40-26
 Permeability, calculations, 26-16 changes, effect on radial flow, 54-9 consideration in waterflooding, 44-2 conversion of units in Darcy's law, 26-13 to 26-15 correlation with tube-wave data, 51-48 damage, 30-13, 30-14 definition of, 27-1, 28-1, 55-1 distribution, 26-26, 36-3, 36-7, 39-16, 39-18 to 39-20, 40-12, 40-18 to 40-20, 40-24, 40-25, 44-8, 44-15, 45-11, 45-12 distribution factor, 40-16, 40-17

- effective, 26-15, 28-1 to 28-4, 28-6, 28-8, 28-13, 39-17, 44-32, 44-33, 46-21
- factors affecting measurement, 26-18, 26-19
- factors in evaluation of, 26-19, 26-20
- flow systems of simple geometry, 26-11 to 26-13

 - evaluation from acoustic log, 51-30
 - factor to consider in waterflooding, 44-2, 44-3
 - index, 49-38
 - introduction, 26-1, 26-2
 - investigation, 49-26
 - laboratory measurement of, 26-3 to 26-7
 - logs, 49-11, 51-29, 51-31, 51-32
 - measurement comparisons, 26-6
 - methods of determining, 26-4, 26-5
 - of consolidated rocks, 51-29 to 51-32
 - of poorly consolidated rocks, 51-33, 51-34
 - of secondary porosity, 51-31, 51-33
 - of shaly sand, 51-34, 51-35
 - profile, 36-4
 - Rocky Mountain method, 49-31, 49-32
 - velocity relationship, 51-5
- Porosity determination,
 - bulk-density measurement, 50-1, 50-2
 - gamma-gamma density devices, 50-26 to 50-28
 - neutron-porosity devices, 50-28 to 50-33
- Porous-diaphragm method of capillary-pressure measurement, 26-24, 26-25
- Porous diaphragm or membrane, 26-24
- Porous reservoir models, 44-17
- Port configurations, gas-lift valve, 5-15
- Port size, selection for gas-lift valves, 5-28
- Port-to-bellows area ratio, 5-15
- Portable well testers, 32-6 to 32-8
- Portland cement, 46-19
- Portugal, 58-20
- Position-sensing valve switch, 16-3
- Positive-depth indicator, 56-5
- Positive-displacement meter, 12-6, 12-18, 12-19, 16-2, 16-5 to 16-7, 16-12, 17-4 to 17-6, 32-6 to 32-8, 32-10 to 32-12
- Positive-displacement meter, measurement of petroleum liquid hydrocarbons by, 17-4
- Positive-displacement-meter prover tanks, tables, 17-6
- Positive-displacement-meter-type LACT system, 16-13
- Positive-displacement pumps, 6-1, 6-34, 6-49 to 6-51, 6-62, 13-54, 15-14, 15-17, 28-4, 44-47
- Positive-seal double-bag model, 7-11
- Positive-seal protector, 7-4, 7-5

- Positive-volume dump meters, 16-13
 Positive-volume meters, 16-2, 16-5, 16-7
 Possible reserves, definition, 40-4
 Posted barges, 18-2
 Potassium, 24-5, 24-9, 24-18, 24-20, 50-2 to 50-4, 50-16, 50-18, 50-24 to 50-27, 50-34, 50-35
 Potassium chloride for control of clay swelling, 46-20
 Potential distribution, 39-20
 Potential energy, 6-1, 6-34, 13-1, 13-2, 34-28, 34-29, 34-36
 Potential function, 26-11
 Potential gradient, 26-11, 39-21
 Potential of a process, 13-50
 Potential tests, 12-17, 41-19
 Potential tests of oil wells, 32-1 to 32-16
 Potentiometric model, 39-21, 39-22, 44-17, 44-19, 44-34
 Potentiometric model studies, 39-20, 39-21
 Potentiometric transducer, 30-5, 30-6
 Poth "A" sand, 46-29 to 46-32
 Pothead, 7-5
 Pounding, 6-33, 6-34
 Pour point, 21-7, 21-9, 21-10, 46-27, 46-31, 46-33
 Power cable, ESP, 7-5, 7-6
 Power control manifold module, 6-54, 6-56
 Power, definition of, 6-14
 Power-distribution system, offshore, 18-45
 Power equivalents, table, 1-78
 Power-factor correction, 10-35
 Power factor of motor, 10-25, 10-33 to 10-35
 Power fluctuations, ESP, 7-14
 Power fluid, 6-1 to 6-5, 6-9, 6-10, 6-20, 6-21, 6-24 to 6-30, 6-34, 6-37, 6-38, 6-41, 6-42, 6-48, 6-51, 6-60, 6-62
 Power-fluid discharge-pressure friction, 6-27
 Power-fluid flow through nozzle, 6-42
 Power-fluid friction, 6-30
 Power-fluid friction pressure, 6-27
 Power-fluid gradient, 6-25, 6-26, 6-29, 6-30
 Power-fluid pressure, 6-7, 6-9, 6-16 to 6-18, 6-25, 6-27, 6-28, 6-41 to 6-43
 Power-fluid systems, 6-54 to 6-57
 Power-fluid tubing friction pressure, 6-42
 Power-fluid tubing string, 6-2, 6-3
 Power-law coefficient, 47-4, 47-9
 Power-law model, 47-4, 55-5
 Power method for parameter determination, 48-16
 Power-oil emulsion, 6-31
 Power-oil plunger pumps, 6-33
 Power-oil tank and accessories, closed system, 6-59
 open system, 6-57 to 6-59
 Power stroke, 10-14
 Power supplies, uninterruptible (UPS's), 18-45
 Power triangle of motor, 10-33 to 10-35
 Power, unit and definition, 58-11, 58-23, 58-24, 58-32
 Powers of numbers, three-halves table, 1-19, 1-20
 Powers of numbers, two-thirds table, 1-20
 Powers of SI units, 58-12
 Pozzolan, 46-19
 Precision of gas meter, 13-1
 Precision vs. accuracy, 58-8, 58-9
 Predicted reservoir performance, 42-5, 42-6
 Pre-exponential factor, 46-12
 Preferred metric unit, 58-21, 58-26 to 58-38
 Preflush, hydrochloric acid, 56-5
 micellar-polymer flooding, 47-10, 47-16
 systems, 56-3
 PREOS, 25-8, 25-9, 25-16
 Preparation of well for testing, 33-6
 Present value or present worth, 41-3 to 41-8, 41-12, 41-16, 41-17, 41-23, 41-25, 41-27, 41-29, 42-6
 Present-worth factor, 41-25
 Present worth of an annuity, table, 1-66
 Pressure and force in static plunger and cylinder assembly, 6-18
 Pressure, average drainage-region, 35-19, 35-20
 Pressure-balanced valves, 13-55
 Pressure-base factor, 13-3, 13-12
 Pressure behavior, constant rate in closed reservoir, 35-2, 35-3
 Pressure bombs, 30-4
 Pressure-buildup analysis, 39-18, 39-19
 Pressure-buildup behavior, 30-14
 Pressure-buildup data, 6-48
 Pressure-buildup tests, 42-3, 42-4, 48-8
 Pressure changes in wellbore, calculations including, 46-6
 Pressure-composition phase diagram, 23-2, 23-3, 23-6, 23-8, 23-9
 Pressure control for high-pressure well, 13-56
 Pressure controls, separators, 12-39
 Pressure conversions, 58-7, 58-28, 58-29
 Pressure correction for gas viscosities, 20-9
 Pressure decline, rapid, 37-1, 37-2
 Pressure dependence, of compressional- and shear-wave attenuation, 51-6
 of compressional- and shear-wave velocities, 51-5
 of porosity, 51-6
 Pressure depletion, 26-21, 39-7 to 39-16, 39-23, 39-24, 39-26, 44-1
 Pressure-depletion behavior, 39-4
 Pressure-depletion operation of GC reservoir, hydrocarbon/liquid-condensation effect, 39-13
 prediction with laboratory-derived data and hydrocarbon analysis, 39-10, 39-11
 prediction with vapor/liquid equilibrium calculation and correlation, 39-11 to 39-13
 pressure drawdown at wells, effect on productivity and recovery, 39-13
 relative merits of measured vs. calculated behavior, 39-13, 39-15
 Pressure-depth diagram, 5-21
 Pressure distribution, 35-6, 44-17, 44-30
 Pressure drawdown, 6-48, 34-31, 34-34, 35-6, 37-2, 37-19 to 37-21, 48-10
 Pressure drop, across sand-filled perforations, 56-4
 in flowing gas column, 34-9
 in gas lines, 15-5, 15-7
 in liquid lines, 15-2, 15-3
 in tubing, 6-70, 6-71
 Pressure, effect on acid-reaction rate, 54-4, 54-5
 effect on gas-saturated crude oils, 22-16
 effect on tubing string, 4-9
 Pressure equivalents, table, 1-77
 Pressure evaluation, 52-26 to 52-28
 Pressure filters, 44-47
 Pressure for hydrate formation, 25-8
 Pressure, force and flow in dynamic plunger and cylinder assembly, 6-18
 Pressure function, 34-35, 37-8
 Pressure gauges, 12-42
 Pressure gradient, 2-39, 34-29, 38-13, 39-21, 41-3, 41-6, 41-16
 Pressure-gradient curves, 34-36
 Pressure-gradient traverse, 5-25
 Pressure-hydrometer test method, 17-5
 Pressure hysteresis, 48-10
 Pressure-loaded balanced diaphragm valve, 13-56
 Pressure log, 52-1, 52-26
 Pressure maintenance, 23-1, 40-4, 40-14, 43-11 to 43-16, 48-2, 48-4
 Pressure-maintenance operations, 18-44, 34-28, 43-1 to 43-3, 43-8
 Pressure maintenance or cycling of GC reservoirs, choosing between, 39-26
 combination recovery procedures, 39-24
 reservoir cycling, gas injection, 39-16 to 39-24
 water drive and water injection, 39-15, 39-16
 Pressure-multiplier pump, 55-9
 Pressure-operated gas-lift valve, 5-24
 Pressure, optimum of separator, 12-4
 Pressure/permeability data, 44-3
 Pressure pilot, 13-56
 Pressure/production history, 37-3, 37-6
 Pressure profiles, 4-6, 35-4
 Pressure pulses, 53-1
 Pressure radius, 44-33
 Pressure range, GC reservoirs, 39-2
 Pressure rating classes of fittings, 15-13
 Pressure ratings for steel pipe, 15-11
 Pressure ratio, 6-36, 6-37, 6-45
 Pressure recorders, 6-48
 Pressure-recording charts, two-pen, 5-18, 5-23, 5-39, 5-41
 Pressure-reducing regulator, 5-13, 12-39
 Pressure-reducing valve, 13-55
 Pressure reduction in gas analysis, 52-17
 Pressure-reduction regulation, 13-54
 Pressure regulators, 13-54
 Pressure relationships used to estimate producing BHP, 6-28
 Pressure relief of storage tanks, 11-7
 Pressure-relief valve, 6-51, 11-8, 11-9, 12-39, 19-28
 Pressure ridges, 18-39
 Pressure-sensing instrument (PSI), 7-7, 7-8
 Pressure shock loads, 12-42
 Pressure, SI unit for, 58-5, 58-11, 58-23 to 58-25, 58-28, 58-29
 Pressure storage of products, 11-12
 Pressure, surface closing, gas lift valves, 5-44 to 5-46
 Pressure surveys, 5-2
 Pressure switches, 16-4
 Pressure/temperature diagram, 14-2
 Pressure/temperature phase diagram, 23-6
 Pressure/temperature rating of steel, 3-38
 Pressure-transducer technology, 30-6 to 30-8
 Pressure transducers, 46-21
 Pressure-transient behavior, 35-4
 Pressure-transient tests, 5-3
 Pressure transition zone, 52-21
 Pressure traverses, 34-36, 34-41 to 34-44, 41-41 to 41-44
 Pressure/vacuum relieving system, 11-13
 Pressure/vacuum valves, 11-8, 11-9
 Pressure/volume (PV), compressibility, 51-49
 diagram for pure components, 20-2
 equilibrium cell, 20-4
 method for waterflood water requirements, 44-41
 relation, 20-2, 20-6, 39-7
 Pressure-volume-temperature (PVT), analysis, 22-1, 22-2, 22-10, 22-12, 10-21
 cell, 39-13

 Unit of weights and measures, definition of, 1-68
 Unit operations, 57-7, 57-8
 Unit pressure of fluid columns, 6-22, 6-23
 Unit-recovery equation,
 depletion recovery factors, 40-10 to 40-12
 depletion-type reservoir, 40-8
 dry-gas reservoir, 40-25
 Muskat's method, 40-9
 Tarnier's method, 40-9, 40-10
 water-drive reservoir, 40-16
 Unit-recovery factor, 40-16, 40-18, 40-19, 40-24
 Unit recovery for gas reservoir without water drive, 40-24
 Unit response function, 35-8, 35-9
 United Geophysical, 51-1
 United States (U.S.), 1-68 to 1-71, 9-8, 12-38, 12-39, 17-4, 18-3, 18-18, 18-20, 18-23, 18-25, 18-46, 24-1, 24-2, 24-6, 24-21, 36-2, 39-16, 40-16, 41-12, 44-1, 44-4, 51-1, 52-22, 52-26, 52-30
 U.S. areas, core-analysis data from, 27-9
 U.S. Beaufort Sea, 18-3
 U.S. Bureau of Mines (USBM), 1-80, 33-1, 33-3
 USBM BHP gauge, 30-1
 U.S. Bureau of Standards, 21-8
 U.S. bushel, 1-69, 1-70
 U.S. Coast Guard jurisdiction, 18-44
 U.S. customary units, 58-9
 U.S. Dept. of Interior, 57-11
 U.S. DOE, 21-9, 45-1
 U.S. gallon, 1-69, 1-70
 United States Geological Survey (USGS), 3-39, 41-9
 U.S. Government, 53-5
 U.S. gulf coast area, 24-7, 24-8, 24-17
 U.S. Metric Board, 1-69
 U.S. Mineral Management Service, 18-5
 U.S. Natural Gas Policy Act of 1978, 57-10
 U.S. Navy, 18-4
 U.S. oil production by EOR, 46-3
 U.S. OCS Orders, 18-46, 18-47
 U.S. Prototype Kilogram No. 20, 1-69, 1-70
 U.S. sieve number, 56-6, 56-7
 U.S. survey foot, 1-69
 U.S. system of weights and measures, 1-69, 1-70
 U.S. Tax Reduction Act of 1975, 57-11
 U.S. Weather Bureau, 31-2
 Unitization agreements, 41-9, 57-8
 Unitization, definition of, 57-7

Unitization of tank batteries, 32-7
 Unitized BOP stack, 18-12
 Unitized pressure-energized secondary seal, 3-6
 Uitorque geometry, 10-4
 Units and names to be avoided, 58-5
 Units and systems of weights and measures,
 British and U.S. systems, 1-69, 1-70
 relative density and density, 1-80
 standards of, 1-70, 1-71
 subdivision of units, 1-70
 tables of, 1-71 to 1-80
 the metric system, 1-68, 1-69
 unit and standard definitions, 1-68
 Universal rails, motor mounts, 10-19
 U. of Houston, 50-15
 Unloading and loading sucker rods, 9-10
 Unloading daily production rate, 5-23
 Unloading flowing-pressure traverse, 5-28, 5-32
 Unloading flowing-temperature-at-depth traverse, 5-32
 Unloading gas-lift valve, 5-55
 Unloading gas-lift valve depths, 5-51
 Unloading gas-lift valve temperature, 5-46, 5-48
 Unloading intermittent-spacing-factor traverse, 5-45, 5-46
 Unloading procedure, gas lift, 5-53 to 5-55
 Unloading temperature traverse, 5-46
 Unrecoverable oil, 44-11
 Unsegregated reservoir, 37-5
 Unstable properties, sample for determining, 24-4
 Unsteady-state methods of relative-permeability measurement, 28-3, 28-10, 28-12, 28-14
 Upflow filters, 15-20
 Upkicking, 6-31
 Upset configuration, 9-2
 Upstream taps, 13-26 to 13-29, 13-33, 13-34, 13-37
 Uranium, 24-16, 50-2 to 50-4, 50-15, 50-16, 50-23 to 50-27, 50-34, 50-35
 Urethane jacket, 18-49
 Utah, 24-8, 24-20, 24-21, 46-16, 46-30, 46-31, 46-33, 46-34
