Mist Flow. In *mist flow* the slip between the gas and liquid phases is essentially zero. The fraction of gas flowing can be expressed, therefore, as

$$f_g = \frac{q_g}{q_g + q_L} \quad (114)$$

Average flowing density is given by

$$\bar{\rho} = (1 - f_g)\rho_L + f_g\rho_g \quad (115)$$

The friction loss gradient for mist flow is primarily a result of the gas phase and is given by

$$\tau_f = \frac{f\rho_g v_{gs}^2}{2g_c d_H \cos\theta} \quad (116)$$

where v_{gs} is the superficial gas velocity and f is a function of the gas Reynolds number,

$$N_{Re} = 1488 \frac{\rho_g d_H v_{gs}}{\mu_g} \quad (117)$$

and a modified relative roughness factor, ϵ/d_H , which was developed by Duns and Ros. The roughness factor for mist flow is a function of the liquid film wetting the pipe walls and is given by the following set of equations and constraints. Let

$$N = 4.52(10^{-7})(v_{gs}\mu_L/\sigma)^2(\rho_g/\rho_L) \quad (118)$$

where N is a dimensionless number. Then for $N < 0.005$,

$$\frac{\epsilon}{d_H} = \frac{34\sigma}{\rho_g v_{gs}^2 d_H} \quad (119)$$

and for $N > 0.005$,

$$\frac{\epsilon}{d_H} = \frac{174.8\sigma(N)^{0.302}}{\rho_g v_{gs}^2 d_H} \quad (120)$$

Eqs. 119 and 120 are limited by upper and lower bounds for ϵ/d_H of 0.001 and 0.05.

Camacho³¹ studied 111 wells with high gas/liquid ratios and concluded that Orkiszewski's method performed better when mist flow calculations were used for gas/liquid ratios greater than 10,000. Obviously, if this approach is taken, an appropriate transition zone between slug and mist flow should be used to avoid abrupt pressure gradient changes. In another study, Gould *et al.*²⁷ also indicate that the onset of mist flow should occur at lower dimensionless gas velocities, especially for dimensionless liquid velocities less than 0.1.

Continuous-Flow Gas Lift Design Procedures

Gas lift^{28,33,37} is a method of artificial lift that uses the compressional energy of a gas to lift the reservoir fluid (see Chap. 5). The prime requisite is an adequate source of gas at a desired pressure and volume.

Wells having high water/oil ratios (WOR) and high productivity indices (that is, producing large volumes of fluid with high sustaining reservoir pressures) can be efficiently gas lifted through the tubing or the well annulus. Quite often it is necessary to produce very large volumes of water to obtain economic rates of oil production. Situations are known where it is possible to gas lift economically as much as 5,000 to 10,000 B/D total fluid, with the oil present being 1% of the total fluid produced and the rest being water. In applying the correlations to gas lift design calculations, the following procedure is recommended.

1. Establish the flow characteristics of the well—i.e., productivity index, WOR, gas/oil ratio (GOR), fluid properties, tubing size, etc.
2. Calculate the pressure traverses below the injection point for the range of flow rates.
3. Calculate the pressure traverses above the point of injection for different injection GOR's, holding the surface tubing or casing pressure constant.

From these three steps, as illustrated in Fig. 34.10, the horsepower requirements, pressure at injection point, depth of injection, and injection GOR's for a given rate of production, tubing size, and tubing or casing pressure can be calculated.

For a given set of well conditions and fluid production, there is an optimum depth and injection pressure that result in minimum horsepower requirements. In some cases, the optimal injection depth will be at the total depth of the well. There are two ranges of operation in gas lifting a reservoir fluid. One is an inefficient range characterized by high GOR and high horsepower requirements, and the other is an efficient range characterized by low GOR and low horsepower requirements. A plot of GOR vs. injection pressure is shown in Fig. 34.11.

In the inefficient range of operation, gas literally is "blown" through the flow string. The efficient range is to the left of the minimum injection pressure, and the inefficient range to the right. Inefficient and efficient ranges of operation have been observed in the laboratory on experimental gas lift involving short lengths of tubing.³⁸⁻⁴⁰ One investigator used a large amount of field data from a California field to develop empirically curves similar to those shown in Fig. 34.11 but had no way of predicting these curves for other fields where the physical properties of the fluids and the production data were different.⁴¹ In a plot of horsepower requirement vs. injection pressure (Fig. 34.12) the horsepower generally passes through a minimum value, which represents the maximum efficiency of the operation. Another interesting result of these gas lift calculations has been to show that the lower the surface pressure of the flow string that can be maintained consistent with efficient surface operations, the less will be the horsepower required to lift the reservoir fluid.

The use of the calculation procedure can best be expressed by use of a typical example problem.⁴²

Example Problem 9. It is desired to gas lift a well by flowing through the annulus. The well has a productivity index of 10.0 bbl total liquid per day per psi pressure drop. The static reservoir pressure is 3,800 psia at a well depth of 10,000 ft. The WOR is 18.33. Other pertinent information is as follows.

Fig. 34.10—Pressure traverse in gas-lift well.

Fig. 34.11—Effect of injection pressure on injection GOR.

Tubing ID (2½ in. nominal, 6.5 lbm/ft)=2.441 in.; tubing OD (2½ in. nominal, 6.5 lbm/ft)=2.875 in.; casing ID (7 in. nominal, 26 lbm/ft)=6.276 in.; casing pressure=100 psia; average flowing temperature in annulus above injection depth=155°F; average flowing temperature in annulus below injection depth=185°F; average flowing temperature in tubing=140°F; gravity of stock-tank oil at 60°F=0.8390; gravity of separator gas (air=1.0)=0.625; gravity of produced water=1.15; $B=0.0000723p+1.114$; $R_s=0.1875p+17$; and $R=600$ cu ft/bbl oil.

Fig. 34.12—Effect of injection pressure on horsepower requirements.

Calculate the variation of injection GOR with injection pressure and injection depth for a total liquid production rate of 4,000 B/D. Calculate the horsepower requirements to lift the oil as a function of injection pressure.

The solution of the problem involves the following steps.

1. Calculate the pressure traverse below the point of gas injection.
2. Calculate the pressure traverses above the point of gas injection for various GOR's.
3. Solve 1 and 2 simultaneously to determine the depth of injection for various injection GOR's and a casing pressure of 100 psia.
4. Calculate the theoretical adiabatic horsepower required to compress the gas from 100 psia to the injection-point pressure.

The first step in the solution of this problem is the calculation of the flowing density of the three-phase fluid produced into the well as a function of the pressure. Using Fig. 34.13, the differential pressure gradients were determined as a function of fluid density and, therefore, pressure. These calculations are illustrated in Table 34.6. These results then were placed on a plot of dD/dp vs. p . The depth traveled by the fluid flowing from the BHP to any lower pressure was determined by integrating this curve. In this way, Curve A in Fig. 34.14 was determined.

The second step of the solution was carried out mechanically the same as the first step, with the exceptions that the fluid densities were calculated for injection GOR's of 3,000, 3,500, 4,000, 5,000, and 7,500 scf/bbl, and that the integrations were carried out from the wellhead casing pressure of 100 psia to the pressures farther down the casing. The results of these calculations are shown in Fig.

Fig. 34.13—Calculation of pressure traverses for flow in annulus. Tubing size is 2½ in. nominal (6.5 lbm/ft, 2.441-in. ID, 2.875-in. OD). Casing size is 7.0 in. nominal (26 lbm/ft, 6.276-in. ID).

TABLE 34.6—CALCULATION OF THE PRESSURE TRAVERSE BELOW THE POINT OF GAS INJECTION

$$q_o = \frac{4,000}{19.33} = 206.9 \text{ B/D}$$

$$q_o m = 1.594 \times 10^6 \text{ lbm/D}$$

$$\rho = \frac{m}{V_m} = \frac{7701.5}{5.61B + \frac{18.29(600 - R_s)}{p/z} + 102.8} \text{ lbm/cu ft}$$

34.14 as curves B, C, D, E, and F. The intersections of these curves with Curve A represent the injection points for these flow rates and injection GOR's.

The injection GOR is plotted as a function of the injection pressure at injection depth in Fig. 34.15. For the conditions of this example problem, it will be noted that the injection pressure continually decreases as the GOR is increased from 3,000 to 7,500 scf/bbl. Fig. 34.16 shows the relationship between injection depth and injection GOR. This plot shows that, as the injection GOR is decreased, the point of injection is moved down the hole.

**Fig. 34.16—Injection depth vs. injection GOR.**

Fig. 34.17—Horsepower vs. injection pressure.

Fig. 34.17 shows the theoretical adiabatic horsepower required to compress the injected gas from the surface pressure to the injection pressure. For the conditions of this problem, the minimum horsepower is required when the injection point is at the bottom of the well, although, as pointed out in the earlier discussion, it is theoretically possible to obtain minimum horsepower requirements at points other than at the bottom of the hole.

The literature reports an interesting series of well tests in which curves calculated by the procedure described above completely characterize the gas lift performance

Fig. 34.18—Equipment arrangement.

of the well tested.⁴³ Fig. 34.18 shows the physical installation of the well tested. Tests were conducted at two points of gas injection, 3,800 and 4,502 ft. Detailed descriptions of the tests are available from Ref. 43.

Figs. 34.19 and 34.20 show a comparison of the observed and calculated pressure traverses above the point of gas injection. The comparison indicates good agreement.

Fig. 34.21 shows a comparison of observed data with curves calculated for average well conditions of total liquid flow vs. rate of gas injection.

Fig. 34.19—Calculated and field-measured pressure traverses— injection depth is 4,502 ft.

Fig. 34.20—Calculated and field-measured pressure traverses— injection depth is 3,810 ft.

Fig. 34.21—Total liquid flow vs. rate of gas injection.

Fig. 34.22 is an example of a very useful type of plot that can be calculated for the optimum conditions of lift. It is a plot of ideal adiabatic horsepower per barrel per day of total fluid produced vs. total barrels of fluid produced per day under the conditions as indicated. Horsepower as used here is the horsepower required to compress the injected gas between the tubing pressure and injection pressure.

Flow Through Chokes

A wellhead choke or "bean" is used to control the production rate from a well. In the design of tubing and well completions (perforations, etc.), one must ensure that neither the tubing nor perforations control the production from the well. The flow capacity of the tubing and perforations always should be greater than the inflow performance behavior of the reservoir. It is the choke that is designed to control the production rate from a well. Wellhead chokes usually are selected so that fluctuations in the line pressure downstream of the choke have no effect on the well flow rate. To ensure this condition, flow through the choke must be at critical flow conditions; that is, flow through the coke is at the acoustic velocity. For this condition to exist, downstream line pressure must be approximately 0.55 or less of the tubing or upstream pressure. Under these conditions the flow rate is a function of the upstream or tubing pressure only.

For single-phase gas flow through a choke, the following equation is used:

$$q_g = \frac{Cp}{\sqrt{\gamma_g T}} \quad (121)$$

where

p = upstream pressure, psia,

γ_g = gas gravity,

T = upstream or wellhead temperature, °R,

C = coefficient, and

q_g = flow rate measured at either 14.4 or 14.7 psia and 60°F, 10^3 cu ft/D.

Fig. 34.22—Horsepower requirements vs. total fluid produced.

The coefficient, C , will vary depending on the base pressure.

Table 34.7 presents values of C taken from Rawlins and Schellhardt.⁴⁴ These values are for a standard pressure of 14.4 psia. Rawlins and Schellhardt did not make corrections for deviation from ideal gas. Correction can be made to Eq. 121 by multiplying the right side of the equation by $\sqrt{1/z}$, where z is the compressibility factor of the gas at the upstream pressure p and temperature T .

In the case of multiphase flow, Gilbert developed the following empirical equation based on data from flowing wells in the Ten Section field of California relating oil flow, GOR, tubing pressure, and choke size.⁴⁵

$$p_{tf} = \frac{435 R_{gL}^{0.546} q_l}{S^{1.89}} \quad (122)$$

where

p_{tf} = tubing flowing pressure, psig,

R_{gL} = gas/liquid ratio, 10^3 scf/bbl,

q_l = gross liquid rate (oil and water), B/D, and

S = choke size in 1/64 in.

Gilbert's equation may be written in the form:

$$p_{tf} = A q_l \quad (123)$$

TABLE 34.7—
COEFFICIENTS FOR
CHOKE NIPPLE

Orifice size (in.)	C
1/8	0.125
3/16	0.188
1/4	0.250
5/16	0.313
3/8	0.375
7/16	0.438
1/2	0.500
5/8	0.625
3/4	0.750

where $A = 435R_{gL}^{0.546}/S^{1.89}$ and where the tubing pressure is proportional to the production rate. This is true only under conditions of acoustic flow through the choke. At low flow rates, the rate is also a function of the downstream pressure and Eq. 123 no longer holds.

Ros presented a theoretical analysis on the mechanism of simultaneous flow of gas and liquid through a restriction at acoustic velocity.^{46,47} The result was a complex equation relating mass flow of gas and liquid, restriction size, and upstream pressure. Ros' equation was checked against oilfield data under critical flow conditions with good results. However, the equation is expressed in a form not really amenable to use by oilfield personnel.

Using Ros' analysis, Poettmann and Beck converted Ros' equation to oilfield units and reduced it to graphical form.⁴⁸ The result was Figs. 34.23 through 34.25 for oil gravities of 20, 30, and 40°API. The 20° gravity chart should be used for gravities ranging from 15 to 24°API; similarly, the 30° chart should be used for gravities ranging from 25 to 34°, and the 40° chart for gravities ranging from 35° on up. The charts are not valid if there is appreciable water production with the oil.

The charts can be entered from either the top or bottom scale. When entering from the GOR scale, go first to the tubing pressure curve and then horizontally to the choke size curve and then read the oil flow rate from the top scale. Conversely, when entering the chart at the oil flow rate scale, the reverse order is followed. Reliable estimates of gas rates, oil rates, tubing pressures, and choke sizes can be made by using these charts.

Chokes are subject to sand and gas cutting as well as asphalt and wax deposition, which changes the shape and size of the choke. This, then, could result in considerable error when compared to calculated values of flow for a standard choke size. A small error in choke size caused by a worn choke can effect a considerable error in the predicted oil rate. Thus, a cut choke could result in estimated oil rates considerably lower than measured.

From the inflow performance relationship of a well and by knowing the tubing size in the well, the tubing pressure curve for various flow rates can be calculated. The intersection of the choke performance curve for different choke sizes with the tubing pressure curve then gives one the wellhead pressures and flow rates for any choke size, as illustrated in Fig. 34.26.

Example Problem 10.⁴⁸

1. Determine the flow rate from a well flowing through a $\frac{5}{64}$ -in. choke at a flowing tubing pressure of 1,264 psia and a producing GOR of 2,250 cu ft/bbl. Stock-tank gravity is 44.4°. From Fig. 34.25, the solution is 60 B/D oil.

2. For this example, estimate the free gas present in the tubing. The solution gas at a tubing pressure of 1,264 psia from Fig. 34.25 is $R_s = 310$ cu ft/bbl. Then, the free gas present is $R - R_s = 2,250 - 310$ or 1,940 cu ft/bbl of oil at the wellhead.

3. It is desired to produce a well at 100 B/D oil. The producing GOR is 4,000 cu ft/bbl. At this rate the tubing pressure is 1,800 psia. Estimate choke size.

All three charts show estimated choke size to be $\frac{5}{64}$ in. Gilbert's charts also give $\frac{5}{64}$ in.⁴⁵

A number of other choke design correlations have been suggested. However, Poettmann and Beck's adaption of the Ros equation is recommended when no water is pro-

duced with the oil, and Gilbert's equation can be used when water is present.

Liquid Loading in Wells

Liquid loading in wells occurs when the gas phase does not provide sufficient transport energy to lift the liquids out of the well. This type of well does not produce at a flow rate large enough to keep the liquids moving at the same velocity as the gas. The accumulation of liquid will impose an additional backpressure on the formation that can affect the production capacity of the well significantly. Initially, the occurrence of liquid holdup may be reflected in the backpressure data obtained on a well wherein at the lower flow rates its performance, expressed as a backpressure curve, is worse than expected. Eventually, the well is likely to experience "heading" (fluctuating flow rates) followed by "load up" and cease to produce. Methods sometimes used to continue production from "loading" wells are pumping units, plunger lifts, smaller-diameter tubing, soap injection, and flow controllers.

This section is directed mainly toward relating loading to flow conditions within the well. In the simplest context, loading, as reflected on a deterioration of flow performance at lower flow rates on a backpressure curve, is related to the superficial velocity of the gas in the conduit at wellhead conditions. Duggan⁴⁹ found that a velocity of 5 ft/sec would keep wells unloaded whereas Lisbon and Henry⁵⁰ found that 1,000 ft/min (16.7 ft/sec) could be required.

R.V. Smith⁵¹ reported that experience with low-pressure wells in the West Panhandle and Hugoton fields showed that a velocity of 5 to 10 ft/sec is necessary to remove hydrocarbon liquids consistently and a velocity of 10 to 20 ft/sec is required for water.

Turner *et al.*⁵² analyzed the problem of liquid holdup on the basis of two proposed physical models: (1) liquid film movement along the walls of the pipe and (2) liquid droplets entrained in the high-velocity core. They concluded, on the basis of comparisons with field data, that the entrained drop movement was the controlling mechanism for removal of liquids. Their results indicated that in most instances wellhead conditions were controlling and the fluid velocity required to remove liquids could be expressed by the following equation.

$$v_f = \frac{20.4\sigma^{0.25}(\rho_L - \rho_g)^{0.25}}{\rho_g^{0.5}}, \dots\dots\dots (124)$$

where

v_f = terminal velocity of free-falling particle,
ft/sec,

σ = interfacial tension, dynes/cm,

ρ_g = gas phase density, lbm/cu ft, and

ρ_L = liquid phase density, lbm/cu ft.

Using simplifying assumptions with respect to gas, condensate, and water properties as given in Table 34.8, Eq. 124 can be expressed for water as

$$v_{gw} = \frac{5.62(67 - 0.0031p)^{0.25}}{(0.0031p)^{0.5}} \dots\dots\dots (125)$$

(continued on Page 34-50)

Fig. 34.23—Simultaneous gas/oil flow through chokes.

and for condensate as

$$v_{gc} = \frac{4.02(45 - 0.0031p)^{0.25}}{(0.0031p)^{0.5}}, \dots\dots\dots (126)$$

where

v_{gw} = gas velocity for water, ft/sec,
 v_{gc} = gas velocity for condensate, ft/sec, and
 p = pressure, psi.

Further, a minimum flow rate for a particular set of conditions (pressure and conduit geometry) can be calculated using Eqs. 125 through 127.

$$q_g = \frac{3.06pv_gA}{Tz}, \dots\dots\dots (127)$$

where

q_g = gas flow rate, 10^6 scf/D,
 A = flow area of conduit, sq ft,
 T = temperature, °R, and
 z = gas deviation factor.

Tek *et al.*⁵³ introduced a concept called “the lifting potential” to explain loading, unloading, heading, and dying of wells. Further, the concept relates the inflow behavior of the well with the multiphase flow in the well. Accordingly, it appears possible to address engineering considerations directed toward performance analysis or design of well equipment. Calculation procedures described earlier in this chapter with respect to well inflow performance and multiphase flow in the well should be adaptable to use the lifting potential concept.

Chapter 35

Well Performance Equations

R.A. Wattenbarger, Texas A&M U.*

Introduction

This chapter summarizes the equations that apply to the performance of a well in a reservoir. The equations are used to calculate the relationship between rate and pressure of a well and the properties of the fluids and formation. These equations apply only in the "drainage area" of the well and do not describe the entire reservoir performance, except for the case of a single-well depletion reservoir. For more complete treatment of the entire reservoir performance, refer to Chap. 37—Solution-Gas-Drive Oil Reservoirs, Chap. 38—Waterdrive Oil Reservoirs, or Chap. 39—Gas Condensate Reservoirs.

There have been several excellent references developed over the past few years on well pressure behavior.¹⁻⁷ These are much more detailed than this chapter and the reader should be aware of them. This chapter is a brief summary of this technology.

Diffusivity Equation

The equations that relate pressure and rates for a well are solutions of the diffusivity equation. This equation can be written as

$$\nabla^2 p = \frac{1}{0.000264} \frac{\phi \mu c_t}{k} \frac{\partial p}{\partial t}, \quad \dots \dots \dots (1)$$

where

- p = pressure, psi,
- ϕ = porosity of reservoir rock, fraction,
- μ = fluid viscosity, cp,
- c_t = total compressibility of system (see Eq. 5),
psi⁻¹,
- k = permeability of reservoir rock, md, and
- t = time, hours.

The vector notation used on the left side of the equation has the following meaning. In one dimension (1D),

$$\frac{\partial^2 p}{\partial x^2} = \frac{1}{0.000264} \frac{\phi \mu c_t}{k} \frac{\partial p}{\partial t}, \quad \dots \dots \dots (2a)$$

where x is the distance coordinate in a one-dimensional flow system, ft. In two dimensions (2D),

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} = \frac{1}{0.000264} \frac{\phi \mu c_t}{k} \frac{\partial p}{\partial t}, \quad \dots \dots \dots (2b)$$

where x and y are distance coordinates in a 2D flow system, ft. In radial coordinates,

$$\frac{\partial^2 p}{\partial r^2} + \frac{1}{r} \frac{\partial p}{\partial r} = \frac{1}{0.000264} \frac{\phi \mu c_t}{k} \frac{\partial p}{\partial t}, \quad \dots \dots \dots (2c)$$

where r is the radius in radial flow system, ft.

Eq. 2c gives the most useful solution of the diffusivity equation for reservoir and well performance.

The geometry of the reservoir is in cylindrical coordinates with an inner radius, r_w , into which the fluid flows at a constant rate and an outer boundary, r_e , which is closed and represents the outer boundary of the reservoir. The solutions of this cylindrical coordinate problem have been presented by van Everdingen and Hurst⁸ and are presented again in Chap. 38.

Eq. 1 is a linear partial differential equation that models how pressure changes with location and time. Theoretically, solutions of Eq. 1 are valid only for reservoirs where the fluid and rock properties are constant. The application of the solutions of Eq. 1, then, are literally applicable for fluids with constant compressibility and

* Author of the original chapter on this topic in the 1962 edition was Ralph F. Neilsen.

Fig. 35.1—Pressure behavior for constant rate in a closed reservoir.

viscosity and for formations with constant permeability. These conditions are very nearly met in the case of aquifer flow or for oil reservoir flow at pressures above the bubblepoint. The solutions of Eqs. 1 and 2 can be extended to multiphase reservoir flow for most practical cases.

Multiphase Flow

When more than one phase exists in the reservoir, it is still possible to write the differential equation in a form similar to Eq. 1. This equation was presented by Martin⁹ as

$$\nabla \left(\frac{k}{\mu} \right) \nabla p = \frac{1}{0.000264} \phi c_t \frac{\partial p}{\partial t} \quad (3)$$

This equation shows that the conditions of homogeneity are not necessarily met. The concepts of total mobility, $(k/\mu)_t$, and total compressibility, c_t , are introduced.

The total mobility is the sum of the individual phase mobility as follows.

$$\left(\frac{k}{\mu} \right)_t = \frac{k_o}{\mu_o} + \frac{k_g}{\mu_g} + \frac{k_w}{\mu_w} \quad (4)$$

TABLE 35.1—ANALOGIES OF SINGLE-PHASE VALUE TO MULTIPHASE EQUIVALENT

Single-Phase Value	Multiphase Equivalent
k/μ	$(k/\mu)_t$
c	c_t
qB	$q_t B_t$

where

- k_o = effective permeability to oil, md,
- k_g = effective permeability to gas, md,
- k_w = effective permeability to water, md,
- μ_o = oil viscosity, cp,
- μ_g = gas viscosity, cp, and
- μ_w = water viscosity, cp.

The total compressibility is the volumetrically weighted average of the compressibilities of the fluids and pore space as follows.

$$c_t = c_f + S_o c_o + S_g c_g + S_w c_w \quad (5)$$

where

- c_f = formation compressibility, psi^{-1} ,
- S_o = oil saturation, fraction of pore volume (PV),
- c_o = oil compressibility, psi^{-1} ,
- S_g = gas saturation, fraction of PV,
- c_g = gas compressibility, psi^{-1} ,
- S_w = water saturation, fraction of PV, and
- c_w = water compressibility, psi^{-1} .

The flow rate also must be expressed in terms of the equivalent total flow rate for multiphase flow. The expression for total reservoir flow rate is

$$q_t B_t = q_o B_o + (1,000 q_g - R_s q_o) B_g / 5.615 + q_w B_w \quad (6)$$

where

- q_t = total reservoir flow rate, STB/D,
- B_t = total formation volume factor, RB/STB,
- q_o = oil flow rate, STB/D,
- B_o = oil formation volume factor, RB/STB,
- q_g = gas flow rate, Mscf/D,
- R_s = solution gas-oil ratio, scf/STB,
- B_g = gas formation volume factor, res cu ft/scf
- q_w = water flow rate, STB/D, and
- B_w = water formation volume factor, RB/STB.

Martin's equation is a nonlinear partial differential equation. Therefore the general case does not have analytical solutions. However, for practical purposes, Eqs. 3 through 6 can be used for most well performance equations if the meaning of the mobility, compressibility, and flow rate are taken in this general three-phase sense. The single-phase solutions of Eq. 1 can be applied to the multiphase case by using the analogies given in Table 35.1.

Oil Well Performance

Well Pressure Performance—Closed Reservoir

The performance of a constant-rate well in a closed reservoir (of any geometry or heterogeneity) has the general form shown in Fig. 35.1.

The lower curve of Fig. 35.1 shows that the wellbore flowing pressure, p_{wf} , goes through a rapid pressure drop

at early (transient) times and then flattens out until it reaches a constant slope. On this coordinate plot, the closed-reservoir, constant-rate case has the properties

$$\frac{\partial p_{wf}}{\partial t} < 0$$

and

$$\frac{\partial^2 p_{wf}}{\partial t^2} \geq 0.$$

When p_{wf} reaches a straight line on the coordinate plot, the period of *pseudosteady state* has been reached. Every pressure point in the reservoir declines at the same constant rate of depletion after that time. Of particular importance is the decline of the average reservoir pressure, \bar{p}_R , which assumes the pseudosteady-state depletion rate from the very beginning of production.

The constant slope of Fig. 35.1 is valid only for constant-compressibility single-phase fluid. However, the general concept of the transient period and the pseudosteady-state period is the same for a multiphase flow with changing compressibilities. The \bar{p}_R slope would be changing according to the changes in compressibility, and the \bar{p}_R curve after a pseudosteady-state would not be exactly parallel to the p_{wf} curve. This nonideal behavior would be typical of a solution gas drive reservoir or a dry gas reservoir where the compressibility and mobilities are continually changing. The infinite-acting solutions and the pseudosteady-state solutions to follow are still ap-

Fig. 35.2—Typical constant-rate drawdown test graph.

plicable for the multiphase flow case by using the analogies in Table 35.1. The value of \bar{p}_R , however, must be calculated by the material balance method that applies for this case.

Infinite-Acting Solution (MTR)

The pressure behavior of constant-rate flow in a closed reservoir goes through several periods: the early-time region (ETR), middle-time region (MTR), and late-time region (LTR). These periods are illustrated on a semilog plot of p_{wf} vs. $\log t$ in Fig. 35.2. The MTR solution is discussed first.

Eq. 1 can be solved for the infinite-reservoir case, which is useful for application at early times. The solution applies to a well producing at constant rate, beginning at $t=0$, and a homogeneous reservoir of constant thickness.

Fig. 35.3—Dimensionless pressure for a single well in an infinite system, no wellbore storage, no skin. Exponential-integral solution.

There are two important solutions for the infinite-reservoir case. One solution⁸ assumes that the wellbore has a finite radius, r_w . This solution is used mostly for aquifer behavior with the oil field being the inner radius rather than a wellbore. This solution is given in Chap. 38 for the infinite-aquifer case.

A simpler solution applies for well behavior. This solution, called the "line-source" or "exponential-integral" solution, assumes that the wellbore radius, r_w , approaches zero. This solution has the form

$$p_D(r_D, t_D) = -\frac{1}{2} Ei\left(\frac{-r_D^2}{4t_D}\right), \quad \dots\dots\dots (7)$$

where

$$\begin{aligned} p_D &= kh(p_i - p)/(141.2 qB\mu) = \text{dimensionless pressure,} \\ r_D &= r/r_w = \text{dimensionless radius,} \\ t_D &= (0.000264kt)/\phi\mu c_i r_w^2 = \text{dimensionless time,} \\ h &= \text{formation thickness, ft,} \\ p_i &= \text{initial pressure, psi, and} \\ r_w &= \text{wellbore radius, ft.} \end{aligned}$$

The exponential-integral function, Ei , is a special function that results from the solution of the line-source problem. A more practical solution to the problem is the plot of the dimensionless p_D vs. t_D/r_D^2 , which is shown in Fig. 35.3. The t_D term is the dimensionless time based on external radius, r_e . Fig. 35.3 can be used to determine the pressure at any time and radius from the producing well. This solution is valid as long as the radius at which the pressure is calculated is greater than $20 r_w$ or at the wellbore of the producing well (at r_w) at a value of $t_D/r_D^2 > 10$.

Fig. 35.3 is used mostly to determine the pressure at distances away from the well such as at a nearby well location during an interference test.

The more common solution of the exponential integral solution is the "semilog straight line solution," which applies after t_D is greater than 100. After this time, Eq. 8 applies at the wellbore:

$$p_D = \frac{1}{2} \ln t_D + 0.4045. \quad \dots\dots\dots (8)$$

In customary oilfield units, this equation has the form

$$p_{wf} = p_i - m \left(\log \frac{kt}{\phi\mu c_i r_w^2} - 3.23 \right), \quad \dots\dots\dots (9)$$

where m equals $(162.6qB\mu)/kh$ and p_{wf} is the flowing bottomhole pressure, psi. This equation results in a semilog plot of p_{wf} vs. $\log t$ with a slope of $-m$ psi/cycle (the MTR of Fig. 35.2.)

Eqs. 7 through 9 are used for infinite-acting solutions before the effects of boundaries affect the pressure transient behavior. When the closest boundary begins affecting the behavior at the wellbore, this time is the end of the semilog straight line, t_{end} . The last column in Table 35.2 shows t_{end} for various drainage shapes (shape factors).

Skin Effect

The solutions to Eq. 1 are modified to account for formation damage near the wellbore. The damage near the wellbore can be considered concentrated into a very thin radius around the wellbore such that the thickness of the damage is insignificant but a finite pressure drop results from this damage.

Fig. 35.4 shows a sketch of the physical concept of the damaged region and Fig. 35.5 shows the pressure profile resulting from this damage.

The magnitude of the pressure drop caused by the skin effect Δp_s is

$$\Delta p_s = 0.87ms, \quad \dots\dots\dots (10)$$

where s is the skin effect, defined in terms of dimensionless pressure such that it would have the following effect on Eq. 8.

$$p_D = \frac{1}{2} \ln t_D + 0.4045 + s. \quad \dots\dots\dots (11)$$

The value of the skin effect is calculated from transient well test data such as a buildup test or a drawdown test. The exact nature of the cause of the skin effect might not be known but might be caused by a combination of several factors. Some of these factors are (1) mud filtrate or mud damage near the wellbore, (2) the cement bond, (3) limited perforations through the casing and cement bond, and (4) partial penetration (completion). On the other hand, the value of the skin effect, s , might be negative. This would indicate an improved wellbore condition, which might be caused by (1) improved permeability in the vicinity of the wellbore because of acidizing or other well treatments, (2) a vertical or horizontal hydraulic fracture at the wellbore, or (3) a wellbore at an angle rather than normal to the bedding plane.

The determination of the skin effect is important in determining the need for a workover or the benefits of a workover. The effect of the skin can be stated as a modification to the wellbore radius by calculating an effective wellbore radius, r'_w , calculated by

$$r'_w = r_w e^{-s}. \quad \dots\dots\dots (12)$$

This effective wellbore radius, r'_w , can be considered the equivalent wellbore radius in an undamaged or unimproved formation, which would have the same flow characteristics as the actual well with the skin effect.

Wellbore Storage Effect (ETR)

At very early times the fluid production tends to come from the expansion of the fluid in the wellbore rather than the formation. This tends to delay the production rate from the formation. The relationship between the surface production rate, the expansion of the wellbore fluids, and the formation production rate are shown in Eq. 13:

$$q_{sf} = q + \frac{24C_s}{B} \frac{\partial p}{\partial t}, \quad \dots\dots\dots (13)$$

Fig. 35.4—Radial flow model showing damaged zone.

where C_s equals $V_w c_{wf}$ and q_{sf} is the flow rate at the "sandface," STB/D and C_s is the wellbore storage constant, equal to the volume of the wellbore, V_w , times the wellbore fluid compressibility, c_{wf} .

The effect of the wellbore storage is to make the very early transient pressure behave as though it were reflecting production only from the wellbore fluid expansion. This pressure drop can be calculated from

$$p_i - p_{wf} = \frac{qB}{24C_s} t. \quad (14)$$

Note that this shows a linear relationship between Δp and time. Consequently, a p vs. t plot will be linear during the wellbore storage period. Also, a plot of $\log \Delta p$ vs. $\log t$ is a straight line with a slope of unity. This wellbore storage effect may last for just a few seconds or it may last for many hours—i.e., for a deep, low-permeability gas well that has a large storage volume in the wellbore, a high-compressibility gas, and great resistance to flow from the formation.

After a period of time, this wellbore storage solution gives way to the semilog straight line (for the radial flow case). The period between the linear relationship and the semilog straight line is from one to one and one-half cycles of $\log t$. Fig. 35.6 shows that Eq. 12 applies during ETR, then gives way to Eq. 11 during MTR.¹⁰ This log-log dimensionless plot has the same shape as a plot of $\log (p_i - p_{wf})$ vs. $\log t$. This is sometimes called a "type curve."

Pseudosteady-State Behavior (LTR)

After a well produces at constant rate for a period of time, the boundary effects interrupt the infinite-acting pressure behavior. If the well is in an irregularly shaped drainage area, the closest boundary to the well causes the earliest departure from the infinite-acting pressure solution. After a transition period, the well begins pseudosteady-state behavior. The pseudosteady-state behavior begins after the effects of the farthest boundary have been felt at the wellbore.

When pseudosteady-state behavior begins (see Fig. 35.2) the rate of pressure decline, $(\partial p / \partial t)_{pss}$, is constant

Fig. 35.5—Schematic of pressure distribution near wellbore.

at every point throughout the reservoir. This is a depletion period at which every point of the reservoir drops at a rate according to the pore volume, V_p , and compressibility of the drainage area, c_t .

$$\left(\frac{\partial p}{\partial t} \right)_{pss} = \frac{-0.234qB}{V_p c_t} \quad (15)$$

During pseudosteady-state behavior, wellbore pressure is related to the average reservoir pressure, \bar{p}_R , by a productivity index (PI), J , as follows.

$$q = J(\bar{p}_R - p_{wf}). \quad (16)$$

This PI equation relates the pressure drawdown to the production rate. For a circular drainage area we can write out the complete expression for the PI equation as

$$q = \left[\frac{7.08 \times 10^{-3} kh / (B\mu)}{\ln r_e / r_w - 0.75 + s} \right] (\bar{p}_R - p_{wf}), \quad (17)$$

where r_e is the exterior boundary radius, ft. Note that the quantity in brackets is equivalent to J in Eq. 16 for the circular drainage area. J is a constant if the viscosity and formation volume factor of the producing fluid are constant. If these fluid properties are not constant, Eqs. 16 and 17 still apply but the PI value changes with the changing fluid properties. For multiphase flow these equations still can be used by substituting the definition in Table 35.1 into Eqs. 16 and 17.

Eq. 17 has to be modified if the drainage area is not circular with the well in the center. A general form of the pseudosteady-state equation has been worked out by Dietz¹¹ and has been cited by other authors.¹⁻⁵ The generalized pseudosteady-state equation has the form

$$q = \left[\frac{7.08 \times 10^{-3} kh / (B\mu)}{\frac{2.2458}{C_A} \frac{A}{r_w^2} + s} \right] (\bar{p}_R - p_{wf}), \quad (18)$$

Fig. 35.6—Dimensionless pressure for a single well in an infinite reservoir including wellbore storage and a finite skin—composite reservoir.

where A is the drainage area, sq ft, and C_A is the shape factor (Table 35.2). This equation can be applied by using the values for C_A in Table 35.2 or by moving the terms in the denominator to the form

$$q = \left[\frac{7.08 \times 10^{-3} kh / (B\mu)}{\frac{1}{2} \ln \frac{2.2458}{C_A} + \frac{1}{2} \ln \frac{A}{r_w^2} + s} \right] (\bar{p}_R - p_{wf}) \quad (19)$$

This form is easier to use because the first term of the denominator also is tabulated in Table 35.2.

In Table 35.2, x_e is the distance from the well to the side of the square drainage area, and x_f is the distance from the well to either end of the vertical fracture. Table 35.2 also shows the dimensionless time, t_{DA} , at which the infinite-acting solution ends, and also the time at which pseudosteady state begins, $(t_{DA})_{pss}$.

Example Problem 1 (Transient and Pseudosteady State). A well is centered in an approximately square drainage area. The following data are given.

$$\begin{aligned} A &= 1.74 \times 10^6 \text{ sq ft (40 acres),} \\ h &= 21 \text{ ft,} \\ s &= 1.6, \\ r_w &= 0.25 \text{ ft,} \\ k_o &= 45 \text{ md,} \\ \mu_o &= 1.5 \text{ cp,} \\ \phi &= 0.18, \\ c_o &= 8.5 \times 10^{-6} \text{ psi}^{-1}, \\ c_w &= 3.2 \times 10^{-6} \text{ psi}^{-1}, \\ c_f &= 3.0 \times 10^{-6} \text{ psi}^{-1}, \\ S_w &= 0.25, \\ B_o &= 1.12, \text{ and} \\ p_i &= 5,100 \text{ psi.} \end{aligned}$$

Calculate the bottomhole pressure (BHP), p_{wf} , after 12 hours and after 120 days for a constant oil production rate of 80 STB/D.

Solution. From Eq. 5,

$$\begin{aligned} c_t &= c_f + S_o c_o + S_w c_w \\ &= [3.0 + (0.75)(8.5) + (0.25)(3.2)] \times 10^{-6} \\ &= 10.2 \times 10^{-6} \text{ psi}^{-1}. \end{aligned}$$

Calculate the time required to reach pseudosteady state. From Table 35.2,

$$(t_{DA})_{pss} = 0.1 = \frac{0.000264(45)t_{pss}}{(0.18)(1.5)(10.2 \times 10^{-6})(1.74 \times 10^6)},$$

where t_{pss} is 40.3 hours. So the well is infinite acting after 12 hours. By using Eq. 11,

$$p_D = \frac{1}{2} \ln t_D + 0.4045 + s.$$

By using the definitions of p_D and t_D in Eq. 8, we have

$$\begin{aligned} &\frac{(45)(21)(5,100 - p_{wf})}{141.2(80)(1.12)(1.5)} \\ &= \frac{1}{2} \ln \frac{0.000264(45)(12)}{(0.18)(1.5)(10.2 \times 10^{-6})(0.25)^2} + 0.4045 + 1.6; \\ &0.0498(5,100 - p_{wf}) = \frac{1}{2} \ln (8.28 \times 10^5) + 0.4045 + 1.6; \\ &5,100 - p_{wf} = (8.82)/(0.0498) = 177; \text{ and} \\ &p_{wf} = 4,923 \text{ psi at 12 hours.} \end{aligned}$$

Fig. 35.7—Schematic representation of a variable production-rate schedule.

At 120 days, the well is in pseudosteady state (greater than 40.3 hours). First, calculate \bar{p}_R . Using Eq. 15, the rate of pressure decline can be calculated.

$$\left(\frac{\partial p}{\partial t}\right)_{pss} = \frac{-0.234qB}{V_p c_t}$$

$$= \frac{-0.234(80)(1.12)}{(21)(0.18)(1.74 \times 10^{-6})(10.2 \times 10^{-6})}$$

$$= -0.313 \text{ psi/hr.}$$

$$\bar{p}_R = 5,100 - 0.313(120)(24)$$

$$= 4,199 \text{ psi.}$$

Now, using Eq. 19,

$$q_o = \left[\frac{7.08 \times 10^{-3} kh/(B\mu)}{\frac{1}{2} \ln \frac{2.2458}{C_A} + \frac{1}{2} \ln \frac{A}{r_w^2} + s} \right]$$

$$\cdot (\bar{p}_R - p_{wf});$$

$$(80) = \left[\frac{7.08 \times 10^{-3} (45)(21)/(1.12 \times 1.5)}{-1.3224 + \frac{1}{2} \ln \frac{1.74 \times 10^{-6}}{(0.25)^2} + 1.6} \right]$$

$$\cdot (4,199 - p_{wf});$$

$$(80) = \left[\frac{3.982}{-1.3224 + 8.571 + 1.6} \right] (4,199 - p_{wf});$$

$$4,199 - p_{wf} = 178; \text{ and}$$

$$p_{wf} = 4,021 \text{ psi at 120 days.}$$

Production Rate Variation (Superposition)

These solutions have included only the constant-rate case. Of general interest, of course, are the cases where rate changes with time. These cases are best handled by using the principle of superposition.

The principle of superposition amounts to dividing the production history into a sequence of rate changes such as that shown in Fig. 35.7. The total effect of the production on the pressure response, Δp , is the additive effects of each of the rate changes. In Fig. 35.7, rate q_1 applies from $t=0$ to the current time. At t_1 the rate increases to q_2 . The effect of this rate change can be viewed as an incremental rate, $q_2 - q_1$, which has been in effect for a period of time $t - t_1$. Then q_3 would also be seen as a rate change, $q_3 - q_2$, which has been in effect for a period of time $t - t_2$. The effect of all these rate changes is computed by superposing the solutions that applied to each rate change and its corresponding time that it has been in effect. The equation for computing the total pressure drop, Δp_i , is

$$p_i - p_{wf} = \sum_{i=1}^N (q_i - q_{i-1}) f(t - t_{i-1}) \dots \dots \dots (20)$$

when $q_{i-1} = 0$ when $i = 1$.

The function $f(t)$ can be called the *unit response function*. The unit response function is the pressure drop, $p_i - p_{wf}$, which occurs at time t for a unit production rate ($q=1$). The unit response functions may be quantified by the cases described such as the wellbore storage equation at early times (ETR), the semilog straight line solution at MTR, and finally the pseudosteady-state solution at later times (LTR). For example, if q_1 had been in effect for a time longer than t_{pss} , its contribution to the pressure drop at time t would be calculated from the pseudosteady-state equations, which would comprise the calculation of the reduction in \bar{p} from Eq. 15 and the pressure drop from \bar{p}_R to p_{wf} in Eq. 16. The effect of the second rate might be still in the transient period, which would call for Eq. 11 to be applied.

Note that the calculation of the pressure decline of \bar{p}_R can be calculated with Eq. 15 only for the constant-compressibility case. For the general case, such as a solution gas drive reservoir, the appropriate material balance equations would be applicable to calculate \bar{p}_R . If the last rate change has been in effect for a time greater than t_{pss} and the system has constant compressibility, the following simplification can be made for Eq. 15.

$$\bar{p}_R = p_i - \frac{5.615 N_p B_o}{V_p c_t} \dots \dots \dots (21)$$

The following example problem shows how superposition can be applied for a case where both pseudosteady-state and transient pressure drops are added.

Example Problem 2 (Superposition). The well in Example Problem 1 produces according to the following schedule.

time (hours)	q_o (STB/D)
0 to 2	300
2 to 8	120
thereafter	80

Calculate p_{wf} at 12 hours and at 120 days.

Solution. As we observed in Example Problem 1, the well was infinite acting after 12 hours, so we use Eq. 20.

$$p_i - p_{wf} = \sum_{i=1}^N (q_i - q_{i-1}) f(t - t_{i-1}).$$

We first need $f(t)$, the unit response function. We can use Eq. 11 to find Δp in terms of t for $q=1$:

$$p_D = \frac{1}{2} \ln t_D + 0.4045 + s,$$

$$\frac{(45)(21)\Delta p}{141.2(1)(1.12)(1.5)}$$

$$= \frac{1}{2} \ln \frac{0.000264(45)t}{(0.18)(1.5)(10.2 \times 10^{-6})(0.25)^2}$$

$$+ 0.4045 + 1.6,$$

$$3.98\Delta p = \frac{1}{2} \ln 6.90 \times 10^4 t + 2.004, \text{ and}$$

$$\Delta p = 0.1256 \ln(6.90 \times 10^4 t) + 0.504,$$

so

$$f(t) = \Delta p = 0.1256 \ln(6.90 \times 10^4 t) + 0.504.$$

Substituting into Eq. 20,

$$p_i - p_{wf} = (q_1 - q_0)f(t - t_0)$$

$$+ (q_2 - q_1)f(t - t_1)$$

$$+ (q_3 - q_2)f(t - t_2);$$

$$p_i - p_{wf} = (300 - 0)f(12 - 0)$$

$$+ (120 - 300)f(12 - 2)$$

$$+ (80 - 120)f(12 - 8),$$

so the values of $f(12)$, $f(10)$, and $f(4)$ are used, giving

$$5,100 - p_{wf} = (300)[0.1256 \ln(6.9 \times 10^4 \times 12) + 0.504]$$

$$- (180)[0.1256 \ln(6.9 \times 10^4 \times 10) + 0.504]$$

$$- (40)[0.1256 \ln(6.9 \times 10^4 \times 4) + 0.504]$$

$$= (300)(2.22)$$

$$- (180)(2.19)$$

$$- (40)(2.08)$$

$$= 189;$$

$$p_{wf} = 4,911 \text{ psi at 12 hours.}$$

At 120 days, the well has a cumulative production of

$$N_p = 300 \text{ STB/D} \times (2/24 \text{ days})$$

$$+ 120 \text{ STB/D} \times (6/24 \text{ days})$$

$$+ 80 \text{ STB/D} \times (119.5 \text{ days})$$

$$= 9,615 \text{ STB.}$$

Using Eq. 21,

$$\bar{p}_R = p_i - \frac{5.615 N_p B_o}{V_p C_t}$$

$$= (5,100) - \frac{5.615(9,615)(1.12)}{(21)(0.18)(1.74 \times 10^6)(10.2 \times 10^{-6})}$$

$$= 5,100 - 901 = 4,199.$$

Using Eq. 19 (the same as Example Problem 1), we calculate

$$\bar{p}_R - p_{wf} = 178,$$

and again,

$$p_{wf} = 4,199 - 178 = 4,021 \text{ psi at 120 days.}$$

The effect of the early rate variation is “forgotten” after the rate is constant for $t_{pss} = 40.3$ hours, except for the slight increase in cumulative barrels (15 STB), which is negligible in this case.

Gas Well Performance

The performance of gas wells is similar to oil wells (liquid reservoirs) except for two major differences: (1) the fluid properties of gas change dramatically with pressure and (2) flow can become partially turbulent near the wellbore, resulting in a rate-dependent skin factor. These two factors are discussed and alternative forms of gas performance equations are presented.

The application of these principles to gas flow is only slightly more complicated than to liquid flow, but there is often much confusion about gas wells. There are several reasons for this. One reason is that there are many versions of gas flow equations in the literature. Some are in terms of p , some in terms of p^2 , and some in terms of a real gas pseudopressure, $m(p)$. All these equations can be used and are valid forms. Another reason for confusion is the different coefficients in the equations, which sometimes arise from the assumed temperature and pressure base of a standard cubic foot of gas. The following equations use only the symbols T_{sc} and p_{sc} , since the pressure base in different areas does vary significantly.

Still another reason for confusion is that deliverability testing has been customary with gas wells because of government requirements. Deliverability testing, based on a $\log(p_R^2 - p_{wf}^2)$ vs. $\log q_g$ plot, is largely an empirical approach. The deliverability plot approach was developed mainly for low-pressure gas wells and does not work well with the deeper, higher-temperature, and higher-pressure wells that are more common today.

The Effect of Gas Properties

In the derivation of the diffusivity equation, the form of Eq. 1 is not achieved because the values of z and μ vary with pressure. Consequently the following form occurs in the derivation.

$$\nabla \frac{p}{z\mu} \nabla p = \frac{1}{0.000264} \frac{\phi}{k} \frac{\partial p}{\partial t}, \quad \dots \quad (22)$$

where z is the dimensionless gas-law deviation factor. This equation is a nonlinear partial differential equation and cannot be solved analytically by the methods applied to Eq. 1.

A method for "linearizing" the partial differential equation was developed by Al-Hussainy *et al.*¹² They introduced a *real gas pseudopressure*, which may be defined as

$$m(p) = 2 \int_0^p \frac{p}{z\mu} dp. \quad \dots \quad (23)$$

This pressure-dependent function integrates the variations of p , z , and μ with pressure. When this function is introduced into the derivation of the diffusivity equation, the diffusivity equation for a real gas takes the form

$$\nabla^2 m(p) = \frac{1}{0.000264} \frac{\phi \mu c_g}{k} \frac{\partial m(p)}{\partial t}. \quad \dots \quad (24)$$

This equation still is not quite a linear differential equation because μ and c_g vary significantly with pressure.

The gas compressibility, c_g , can be expressed in terms of z as

$$c_g = \frac{1}{p} - \frac{1}{z} \frac{dz}{dp}. \quad \dots \quad (25)$$

For practical purposes, however, Eq. 23 can be taken as a linear differential equation in terms of $m(p)$. This was confirmed by the result of computer simulations performed by Wattenbarger and Ramey.¹³ They showed that the pressure transient equations can be used, with very good approximation, in terms of $m(p)$. After pseudo-steady-state, PI equations similar to Eqs. 16 through 19 can be used.

The application of the $m(p)$ solutions is not difficult. The values of $m(p)$ vs. p can be determined by graphical integration or can be calculated with computer programs that use built-in correlations to estimate the variation of z and μ with pressure.

Since our equations and graphical techniques depend on equations of a straight line of p either on a linear plot or a semilog plot, it is worth analyzing how the slopes of $m(p)$ are related to the slopes of p plots, or p^2 plots; we can show that the derivative of $m(p)$ with respect to, for example, $\log t$ is as follows.

$$\frac{\partial m(p)}{\partial(\log t)} = \left(\frac{2p}{z\mu} \right) \frac{\partial p}{\partial(\log t)} = \left(\frac{1}{z\mu} \right) \frac{\partial p^2}{\partial(\log t)}. \quad \dots \quad (26)$$

These relationships indicate that an $m(p)$ plot, or a p plot, or a p^2 plot can be used and then the relationships in Eq. 26 applied. The $m(p)$ plot is preferable because it is most likely to have the proper semilog straight line. The p and p^2 plots can be used as shortcuts if the proper MTR slope is identified. For example, the slope of a p vs. $\log t$ plot can be determined from a plot and then the value of the slope of $m(p)$ vs. $\log t$ can be calculated by using Eq. 26 without ever actually plotting values of $m(p)$.

Non-Darcy Flow

Darcy's law applies to gases at lower rates (laminar flow), which are found throughout the reservoir. However, near the wellbore the rates can become extremely high because of the converging flow as the gas approaches the wellbore. At these rates *inertial effects* can become important and Darcy's law no longer applies. The inertial effects take the form of distorted flow paths and also turbulence in different locations in the pore structure. Although the exact nature of this microscopic flow is not known in the reservoir, the net effect is a higher pressure gradient when these inertial effects become important.

For laminar flow we can rearrange Darcy's law to the following form.

$$-\frac{\partial p}{\partial x} = \frac{\mu}{k} v, \quad \dots \quad (30)$$

where $\partial p / \partial x$ is the pressure gradient and v is the macroscopic (Darcy) fluid velocity. At the higher rates, when

inertial effects become important, the Forchheimer equation is used:

$$-\frac{\partial p}{\partial x} = \frac{\mu}{k} v + F_t \rho v |v|, \quad \dots \quad (31)$$

where ρ is the fluid density and F_t is the turbulence factor. The right side of Eq. 31 contains a term for viscous forces and a term for inertial forces, both of which contribute to the pressure loss.

Although a number of workers have correlated the value of F_t with rock properties, for practical purposes the velocity varies too much in the vertical direction near a wellbore to predict the effect of non-Darcy flow in a particular well. One practical approach is to consider the nonDarcy effect near the wellbore as a rate-dependent part of the skin effect:

$$s' = s + F_{Da} |q_g|, \quad \dots \quad (32)$$

where F_{Da} is the non-Darcy (turbulence) factor, $(10^3 \text{ cu ft/D})^{-1}$, $|q_g|$ is the absolute value of gas rate, 10^3 cu ft/D , and s' is the effective skin effect of a well flowing at a rate q_g . Fig. 35.8 shows how s' varies with rate. The value of F_{Da} varies with pressure but for simplicity can be considered constant. The value of F_{Da} must be evaluated by transient testing of the well at several rates and determining corresponding values of s' .

The transient equations (MTR) and pseudosteady-state equations (LTR) are modified for gas wells as shown in the following.

Infinite-Acting Gas Reservoir (MTR)

The transient solution for the infinite-acting gas reservoir is analogous to the liquid case shown in Eq. 11. Eq. 11 then must be modified for the effect of non-Darcy flow and fluid property variation with pressure. This results in the following equation.

$$m_D = \frac{1}{2} \ln t_D + 0.4045 + s + F_{Da} |q_g|, \quad \dots \quad (33)$$

where

$$m_D = 1.987 \times 10^{-5} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \frac{kh}{q_g} \left[m(p_i) - m(p_{wf}) \right]$$

and

$$\begin{aligned} m_D &= \text{dimensionless } m(p), \\ t_D &= \text{dimensionless time,} \\ T_{sc} &= \text{standard condition temperature, } ^\circ\text{R,} \\ p_{sc} &= \text{standard condition pressure, psia,} \\ T_R &= \text{reservoir temperature, } ^\circ\text{R,} \\ m(p_i) &= m(p) \text{ at initial pressure } p_i, \text{ psia}^2/\text{cp, and} \\ m(p_{wf}) &= m(p) \text{ at wellbore flowing pressure } p_{wf}, \\ &\quad \text{psia}^2/\text{cp.} \end{aligned}$$

The value of t_D is evaluated with $\phi\mu c$ evaluated at the initial pressure.

Fig. 35.8—Skin factor determination.

Before putting Eq. 33 into a more practical form, consider that the pressure drop term, $m(p_i) - m(p_{wf})$, can be stated as $\Delta m(p)$ and can be related to Δp and Δp^2 by the relationships

$$\Delta m(p) = \left(\frac{2p}{z\mu} \right)_{\bar{p}} \Delta p = \left(\frac{1}{z\mu} \right)_{\bar{p}} \Delta p^2. \quad \dots \quad (34)$$

The average values shown in parentheses are the integrated average values over the pressure range. For practical purposes it is accurate to evaluate these average quantities at the midpoint pressure. In other words, $2p/z\mu_{\bar{p}}$ is evaluated at \bar{p} , where \bar{p} is equal to $(\bar{p}_R + p_{wf})/2$ and $(1/z\mu)_{\bar{p}}$ is evaluated at \bar{p} , where \bar{p} is equal to $(\bar{p}_R + p_{wf})/2$, or $\sqrt{(\bar{p}_R^2 + p_{wf}^2)/2}$ for the p^2 equation. For the infinite-acting reservoir, the average reservoir pressure, \bar{p}_R , is the same as p_i .

These relationships are important because they allow us to account for the variation of fluid properties, within engineering accuracy, and still express equations simply in terms of p and p^2 . Eq. 33, when put in more practical form, can be expressed in terms of $m(p)$, p , or p^2 , as

$$\begin{aligned} &1.987 \times 10^{-5} \left(\frac{kh}{q_g} \right) \left[m(p_i) - m(p_{wf}) \right] \\ &= \frac{2.303}{2} \log \frac{0.000264kt}{(\phi\mu c)_i r_w^2} \\ &+ 0.4045 + s + F_{Da} |q_g|, \quad \dots \quad (35a) \end{aligned}$$

$$\begin{aligned} &1.987 \times 10^{-5} \left(\frac{kh}{q_g} \right) \left(\frac{2p}{z\mu} \right)_{\bar{p}} (p_i - p_{wf}) \\ &= \frac{2.303}{2} \log \frac{0.000264kt}{(\phi\mu c)_i r_w^2} \\ &+ 0.4045 + s + F_{Da} |q_g|, \quad \dots \quad (35b) \end{aligned}$$

Fig. 35.9—Typical variation of $m(p)$ and $z\mu$ with pressure.

and

$$1.987 \times 10^{-5} \left(\frac{kh}{q_g} \right) \left(\frac{1}{z\mu} \right)_{\bar{p}} (p_i^2 - p_{wf}^2) \\ = \frac{2.303}{2} \log \frac{0.000264kt}{(\phi\mu c)_i r_w^2} \\ + 0.4045 + s + F_{Da} | q_g |, \dots (35c)$$

where $(\phi\mu c)_i = \phi\mu c$ evaluated at p_i . Eq. 35 can be used to predict p_{wf} for the infinite-acting period (MTR) between the wellbore storage period and the beginning of pseudosteady state.

Fig. 35.9 shows a typical relationship of $z\mu$ with pressure. The value of $z\mu$ is almost constant when p is below 2,000 psia. This makes the p^2 type of equation fairly accurate below 2,000 psi because $z\mu$ can be taken out of the integral in Eq. 23 if $z\mu$ is constant. p^2 plots and equations tend to work well in reservoir pressures less than 2,000 psia.

Fig. 35.9 also shows that $m(p)$ tends to be linear with p at higher pressures (above 3,000 psia). This means that p plots and equations tend to work well for higher-pressure reservoirs. If there is a doubt about whether these p^2 or p simplifications apply to a particular reservoir, then $m(p)$ plots and equations should be used.

Pseudosteady-State Solutions (LTR)

The pseudosteady-state solutions are analogous to the liquid solutions and can be put in essentially the same form. The only changes are to allow for the changes of fluid properties with pressure and non-Darcy flow. The inclusion of these effects is the same as discussed above. The result is the following form of the pseudosteady-state equations, in terms of $m(p)$, p , and p^2 .

$$q_g = 1.987 \times 10^{-5} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \cdot \frac{kh}{\frac{1}{2} \ln \frac{2.2458A}{C_A r_w^2} + s + F_{Da} | q_g |} \cdot [m(\bar{p}) - m(p_{wf})], \dots (36a)$$

where $m(\bar{p}) = m(p)$ at p_R , psia²/cp, and C_A = shape factor from Table 35.2.

$$q_g = 1.987 \times 10^{-5} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \cdot \frac{kh}{\frac{1}{2} \ln \frac{2.2458A}{C_A r_w^2} + s + F_{Da} | q_g |} \cdot \left(\frac{2p}{z\mu} \right)_{\bar{p}} (\bar{p} - p_{wf}), \dots (36b)$$

and

$$q_g = 1.987 \times 10^{-5} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \cdot \frac{kh}{\frac{1}{2} \ln \frac{2.2458A}{C_A r_w^2} + s + F_{Da} | q_g |} \cdot \left(\frac{1}{z\mu} \right)_{\bar{p}} (\bar{p}^2 - p_{wf}^2). \dots (36c)$$

Eqs. 36 have general application for pseudosteady-state gas flow. Note that these forms of the pseudosteady-state equations are considerably different from the gas deliverability approach that is used extensively. The gas deliverability approach is empirical and based on a log-log plot of $\bar{p}^2 - p_{wf}^2$ vs. q_g . The comparison between Eqs. 36 and the deliverability plot approach is discussed by Lee.⁵

Long-Term Forecast

Long-term forecasting can be accomplished in a fairly straightforward manner using Eqs. 36 along with a \bar{p}_R/z plot. The \bar{p}_R/z plot, of course, is simply a material balance for a closed gas reservoir. Through this plot the value of \bar{p}_R can be determined for any value of cumulative production, G_p . Given this value of \bar{p}_R , one of the forms of Eqs. 36 then can be used to determine q_g .

Note that in deep, high-pressure reservoirs, the influence of formation and water compressibility can become important compared with gas compressibility. At these high pressures, greater than about 6,000 psig, the \bar{p}_R/z plot should be modified to account for the formation and water compressibilities. A technique for this modified \bar{p}_R/z plot is presented by Ramagost and Farshad.¹⁴

A complete forecast of production rate vs. time can be generated by converting the cumulative production to a time scale. The value of p_{wf} might be fixed as a condition of the production forecast, or it may be solved simultaneously with wellbore hydraulic relationships, such as given in Chap. 34.

Example Problem 3. A gas well produces from a drainage area that approximates a 4:1 rectangle with the well in the center. The following data apply.

$$\begin{aligned} A &= 6.96 \times 10^6 \text{ sq ft (160 acres),} \\ h &= 34 \text{ ft,} \\ s &= 2.3, \\ F_{Da} &= 0.0052 (10^3 \text{ cu ft/D})^{-1}, \\ r_w &= 0.23 \text{ ft,} \\ k_g &= 0.52 \text{ md,} \\ z\mu_g &= \text{see Fig. 35.9,} \\ \phi &= 0.11, \\ T_R &= 210^\circ\text{F} + 460 = 670^\circ\text{R,} \\ T_{sc} &= 60^\circ\text{F} + 460 = 520^\circ\text{R,} \\ p_{sc} &= 14.7 \text{ psia, and} \\ \bar{p}_R &= 4,150 \text{ psia.} \end{aligned}$$

Calculate the pseudosteady-state rate, q_g , if $p_{wf} = 1,500$ psia.

Solution. Use Eq. 36b—the simplest form of the pseudosteady-state equation.

$$\bar{p} = (\bar{p}_R + p_{wf})/2$$

$$= (4,150 + 1,500)/2$$

$$= 2,825 \text{ psia.}$$

From Fig. 35.9, we estimate $z\mu_g$ at 2,825 psia as

$$z\mu_g = 0.0165.$$

So,

$$\left(\frac{2p}{z\mu}\right)_{\bar{p}} = \frac{2(2,825)}{0.0165} = 3.42 \times 10^5.$$

From Table 35.2,

$$C_A = 5.3790.$$

Eq. 36b is

$$\begin{aligned} q_g &= 1.987 \times 10^{-5} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \\ &\quad \cdot \frac{kh}{\frac{1}{2} \ln \frac{2.2458A}{C_A r_w^2} + s + F_{Da} |q_g|} \\ &\quad \cdot \left(\frac{2p}{z\mu} \right)_{\bar{p}} (\bar{p}_R - p_{wf}); \\ q_g &= 1.987 \times 10^{-5} \frac{(520)}{(14.7)(670)} \\ &\quad \cdot \frac{(0.52)(34)}{\frac{1}{2} \ln \frac{2.2458(6.96 \times 10^6)}{(5.379)(0.23)^2} + 2.3 + 0.0052 |q_g|} \\ &\quad \cdot (3.42 \times 10^5)(4,150 - 1,500) \\ &= 1.987 \times 10^{-5} (0.0528) \frac{17.68}{8.91 + 2.3 + 0.0052 |q_g|} \\ &\quad \cdot (3.42 \times 10^5)(2,650) \\ &= \frac{1.68 \times 10^4}{11.21 + 0.0052 |q_g|}. \end{aligned}$$

$$(11.21 + 0.0052 |q_g|) q_g = 1.68 \times 10^4.$$

This equation can be solved as a quadratic equation, or simply by trial and error, by using estimates of $|q_g|$ starting with $|q_g| = 0$:

$$(11.21 + 0) q_g = 1.68 \times 10^4$$

$$q_g = 1,499.$$

Next, try

$$(11.21 + 0.0052 \times 1,499) q_g = 1.68 \times 10^4;$$

$$q_g = 884.$$

Next, try

$$(11.21 + 0.0052 \times 884) q_g = 1.68 \times 10^4;$$

$$q_g = 1,063.$$

Fig. 35.10—Semilog data plot for drawdown test.

Next, try

$$(11.21 + 0.0052 \times 1,063)q_g = 1.68 \times 10^4;$$

$$q_g = 1,004,$$

until the solution converges at

$$q_g = 1,018 \times 10^3 \text{ cu ft/D.}$$

Transient Well Test Analysis

The subject of transient well test analysis can be very complicated and has been covered very thoroughly in the literature.¹⁻⁵ These references show not only the straightforward cases of transient well test analysis but also go into many exceptions, alternative techniques for analysis, and other complications. It is the intent here to cover only the most straightforward and routine methods for analysis of oil and gas wells.

The most common values to calculate from a transient well test analysis are kh , s , and \bar{p}_R . With these three values plus a knowledge of the drainage area and shape of the drainage area (values of C_A and A), the flow rate can be calculated or forecast for a particular BHP, p_{wf} , by using the pseudosteady-state equations. The method of analyzing kh and s for a drawdown test and a buildup test are summarized now.

Drawdown Test

The drawdown test is accomplished simply by putting a well on a constant production rate after the well has been shut in. Variations of the drawdown test involve analysis of variable rates, but only the constant-rate case is covered here. The analysis is based on the infinite-acting solution (MTR). The data are plotted on a pressure vs. log time semilog plot and the slope of the plot, m , is determined graphically in units of psi/cycle (see Fig. 35.10). The equations for determining kh for an oil well or a gas well are as follows.

For oil wells,

$$k_o h = -\frac{162.6 q_o B_o \mu_o}{m}, \quad \dots (37a)$$

and for gas wells,

$$k_g h = \frac{-5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc})}{m^*}, \quad \dots (37b)$$

where m^* is the slope of $m(p)$ plot,

$$k_g h = \frac{-5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc}) \left(\frac{z \mu_g}{2p} \right)_{wb}}{m'}, \quad \dots (37c)$$

where m' is the slope of p plot, or

$$k_g h = \frac{-5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc}) (z \mu_g)_{wb}}{m''}, \quad \dots (37d)$$

where m'' is the slope of p^2 plot and subscript wb refers to wellbore. The values of $z \mu / 2p$ in Eq. 37c and $z \mu$ in Eq. 37d are evaluated at p_{wf} rather than $(\bar{p}_R + p_{wf})/2$, which is used in the pseudosteady-state equations.

The value of the skin effect, s , is determined from one of the following equations for oil and gas wells.

For oil wells,

$$s = 1.151 \left(\left| \frac{p_i - p_1}{m} \right| - \log \frac{k}{\phi \mu c_i r_w^2} + 3.23 \right), \quad \dots (38a)$$

where p_1 is the pressure at $\Delta t = 1$ hour; and for gas wells,

$$s = 1.151 \left(\left| \frac{m(p_i) - m(p_1)}{m^*} \right| - \log \frac{k}{\phi \mu c_i r_w^2} + 3.23 \right), \quad \dots (38b)$$

$$s = 1.151 \left(\left| \frac{p_i - p_1}{m'} \right| - \log \frac{k}{\phi \mu c_i r_w^2} + 3.23 \right), \quad \dots (38c)$$

or

$$s = 1.151 \left(\left| \frac{p_i^2 - p_1^2}{m''} \right| - \log \frac{k}{\phi \mu c_i r_w^2} + 3.23 \right), \quad \dots (38d)$$

The disadvantage of this equation (compared to buildup testing) is that p_i must be known to calculate s .

It is important to evaluate the proper semilog straight line. In many cases it is difficult to tell whether an apparent semilog straight line is in the MTR solution or is still being affected by wellbore effects (ETR). It is often helpful to make a log-log plot of $p_i - p_{wf}$ vs. flowing time, t , to analyze when the wellbore effects are finished. A straight line with a slope of unity on this log-log plot indicates that the pressure behavior is being totally dominated by wellbore storage. The semilog straight line then can be expected to begin at about 1.5 log cycles after the data points leave the log-log straight line of unity slope.

Buildup Testing

Buildup testing is more common than drawdown testing. The main reason for this is that the well rate is known when the well is shut in ($q=0$). The analysis of a buildup test is based on the assumption that a constant flow rate is maintained for a producing time, t_p , and then the well is shut in. Variations of the buildup test include analysis of variation in production rate before shut-in, but only the constant-rate production period is covered here. The pressure, p_{wf} ($\Delta t=0$), is measured just before shut-in and then at different shut-in times, Δt , after the time of shut-in.

A plot is made of the shut-in pressures, p_{wf} , vs. a time scale based on the shut-in time, Δt . The time scale is either $\log \Delta t$ or $\log (t_p + \Delta t)/\Delta t$. The first of these plots (Fig. 35.11) is called an "MDH plot" (Miller, Dyes, and Hutchinson¹⁵). The second type of plot (Fig. 35.12) is called a "Horner plot."¹⁶ Both plots give the same semilog straight line slope, which is also the same as measured in the drawdown test.

The kh for an oil or gas well can be determined from the slope of this semilog straight line by the following equations (identical to Eqs. 37, except for the sign).

For oil wells,

$$k_o h = \frac{162.6 q_o B_o \mu_o}{m}, \quad \dots \dots \dots (39a)$$

and for gas wells,

$$k_g h = \frac{5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc})}{m^*}, \quad \dots \dots \dots (39b)$$

$$k_g h = \frac{5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc})}{m'} \left(\frac{z \mu_g}{2p} \right)_{wb}, \quad \dots \dots (39c)$$

or

$$k_g h = \frac{5.792 \times 10^4 q_g (p_{sc} T_R / T_{sc})}{m''} (z \mu_g)_{wb}, \quad \dots \dots (39d)$$

Note that the signs are reversed for the Horner plot.

The skin factor, s , can be determined from one of the following equations.

For oil wells,

$$s = 1.151 \left(\left| \frac{p_1 - p_{wf}}{m} \right| - \log \frac{k_o}{\phi \mu_o c_t r_w^2} + 3.23 \right), \quad \dots \dots \dots (40a)$$

Fig. 35.11—MDH plot for buildup test.

Fig. 35.12—Horner plot of pressure buildup data from Fig. 35.11.

and for gas wells,

$$s = 1.151 \left(\left| \frac{m(p_1) - m(p_{wf})}{m^*} \right| - \log \frac{k_g}{\phi \mu_g c_t} + 3.23 \right), \quad \dots \dots \dots (40b)$$

$$s = 1.151 \left(\left| \frac{p_1 - p_{wf}}{m'} \right| - \log \frac{k_g}{\phi \mu_g c_t r_w^2} + 3.23 \right), \quad \dots \dots \dots (40c)$$

Fig. 35.13—Horner plot of typical pressure buildup data from a well in a finite reservoir.

or

$$s = 1.151 \left(\left| \frac{p_1^2 - p_{wf}^2}{m''} \right| - \log \frac{k_g}{\phi \mu_g c_t r_w^2} + 3.23 \right) \quad (40d)$$

The slope refers to the corresponding semilog straight line. p_{wf} is the last p_{wf} at $\Delta t = 0$. These equations are based on the equation of the semilog straight line. Therefore, if p_{ws} does not fall on the extrapolated semilog straight line at $\Delta t = 1$ hour, then p_1 is read on the semilog straight line rather than at the actual data.

Again, be reminded that transient well test analysis can be very complicated and can depart in many ways from the simple analysis presented here. These equations are presented only for quick reference and to show the proper interpretation of the real gas formulas for the normal cases. The reader should refer to Refs. 1 through 5 for more details and explanation of departures from these simple cases.

Determination of \bar{p}_R

The value of \bar{p}_R represents the average reservoir pressure in the drainage area of the well. It is important to determine \bar{p}_R from a buildup test so that \bar{p}_R can be used for material balance calculations, history matching in reservoir simulation, or in pseudosteady-state performance equations.

There are several methods for determining \bar{p}_R from a buildup test but the most general is the MBH (Matthews, Brons, and Hazebroek¹⁷). This method is generally applicable because a number of different reservoir drainage area shapes are available for analysis. These reservoir shapes are the same as those used for evaluating shape factors in Table 35.2.

Fig. 35.13 shows how the method is applied. The buildup test has a semilog straight line, which begins bending at the later shut-in times because of the effect of the boundaries. The data normally will bend down and become flat from this curve, but for unusual cases the data actually can bend up from the semilog straight line before it eventually becomes horizontal.

Asymptotically, the data approach the correct value of \bar{p}_R as Δt approaches infinity. Since our shut-in time normally is limited, the MBH method is based on extrapolating the semilog straight line to $\Delta t = \infty$, or $(t_p + \Delta t)/\Delta t = 1.0$. This value is called p^* . The method then provides a correction to calculate the correct value of \bar{p}_R from the extrapolated value of p^* .

The MBH method assumes that the well flowed at a constant rate for t_p and that the drainage area A is known for the well. The dimensionless producing time, t_{pDA} , is calculated. If t_{pDA} is greater than $(t_{pDA})_{pss}$, the later value can be used as t_{pDA} . In other words, it is not important what the rate history was before pseudosteady state was achieved.

Now that p^* has been extrapolated from the data and t_{pDA} has been calculated, then the correction between p^* and \bar{p}_R is made by using the MBH correction curve that best represents the drainage shape. The MBH correction curves are presented in Figs. 35.14 through 35.17. A stepwise procedure to determine \bar{p}_R can be summarized as follows.

1. Make a Horner plot.
2. Extrapolate the semilog straight line to the value of p^* at $(t_p + \Delta t)/\Delta t = 1.0$.
3. Evaluate m , the slope of the semilog straight line.
4. Calculate $t_{pDA} = (0.000264kt_p)/\phi\mu c_t A$.
5. Find the closest approximation to the drainage shape in Figs. 35.14 through 35.17. Choose a correction curve.
6. Read the value of $2.303(p^* - \bar{p}_R)/m$ from the correction curve at t_{pDA} .
7. Calculate the value of \bar{p}_R .

This procedure gives the value of \bar{p}_R in the drainage area of one well. If a number of wells are producing from the reservoir, each well can be analyzed separately to give a \bar{p}_R for its own drainage area. This is done, assuming that all wells are producing in pseudosteady state, by dividing the reservoir up into drainage areas for each well by constructing no-flow boundaries between the wells. Fig. 35.18 shows an illustration of such a segmentation of a reservoir. These no-flow boundaries represent the "watersheds" of the different drainage areas. The drainage areas are calculated so that each drainage area has the same reservoir flow rate compared to its PV. Thus,

$$(q_t/V_p)_1 = (q_t/V_p)_2 = (q_t/V_p)_3 = (q_t/V_p)_i \dots (41)$$

This relationship divides the drainage area (or PV) according to the producing rate of the well. As the well's rates change, then the drainage area changes for the well. If $q = 0$, for example, then no area would be allocated to that well. This procedure of calculating the drainage area and approximating drainage shape is repeated at the time of each pressure survey. The drainage areas and shapes keep changing as rates change.

There is often confusion about the meaning of p^* in the Horner plot. The value of p^* has no physical meaning except in the special case of an infinite-acting well ($r_e = \infty$). This is the case that Horner¹⁶ originally addressed in determining the initial pressure, p_i , in a newly discovered well. In this special infinite-acting case, $p^* = \bar{p}_R = p_i$. Otherwise, p^* has no physical meaning.

Example Problem 4 (Pressure Buildup Analysis) (after Earlougher²). *Pressure Buildup Test Analysis—Horner Method.* Table 35.3 shows pressure buildup data from an oil well with an estimated drainage radius of 2,640 ft. Before shut-in the well had produced at a stabilized rate of 4,900 STB/D for 310 hours. Known reservoir data are

$$\begin{aligned} D &= 10,476 \text{ ft}, \\ r_w &= (4.25/12) \text{ ft}, \\ c_r &= 22.6 \times 10^{-6} \text{ psi}^{-1}, \\ q_o &= 4,900 \text{ STB/D}, \\ h &= 482 \text{ ft}, \\ p_{wf}(\Delta t=0) &= 2,761 \text{ psig}, \\ \mu_o &= 0.20 \text{ cp}, \\ \phi &= 0.09, \\ B_o &= 1.55 \text{ RB/STB}, \\ \text{casing } d_i &= (6.276/12) \text{ ft, and} \\ t_p &= 310 \text{ hours.} \end{aligned}$$

Solution. The Horner plot is shown as Fig. 35.12. Residual wellbore storage or skin effects at shut-in times of less than 0.75 hour are apparent. The straight line, drawn after $\Delta t = 0.75$ hour, has a slope of -40 psig/cycle, so $m = 40$ psig/cycle.

Eq. 37a is used to estimate permeability:

$$k_o = \frac{162.6(4,900)(1.55)(0.20)}{(40)(482)} = 12.8 \text{ md.}$$

Skin factor is estimated from Eq. 40a using $p_{1hr} = 3.266$ psig from Fig. 35.12:

$$\begin{aligned} s &= 1.1513 \left\{ \frac{3,266 - 2,761}{40} \right. \\ &\quad \left. - \log \left[\frac{(12.8)(12)^2}{(0.09)(0.20)(22.6 \times 10^{-6})(4.25)^2} \right] \right. \\ &\quad \left. + 3.2275 \right\} = 8.6. \end{aligned}$$

TABLE 35.3—PRESSURE BUILDUP TEST DATA FOR EXAMPLE 4, $t_p = 310$ HOURS

Δt (hours)	$t_p + \Delta t$ (hours)	$(\Delta t_p + \Delta t)$ Δt	p_{ws} (psig)	$p_{ws} - p_{wf}$ (psig)
0.0	—	—	2,761	—
0.10	310.10	3,101	3,057	296
0.21	310.21	1,477	3,153	392
0.31	310.31	1,001	3,234	473
0.52	310.52	597	3,249	488
0.63	310.63	493	3,256	495
0.73	310.73	426	3,260	499
0.84	310.84	370	3,263	502
0.94	310.94	331	3,266	505
1.05	311.05	296	3,267	506
1.15	311.15	271	3,268	507
1.36	311.36	229	3,271	510
1.68	311.68	186	3,274	513
1.99	311.99	157	3,276	515
2.51	312.51	125	3,280	519

4.08	314.08	77.0	3,289	528
5.03	315.03	62.6	3,293	532
5.97	315.97	52.9	3,297	536
6.07	316.07	52.1	3,297	536
7.01	317.01	45.2	3,300	539
8.06	318.06	39.5	3,303	542
9.00	319.00	35.4	3,305	544
10.05	320.05	31.8	3,306	545
13.09	323.09	24.7	3,310	549
16.02	326.02	20.4	3,313	552
20.00	330.00	16.5	3,317	556
26.07	336.07	12.9	3,320	559
31.03	341.03	11.0	3,322	561
34.98	344.98	9.9	3,323	562
37.54	347.54	9.3	3,323	562

We can estimate Δp across the skin from Eq. 10:

$$\Delta p_s = 0.87(40)(8.6) = 299.$$

Average Drainage-Region Pressure—MBH. We use the pressure-buildup test data of Table 35.3. Pressure buildup data are plotted in Figs. 35.12. Other data are

$$\begin{aligned} A &= \pi r_e^2 \\ &= \pi(2,640)^2 \text{ sq ft.} \end{aligned}$$

To see if we should use $t_p = 310$ hours, we estimate t_{pss} using $(t_{DA})_{pss} = 0.1$ from Table 35.2.

$$\begin{aligned} t_{pss} &= \frac{(0.09)(0.2)(22.6 \times 10^{-6})(\pi)(2,640)^2(0.1)}{(0.0002637)(12.8)} \\ &= 264 \text{ hours.} \end{aligned}$$

Thus, we could replace t_p by 264 hours in the analysis. However, since t_p is only about $1.17 t_{pss}$, we expect no difference in \bar{p}_R from the two methods, so we use $t_p = 310$ hours. As a result, Fig. 35.12 applies.

Fig. 35.12 does not show p^* since $(t_p + \Delta t)/\Delta t$ does not go to 1.0. However, we may compute p^* from p_{ws} at $(t_p + \Delta t)/\Delta t = 10$ by extrapolating one cycle:

$$\begin{aligned} p^* &= 3,325 + (1 \text{ cycle})(40 \text{ psi/cycle}) \\ &= 3,365 \text{ psig.} \end{aligned}$$

Using the definition of t_{pDA} :

$$t_{pDA} = \frac{(0.0002637)(12.8)(310)}{(0.09)(0.20)(22.6 \times 10^{-6})(\pi)(2,640)^2}$$

$$= 0.117.$$

From the curve for the circle in Fig. 35.14, $p_{DMBH}(t_{pDA}=0.117)=1.34$. Then, from our step-wise procedure,

$$\bar{p}_R = 3,365 - \frac{40}{2.303}(1.34)$$

$$= 3.342 \text{ psig.}$$

This is 19 psi higher than the maximum pressure recorded.

Nomenclature

- A = drainage area of well
- c_{ti} = total compressibility evaluated at p_i
- c_{wf} = wellbore fluid compressibility
- C_A = shape factor from Table 35.2
- C_s = wellbore storage constant
- $f(t)$ = unit response function
- F_{Da} = non-Darcy (turbulence) factor
- F_t = turbulence factor
- m = $(162.6qB\mu)/kh$
- m_D = dimensionless $m(p)$
- $m(p) = 2 \int_0^p \frac{p}{z\mu} dp$ = real gas pseudopressure
- $m(\bar{p}) = m(p)$ at \bar{p}_R
- $m(p_i) = m(p)$ at initial pressure p_i
- $m(p_{wf}) = m(p)$ at wellbore flowing pressure p_{wf}
- m^* = slope of $m(p)$ plot
- m' = slope of p plot
- m'' = slope of p^2 plot
- p^* = MTR pressure trend extrapolated to infinite shut-in time
- $p_D = kh(p_i - p)/(141.2qB\mu)$ = dimensionless pressure
- $p_{DMBH} = 2.303(p^* - \bar{p}_R)/m$, dimensionless pressure, MBH method
- Δp_s = additional pressure drop across altered zone
- $|q_g|$ = absolute value of gas rate
- q_{sf} = flow rate at the sandface
- $r_D = r/r_w$ = dimensionless radius
- r_e = external drainage radius
- r_w' = effective wellbore radius
- s' = effective skin effect
- t_D = dimensionless time
- t_{DA} = dimensionless time based on drainage area, A
- $(t_{DA})_{pss}$ = time required to reach pseudosteady state, dimensionless
- t_{end} = end of MTR in drawdown test
- t_{pDA} = dimensionless producing time

t_{pss} = time required to achieve pseudosteady state

v = macroscopic (Darcy) fluid velocity

V_w = volume of the wellbore

x_e = distance from well to side of square drainage area

x_f = distance from well to either end of a vertical fracture

Subscript

wb = wellbore

Key Equations in SI Metric Units

$$\nabla^2 p = \frac{1}{3.557 \times 10^{-9}} \frac{\phi \mu c_t}{k} \frac{\partial p}{\partial t}, \dots \dots \dots (1)$$

where

p is in kPa,
 ϕ is a fraction,
 μ is in Pa·s,
 c_t is in kPa^{-1} ,
 k is in md, and
 t is in hours.

$$q_i B_i = q_o B_o + (q_g - R_s q_o) B_g + q_w B_w, \dots \dots \dots (6)$$

where

q_o, q_i, q_w are in std m^3/d ,
 B_o, B_i, B_w are in res $\text{m}^3/\text{std m}^3$,
 q_g is in std m^3/d , and
 B_g is in res $\text{m}^3/\text{std m}^3$.

$$p_D(r_D, t_D) = -\frac{1}{2} Ei \left(\frac{-r_D^2}{4t_D} \right), \dots \dots \dots (7)$$

where

$p_D = [kh(p_i - p)/(1866qB\mu)]$,

$$r_D = \frac{r}{r_w},$$

$$t_D = \frac{3.557 \times 10^{-9} kt}{\phi \mu c_t r_w^2},$$

h, r, r_w are in m,

k is in md,

p, p_i are in Pa,

q is in m^3/d ,

B is in res $\text{m}^3/\text{std m}^3$,

μ is in Pa·s,

t is in hours,

ϕ is a fraction, and

c_t is in kPa^{-1} .

$$p_{wf} = p_i - m \left(\log \frac{kt}{\phi \mu c_t r_w^2} - 8.10 \right), \dots \dots \dots (9)$$

where $m = 2.149 \times 10^6 qB\mu/(kh)$. See Eq. 7, for other units.

$$\left(\frac{\partial p}{\partial t} \right)_{pss} = \frac{-4.168 \times 10^{-2} qB}{V_p c_t}, \dots \dots \dots (15)$$

where V_p is in m^3 . See Eq. 7 for other units.

$$q = \left(\frac{5.356 \times 10^{-1} \frac{kh}{B\mu}}{\ln \frac{r_e}{r_w} - 0.75 + s} \right) (\bar{p}_R - p_{wf}), \quad \dots \quad (17)$$

where

$r_e = m$,
 s is dimensionless, and
 \bar{p}_R, p_{wf} are in kPa.
 See Eq. 7 for other units.

$$\bar{p}_R = p_i - \frac{N_p B_o}{V_p c_t}, \quad \dots \quad (21)$$

where

N_p is in m^3 ,
 V_p is in m^3 ,
 B_o is in res m^3 /std m^3 ,
 c_t is in kPa^{-1} , and
 \bar{p}_R, p_i are in kPa.

$$\nabla^2 m(p) = \frac{1}{3.557 \times 10^{-9}} \frac{\phi \mu c_g}{k} \frac{\partial m(p)}{\partial t}, \quad \dots \quad (24)$$

where $m(p)$ is in kPa^2 and c_g is in kPa^{-1} . See Eq. 7 for other units.

$$m_D = \frac{1}{2} \ln t_D + 0.4045 + s + F_{Da} |q_g|, \quad \dots \quad (33)$$

where

$$m_D = 2.708 \times 10^{-10} \left(\frac{T_{sc}}{p_{sc} T_R} \right) \frac{kh}{q_g} \cdot [m(p_i) - m(p_{wf})],$$

$$t_D = \frac{3.557 \times 10^{-9} kt}{\phi \mu c_t r_w^2},$$

s is dimensionless,
 F_{Da} is dimensionless,
 q_g is in m^3/d ,
 T_{sc}, T_R are in K,
 p_{sc} is in kPa,
 k is in md,
 h is in m, and
 $m(p_i), m(p_{wf})$ are in $kPa^2/Pa \cdot s$.
 See Eq. 7 for other units.

$$k_o h = - \frac{2.149 \times 10^6 q_o B_o \mu_o}{m}, \quad \dots \quad (37a)$$

See Eqs. 7 and 9 for units.

$$k_g h = \frac{4.250 \times 10^9 q_g \left(\frac{p_{sc} T_R}{T_{sc}} \right)}{m^*}, \quad \dots \quad (37b)$$

where m^* is in $kPa^2/Pa \cdot s \cdot cycle$. See Eq. 33 for other units.

$$s = 1.151 \left(\left| \frac{p_i - p_1}{m} \right| - \log \frac{k}{\phi \mu c_t r_w^2} + 8.10 \right), \quad \dots \quad (38a)$$

where m is in $kPa/cycle$. See Eq. 7 for other units.

Chapter 36

Development Plan for Oil and Gas Reservoirs

Steven W. Poston, Texas A&M U.*

Introduction

The following discussion on the determination of the proper development plan for oil reservoirs or gas reservoirs is a summation of the current thinking in the oil industry. Conditions have changed dramatically since R.C. Craze wrote this chapter for the original book in 1962. At that time, the price of crude oil and gas was so low that the industry was concerned mainly with recovering the gross reserves from a field.

Today's economics have changed our outlook to such a degree that the need for a logical and efficient plan for the orderly development of an oil or gas field is of utmost importance. The bidding competition for reserves often has caused successful field development to be at least partially dependent on getting the most out of the ground with the minimum number of wells.

The oil business was originally an endeavor that allowed one to explore for hydrocarbons in relatively unexplored areas. The probability of finding large fields was quite high, and an excellent return on investment resulted when a new field was found. A majority of the large oil and gas fields have been found after 25 years of intensive exploration. The number of companies searching for hydrocarbons has increased while at the same time the fields are harder to locate. Now we are a very competitive industry in which there is little room for error. In other words, the rules of the game have changed.

New technology and thinking about logical field development has evolved during the last 20 years. Continuity of producing intervals between wells is now known to be much more important than previously thought. Advances in well test analysis have allowed the engineer and geologist to estimate reservoir size and intrawell continuity. Improved seismic techniques have allowed geophysics to play an increasingly important role in allocating well locations for efficient reservoir drainage.

A person interested in developing an oil or a gas field must use a basic understanding of geology, engineering, and economics. Other, more sophisticated techniques may have to be used at times to arrive at a realistic development plan. However, when one begins to develop a field, a number of questions need to be mulled over and should be discussed with colleagues. The thinking process occurs as follows.

Is the Well Being Drilled to Develop Proved, Probable, or Possible Reserves? The drilling of a development well in the middle of a field for proved reserves is considerably different than drilling an outpost well to help define the field limits. Greater reserves must be assigned to well questing for probable or possible reserves than for an infield development well. The drilling for known reserves often allows for a low return on investment. However, the reward must be greater if the risk of drilling and not finding the hydrocarbon accumulation increases. The benchmark for the go/no-go decision for the drilling of a well is a function of not only the return on investment but also the degree of risk to be incurred.

Answering these questions requires a combination of all disciplines in the petroleum industry. The greater the certainty of the reserves, the less the need for geological and engineering opinions.

What Are the Reservoir Rock and Fluid Characteristics? Field development is conducted far differently in a clean, well-developed sand than it is in a place such as the low-porosity and low-permeability Austin chalk region of Texas. High porosities and permeabilities and low oil viscosities permit high offtake rates and wide well spacing. These large "per well" recoveries often preclude the need for the serious study of the minimum economic reserves requirements.

*Author of the original chapter on this topic in the 1962 edition was Rupert C. Craze.

Development drilling will continue at a different pace for a continuous and homogeneous sand than for a field composed of a series of productive intervals sandwiched between shale layers of unknown lateral extent. A well completed in a series of sand stringers of uncertain areal extent should be placed on production for a time to see how much it actually will produce. Extensive drilling in such a field should wait until the economic worth of the total effort is determined from field production figures.

Any knowledge concerning the geology of the prospect attained before the well is drilled would furnish insight into the probable number of completion zones and where the completion intervals should be. The proper well spacing would be predicated on this knowledge.

The type of drive mechanism often will predicate the placement of the development wells. If a water drive is expected, the wells should be placed in the most updip locations possible. However, the updip placement of the wells would be a disaster if there is an expanding gas cap drive. The information is derived from reservoir engineering evaluations.

What Is the Surface Environment? Development considerations are completely different when drilling in a shallow well in west Texas or a Jurassic well in the North Sea. Platform rigs often are used to drill offshore wells. The number of drilling slots is limited, and, once the rig is moved off, it is often prohibitively expensive to move back on if new ideas arise.

What Surface Production Facilities Are Required? There is no sense in drilling an offshore development well if there are no facilities available for production hookup. The production facilities could cost much more than the value of the reserves. Drilling on land in an area where costs may be reduced considerably could allow the production facility costs to be only a fraction of the reserves' worth.

By What Method is the Product to be Sold? Gas must be transmitted by pipeline, whereas oil must be trucked or lightered to a receiving facility. For an oil well, revenue usually begins upon completion, while a gas well must wait for the installation of a pipeline. The cash flow situation for development of either an oil or a gas field is usually different because of the type of product.

What Is the Relationship Between the Costs and the Profit Margin? The margin of profit for an operator will vary considerably according to geographical location and the type of lease. Also, overhead costs may be greater for a large company than for a smaller company. The cost of money may be less for a large company because of a significant and established cash flow. Foreign profit margins are generally much less than margins from U.S. oil and gas sales.

Readers will see other areas of uncertainty in addition to those discussed here. However, the following discussion will shed light on some of the more important points that one should remember concerning the formulation of a development plan for either an oil reservoir or a gas reservoir. There are no handy formulas to use nor are there any tried-and-true rules to follow. Proper field development for a particular set of conditions requires a combination of a variety of oil field disciplines.

Oil and Gas Differences

Method of Sales

Development plans for oil or gas reservoirs generally follow different paths not only because of the optimal depletion characteristics but because of the method of sales.

Crude oil is a reasonably stable substance and, being liquid, may be loaded easily into some type of container for transportation to a sales point. The container is often at or very near atmospheric pressure. The container may be a truck, barge, or pipeline. On most land locations, sales may begin from a well as soon as the production equipment is installed. Also, since oil is contained and moved easily, the buyer of the crude oil may not always be constant.

Natural gas must be kept in some type of container so it will not dissipate into the atmosphere. The high compressibility of the gas permits a smaller container to be used with increased confining pressures. Economics dictates that gas is to be transported through pipelines. The pipeline company must be assured that sufficient reserves are present to justify the expense of installing the pipeline. These capital expenditures often require long-term commitments from all the interested parties.

Sufficient reserves must be proved to justify the expense of laying a pipeline. A number of wells may have to be drilled before any income is derived from the initial discovery. The operator must drill sufficient wells to ensure the quantities of gas required to be delivered over the contract period.

The oil may be transported out by barge or tank truck if the reserves do not justify the expense of installing a pipeline in the case of oil production. Operating expenses are greater when oil is moved by tank truck or barge, but the capital investment is negligible when compared to pipeline installation.

Development drilling in an oil field often may be conducted in a more growth-oriented manner than that in a gas field. Generally speaking, the capital investment required to develop a gas field is greater than for developing the same reserves in an oil field because a pipeline always is required to transport the gas. Non-capital-intensive barges or trucks may be used to transport oil.

The Best Depletion Technique

There are fundamental differences between developing and depleting an oil reservoir and a gas reservoir. These differences are discussed next.

Oil Reservoirs. Every effort should be made to maintain reservoir pressure as high as possible during the depletion of an oil reservoir. A high reservoir pressure helps to preclude the installation of some type of artificial lift system or some method to aid in recovery. High reservoir pressures usually result from an active water drive or gas cap encroachment, both of which displace oil and help to push it toward the wellbore. These displacement mechanisms result in a reduced oil saturation at a relatively high abandonment pressure.

Gas Reservoirs. The compressibility of gas may be up to 1,000 times greater than relatively incompressible oils. These high compressibilities can allow the majority

of the reserves in a gas reservoir to be depleted by simple gas expansion. In fact, ultimate recoveries of 80% of the original gas in place (OGIP) may be achieved by pressure depleting a gas reservoir, even though the remaining gas saturation may be quite high. Conversely, if a gas is trapped behind an advancing water front with a correspondingly lower residual saturation, the remaining gas left behind will be greater because the high compressibility of the gas allows a much greater quantity of gas to be trapped at these higher reservoir pressures.

Example Problem 1—Dry Gas Reservoir. The example given in Table 36.1 indicates the effect of the type of drive mechanism on ultimate recovery from a theoretical dry gas reservoir. Water is assumed to invade the reservoir uniformly in the water influx case. The assumption is not necessarily true in the operational context, but the illustration is made to show the necessity of abandoning gas reservoirs at low pressures.

The effect of the gas FVF in the lower-pressure reaches of the reservoir allow the pressure depletion case to recover more gas.

The previous discussion shows how the development of an oil reservoir may be conducted in a piecemeal and leisurely manner while development of a gas reservoir should be carried out with an eye toward maximizing the reservoir offtake rate to aid in the occurrence of pressure depletion conditions. To arrive at a development plan two basic steps need to be accomplished. These are (1) the characterization of the reservoir and (2) the prediction of the performance of the reservoir under various exploitation schemes and operating conditions.

Characterization of the Reservoir

Geology

Interpretation of Paleo-Environments. The limits of a reservoir and the possible variation of the porosity and permeability within the reservoir may be inferred by studying the well logs and cores taken from wildcat and appraisal wells. The knowledge gained from these studies would be of great help in setting wellsite locations early in the life of a development drilling project. Usually the reservoir productive characteristics are known only after the field or reservoir is maturely developed.

The nature of the reservoir rock often is reflected in the sedimentary record. The sedimentary section is penetrated during the drilling for oil and gas. The character of the sediments may be inferred by logs or by core analyses. For a number of years, geologists have been studying and relating currently occurring sedimentary processes to reservoir rock paleo-environments. Each sedimentary process has been shown to have a particular porosity and permeability distribution and to have a reasonably predictable areal extent.

The interpretation of the probable paleo-environment by log and core analysis of a sedimentary section could be of inestimable value early in the life of field development. The following discussion gives a brief overview of geological interpretive work.

The literature contains an overabundance of work on the evolution of clastic sediments. The reservoir characteristics of a clastic sediment (mainly sandstones) often is related largely to its depositional history.

TABLE 36.1—EXAMPLE OF EFFECTS OF DRIVE MECHANISM ON RECOVERY

$$V_R = 6,400 \text{ acre-ft}$$

$$\phi = 22\%$$

$$S_w = 23\%$$

$$S_{rg} = 34\%$$

$$G = 8.878 \times 10^9 \text{ scf}$$

Pressure (psia)	B_g (scf/cu ft)	Cumulative Production (10^9 scf)	
		Volumetric Reservoir	Waterdrive Reservoir
3,150	188	—	—
2,500	150	1.8	5.8
2,000	120	3.2	6.4
500*	28	7.6	—

*Low reservoir pressures will not be obtained because of the additional energy supplied by the encroaching water; therefore, B_g will be at a higher value at abandonment.

Therefore, a predictive interpretation may be done with some degree of certainty.

Less is known of carbonates. The chemical nature of the depositional processes to form carbonate reservoirs and the usually extensive diagenetic history cloud the true nature of the reservoir character. A large amount of data—i.e., a considerable number of wells—is required before the nature of a carbonate reservoir may be discerned.

Clastic Reservoirs. The depositional environment may be estimated by studying electric log sections that pass through the zone of interest and by analyzing core samples taken from the zone.¹⁻³ The interpretation of these paleo-environments is derived from the study of modern depositional environments. The character of modern streams, deltas, and beaches has been well documented.⁴⁻⁶

Bernard and LeBlanc⁷ divided the major depositional environments into continental, transitional, and deep marine classifications. Continental and deep marine deposits do not contain widespread oil or gas accumulations and are not discussed further. Transitional sediments may be divided into coastal interdeltaic and deltaic environments. The coastal interdeltaic area usually consists of linear, relatively narrow sand beaches, which extend seaward into a normal and then a deep-water environment. The sands composing the normal marine environment are usually very fine grained and are deposited in conjunction with a high percentage of clay. The generally low permeabilities displayed by normal marine sediments preclude a high incidence of commercial oil and gas deposits.⁸ Deepwater marine sediments are composed mostly of shales and are on the whole nonproductive.

The most common and important hydrocarbon-bearing sandstone reservoirs are of deltaic origin. These sediments usually are deposited in a high-energy, often fluctuating atmosphere. In deltaic environments encountered most often during oil and gas drilling operations, delta-bar and distributary channel sediments are the two most prevalent sedimentary environments found, while offshore bars may be found in the delta front areas.

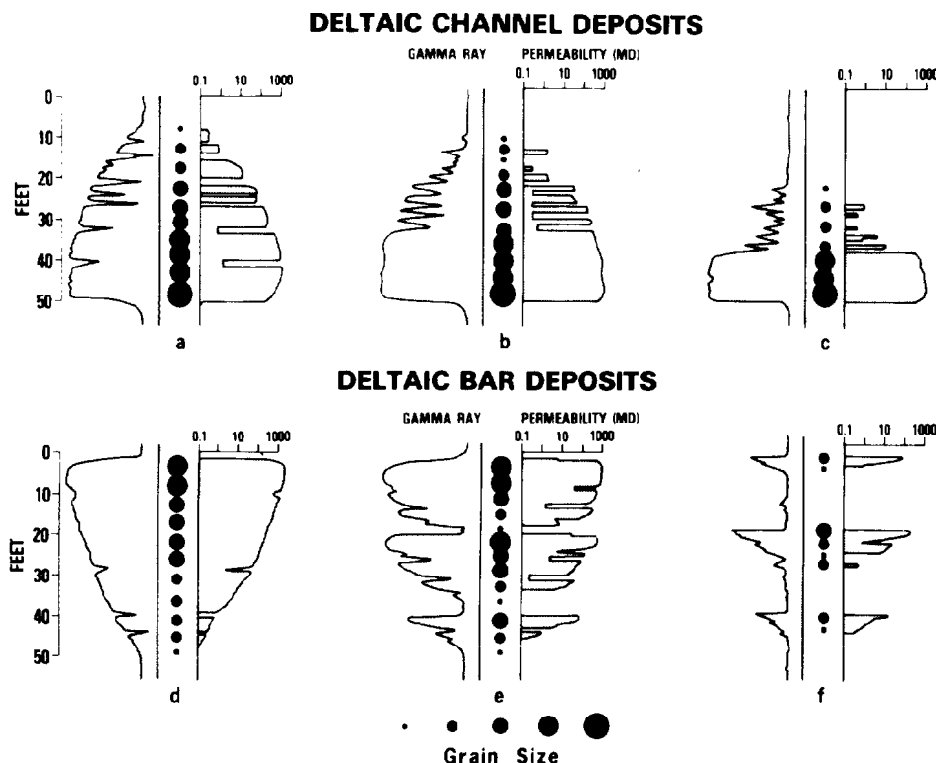

Fig. 36.1—Idealized porosity and permeability profiles—bar and channel deposits.

The delta-bar sequence is typified by an upward gradation from shallow, marine clays at the base through a section that shows an increasing grain size. The progressive upward coarsening of the sand-grain size is the result of the delta advancing over the marine clays. A high-energy regime is seen to increase in the vertical direction. A typical electric log section grades upward from a shale section (deeper water) to gradually increasing amounts of sand⁹ (see Fig. 36.1). The section contains crossbeds, ripple laminations, and modest amounts of quartz. Delta-bar sands grade downdip into pro-delta silts and clays and grade updip into the organic-rich, fresh- and brackish-water clays. Delta sands often are limited in areal extent, even though encompassing a thick sedimentary sequence. Vertical reservoir continuity may be restricted because of the large number of shale stringers present in the delta front sequence.

Distributary (river) channels transport sediments to the delta front. Distributary channels cut through deltas in a variety of meandering ways. Even though they comprise only a small portion of sedimentary record, these sediments often transect deltaic or offshore bar sand reservoirs and incur reservoir discontinuities in an otherwise homogeneous system. Fig. 36.2 is an example of such a discontinuity in the South Pass 27 field located in the offshore waters of south Louisiana.¹⁰ The field is included in the sand/shale sequence generated by prior deposition of the Mississippi River. Notice how the channel cut through the previously deposited sediments and formed a reservoir separate from the original.

Distributary channel sediments initially are deposited in a higher-energy atmosphere, and, hence, display a

coarser grain size toward the bottom of the section. The effect of grain size gradation may be seen in Fig. 36.1. These deposits are characterized by boxy log shapes with a very high sand content. The gradation of the sands is typified by an abrupt change from a shale to a very clean sand and then to a gradual increase in shale/sand ratio in the upward direction. Deposition is parallel to the source of the sediments.

Shoreline or barrier-island sandstones are represented by a sequence of normal marine muds grading upward into laminated sandstones. The section may be overlain by aeolian dune sandstones, which are the emergent portion of the shoreline. Sand gradation is generally coarsening upward. The sand grains are well sorted, and the quartz content of the sand is quite high. Wave action has reduced the less resistant feldspars to clay-sized particles, which have been transported to lower-energy regimes. Deposition is normal to the source of the sediments.¹¹ The sand bodies contain very few shale laminations and they are characterized by excellent lateral continuity.¹² The lowermost layer of a barrier bar sand comprises interbedded sand, silts, and shales. The second layer is made up of a bioturbated thick sand sequence. The penultimate layer consists of laminated sands laid down on the beach or the upper shore face of the barrier bar. The uppermost layer usually consists of oxidized aeolian deposits.¹³

Barrier bar reservoirs offer an excellent opportunity for hydrocarbon exploration. The reservoirs usually are overlain by lagoonal clays, which form an excellent trap. Barrier sands usually exhibit a high degree of internal continuity and are deposited parallel to the coastline.

Fig. 36.2—Reservoir discontinuity—channel and fringe sands.

Carbonate Reservoirs. Carbonate reservoirs are completely different in nature from sandstone reservoirs. The composition of sandstone reservoirs is largely a product of the depositional environment; carbonate reservoirs are a product of not only the depositional environment but also mechanical processes that occur after deposition.¹⁴ The heterogeneities caused by the variety of formative processes may form extremely complex fields such as the Means field shown in Fig. 36.3.¹⁵ Note the field heterogeneity. Carbonates may be deposited in both shallow- and deepwater marine environments. The fields may range from a few acres (pinnacle reefs) to regional in size (carbonate banks). Jardine¹⁶ has discussed how

carbonate fields may be formed in a variety of settings.

Bioherm Reefs. Bioherm or pinnacle reefs usually are characterized by their relatively small size with a high degree of relief. The reefs contain a high percentage of skeletal material at the outermost portions of the accumulation. The interior of the reef is composed of finer-grained material and has less porosity and permeability than the outer limits.

Biostrome Reefs. Biostrome reefs were formed in less rapidly subsiding basins and may extend for hundreds of square miles. Like the bioherm reefs, the biostrome reefs contain a high percentage of skeletal material. Horizontal stratification is present.

Fig. 36.3—Means field schematic.

PRIMARY POROSITY

SECONDARY POROSITY

DEPOSITIONAL TYPES	CONFIGURATION	GRAIN SIZE	POROSITY TYPE	PROCESS	FAVORABLE EFFECTS	UNFAVORABLE EFFECTS

NEAR-SHORE		C M F	VUG CELL I.O. CHALKY	CEMENTATION BY CALCITE DOLOMITE ANHYDRITE PYROBITUMEN QUARTZ		

Fig. 36.4—Distribution of porosity within various types of carbonate reservoirs.

Shelf Carbonates. Shelf carbonates are usually sheet-like or tabular bodies composed of a high percentage of skeletal material, enclosed by surrounding fine-grained material.

Nearshore Deposits. Nearshore deposits are usually of a thin and restricted nature and are generally fine grained. This type of deposit is of minor significance in oil and gas production.

Fig. 36.4¹⁶ summarizes the characteristics of the variety of carbonate deposits. Note the different types of porosity and the processes that affect the reservoir quality.

The development of oil and gas fields in carbonate sediments requires the study of the fossil content, any postdepositional alterations, and characterization of the pore space. This type of reservoir often displays two dissimilar porosity-permeability systems.

Extent of Shale Stringers. The knowledge of the probable lateral composition of a sandstone body soon after

discovery would be of considerable aid for planning of the future development drilling program. Weber¹⁷ combined studies done principally by Zeito,¹⁸ Verrien *et al.*,¹⁹ and Snider *et al.*²⁰ to arrive at Fig. 36.5. The figure summarizes a number of efforts to estimate the effect of depositional environment on the extent of shale stringers on sandstone reservoirs. Note how the marine sands possess the most extensive shale barriers, while the more poorly sorted point bars and distributary channels possess the shale members of least extent. Of course, the more widely correlative a producing interval is, the easier it is to predict future productive patterns. Many channels and point bars have been laid down in such a widely fluctuating atmosphere that correlation between wells is often difficult if not impossible. The recognition of the possible extent of the shale intercalations early in the life of development in the field would be of tremendous aid in the spotting of well locations.

Engineering

Intrawell continuity of the producing zone is one of the main ingredients for successfully depleting an oil or gas reservoir of the majority of the potential reserves. Additional development drilling often is required in a field when sand stringers are found to be discontinuous between producing wells.

The differential movement of fluids within a reservoir caused by rock heterogeneities was noted first in the engineering sense by Stiles.²¹ Poor response to the installation of many of the waterflood projects installed in some of the west Texas carbonate reservoirs in the 1950's and 1960's produced a spate of studies investigating the often discontinuous nature of the reservoirs. Refs. 15 and 22 through 25 are good reviews of some of these investigations. The determination of the degree of noncommunication between adjacent wells may be quantified to a certain degree by geological and reservoir engineering studies. The better-known techniques for estimating the degree of reservoir continuity are discussed next.

Fig. 36.5—Continuity of shale intercalations.

Net Pay/Net Connected Pay Ratio. Irregularities within sedimentary rocks often cause discontinuous productive horizons between wells. The degree of these discontinuities may be discerned by correlating the individual pay zones between adjacent wells. If a particular sand stringer is seen in one well but not in the other then it is called discontinuous. Sands are known to become more discontinuous with distance. A method to estimate the degree of producing-sand-interval intrawell communication is discussed in a paper by Stiles.²³ The continuity between wells is defined as the fraction of the total pay sand volume that is connected to another well.

A productive stringer is defined as continuous when correlatable between two wells. The stringer is classed as discontinuous if it is not correlative. Well pairs are compared, and eventually a figure may be drawn that summarizes the decline in reservoir continuity with distance. Fig. 36.6 is the result of one of these studies.²⁶ Notice the decline of continuity with distance between wells. The figure shows that the number of producing zone discontinuities was found to be much greater than expected when additional infill drilling was carried out in the Means field. A similar type of investigation by Stiles²³ in the Fullerton-Clearfork Unit had indicated a degree of reservoir continuity of 0.72. The estimate compares quite favorably with a material balance of the field.

A more recently published paper indicated that the material balance and the volumetric in-place estimate for a number of reservoirs in the Meren field compared very favorably.²⁷ A sand-by-sand correlation of these same reservoirs in the Meren field indicated a degree of continuity approaching that of unity. One could gather from these studies that communication was uniform throughout the reservoirs and additional infield drilling in all likelihood would not discover many discontinuous sand members. However, infield drilling in the Fullerton-Clearfork Unit could prove fruitful because of the good probability of penetrating previously undrained sand members.

Material Balance Studies. The results of volumetric reserves estimates may be compared to the material balance estimate. The material balance estimate is a function of production, which is derived from the movement of fluid through connected producing zones. Volumetric calculations are determined from net sand maps, which often do not take into account the effect of sand discontinuities on production. The difference between the results of the calculations gives an idea of the degree of discontinuity of a particular reservoir. Stiles²³ used the idea when studying the Fullerton-Clearfork Unit. The material balance method indicated 738 million bbl OIP. A volumetric estimate showed 1.03 billion bbl OIP. The ratio of the material balance estimate to volumetric estimate is 0.72. The low degree of communication would be an indicator of the successful outcome of an infield drilling project.

Computer Simulation Methods. Reservoir simulation studies are simply an extension of the material balance technique. However, the reservoir simulator allows one to take into account the producing and rock characteristics of individual areas within the reservoir.

Fig. 36.6—Continuous pay—Means field.

Details of reservoir simulation are given in Chap. 48.

A study by Weber²⁸ is an excellent example of the use of core and log interpretation principles to aid in determining the paleo-environment. These interpretations then were used in a computer simulation program, which was able to typify the D 1.30 reservoir in the Obigbo field with a high degree of accuracy. Fig. 36.7 is the type log of the reservoir. Note the differentiation of the producing interval into four discrete depositional environments. Each of the environments is represented by an interval of differing productive characteristics. The variations of these environments were noted in the section of each well penetrating the D 1.30 sand interval. Core analyses indicated the range of permeabilities that each of the units would exhibit. A permeability distribution map was drawn for the reservoir as a whole from these machinations. Subsequent modeling of the drainage patterns within the reservoir could be carried out with a high degree of certainty since the pattern of deposition had been replicated.

Interference Testing. The analysis of reservoir pressures has been an age-old reservoir evaluation tool in the petroleum industry. The similarity of pressures within a group of wells usually helps prove or disprove the interwell communication. An abnormally different pressure from a particular well is often the first indication of reservoir separation. Further analysis may disclose a previously undetected fault separating the wells in question. Sometimes wells are seen to display similar static bottomhole pressures even though there is a known fault separation. The similarity of pressures is caused by the production from each well being sufficient to draw the reservoir pressure down to the same degree. A transient pressure test must be run between the well pairs to estimate the degree of interwell communication.

The alteration in the producing or injection rate of a well will have an effect on the pressure in a connected observation well. The study of these effects is called "transient-pressure" or "interference" testing. Interference testing may be done by either a long-term production or injection change in a well (interference testing) or by very short-term rate alterations (pulse testing). Ref. 29 presents a detailed description of the two methods.

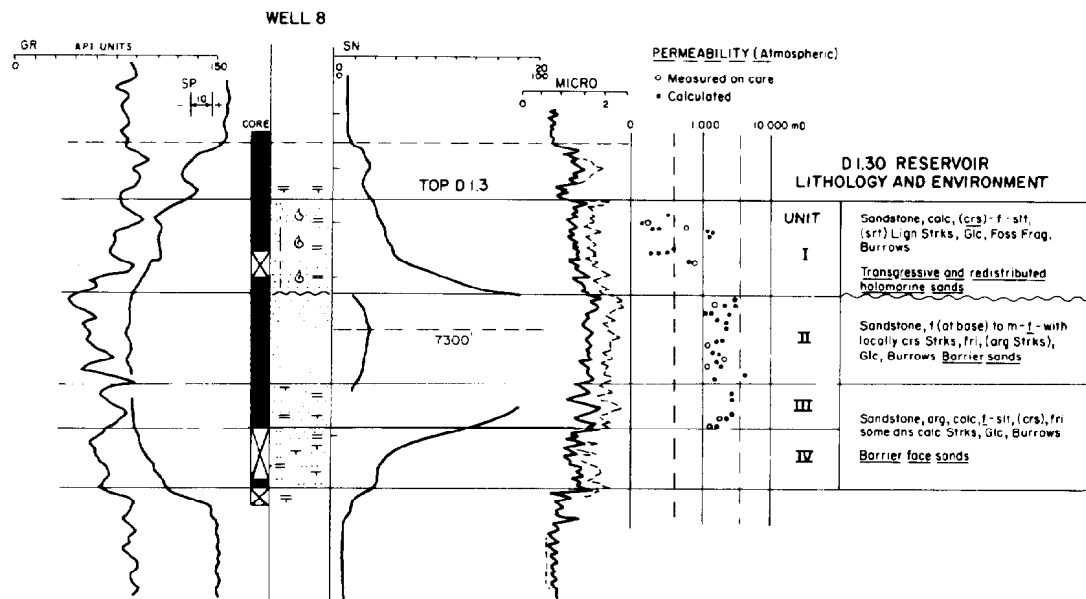

Fig. 36.7—Type log—D 1.30 sand, Obigbo field.

Interference tests comprise a relatively long-term rate alteration. The effect of the rate alteration will be noted in the observation well when there is interwell continuity. Of course, one would assume the presence of a discontinuity if the pressure fluctuation is not seen in the observation well.

The field application of an interference test is well documented in Ref. 30. A fieldwide spacing rule of 40 acres per well had been instituted in the North Anderson Ranch field in Lea County, NM. The engineering effort

was designed to estimate the true drainage area with the field. Four wells were produced and the resulting pressure decline was noted in a central observation well. (See Fig. 36.8 for the plan of the well layout.) The production from the four offsetting wells declined 11 psi after 165 hours' production. The diffusivity equation was used to calculate the expected pressure drop for similar conditions. The theoretically predicted pressure drop was 12 psi. The use of interference tests indicated a well drainage area greatly in excess of the initial 40-acre estimate. An 80-acre drilling pattern would effect a similar recovery with a greatly reduced number of wells.

Pulse testing is often more convenient than interference testing.³¹ The use of very precise pressure gauges coupled with individual design characteristics often allows pulse tests to be carried out within 1 or 2 days. Minor variations in production or injection volumes are able to send a pulse to observation wells. The variation of rates provides a "footprint," which may be noted by precision gauges placed in the observation wells. A pulse test is able to discern reservoir heterogeneities in a manner similar to the previously discussed interference test. However, the test may be carried out in a much shorter time because of the precision of the equipment. Ramey³² discusses the use of the pulse testing technique to determine reservoir anisotropy.

Fig. 36.8—Interference test plan.

Geophysics

3D Seismic Techniques. The three-dimensional (3D) seismic technique is a system of seismic data collection and processing that permits the proper vertical images to be developed and displayed by solving three orthogonal-wave equation migrations. The 3D method is a useful technique to map subsurface structures and to define the field configuration better previous to development. The detailed results allow the fault boundaries and

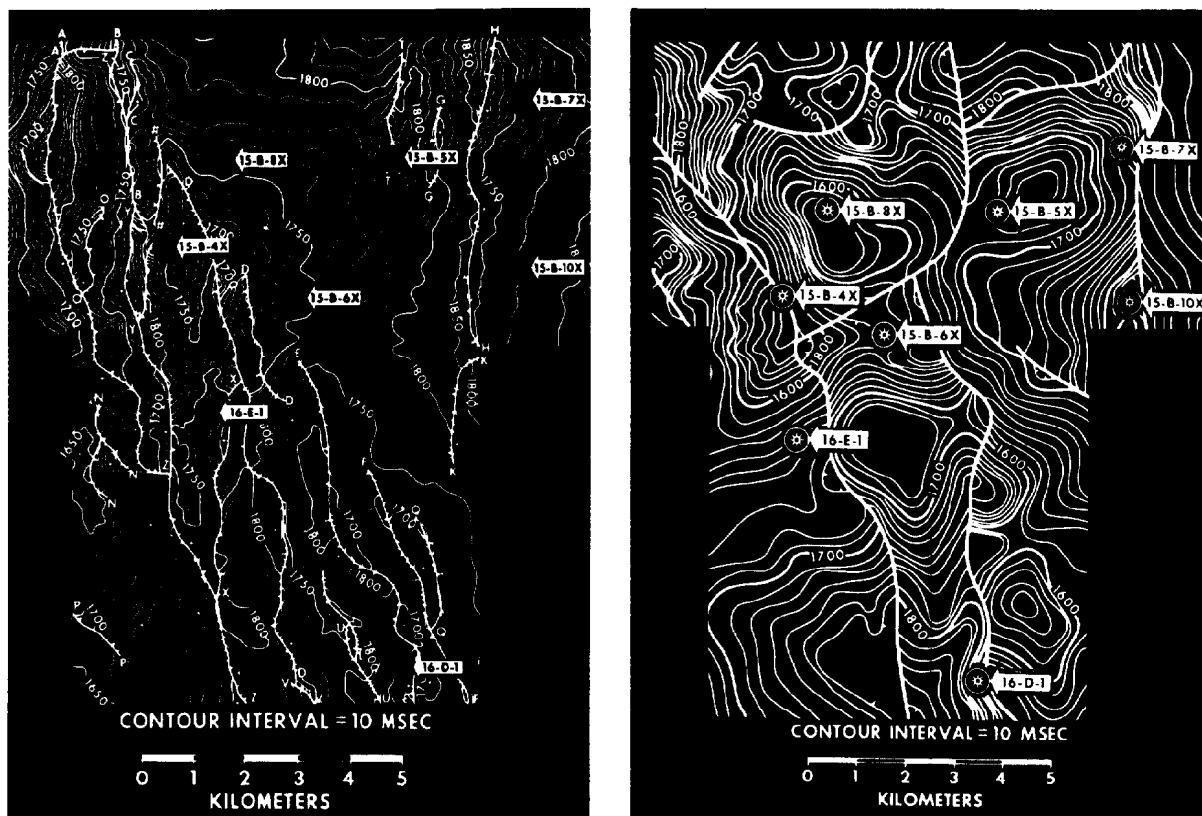

Fig. 36.9—Comparison of 2- and 3D seismic surveys.

stratigraphic limits of a reservoir to be mapped accurately soon after discovery. The number of appraisal wells would be reduced, and a more reliable estimate of the reserves could be obtained early in the life of the prospect. The knowledge of these two important facts would materially affect the overall drilling program.

The method is considerably more expensive than the more mundane seismic techniques, but it has been estimated that 100 sq miles of seismic coverage may be obtained for the cost of one appraisal well.³³ The 3D method provides greater structural definition than the better-known two-dimensional (2D) techniques for the following reasons.³⁴⁻³⁸

1. The placement of the vertical and horizontal reflection images is more accurate. Additionally, both vertical and horizontal sections may be presented for any depth and for any direction.
2. Diffraction events are eliminated.
3. The signal strength normally lost because of scattering problems is restored.
4. The increased control point density permits more accurate mapping.
5. The greater amount of data improves the statistical base for estimating near-surface corrections and velocities.

A particularly interesting example of using the 3D seismic method to evaluate a prospect and to help plan the drilling program may be seen in a study conducted in the Gulf of Thailand.³⁹ Three wildcat wells had disclosed the presence of probably commercial quantities of

gas. However, the prospect appeared to be faulted and a number of appraisal wells would be required to evaluate the potential in this relatively unexplored region. A region of 120 km² was subjected to a 3D seismic reconnaissance shot at 100-m intervals. The program afforded a greater definition of the megastructure, indicated faulting was much more prevalent than previously indicated, and also helped prove the viability of the prospect.

Figs. 36.9a and 36.9b compare the structural interpretations obtained by conventional 2D results with those obtained by 3D vertical migration. Note the increase in the complexity of the structure. The clarity of the 3D subsurface structural interpretation results from the more sharply focused nature of the process. The 2D interpretations give a more blurred or distorted picture because of the coarser sampling, which results in a statistically poorer presentation.

A survey conducted in offshore Trinidad⁴⁰ resulted in a change in the platform location and drilling plan of one prospect and the deletion of another prospect from development until additional exploration in other faultblocks was conducted.

Prediction of Reservoir Performance

After the reservoir has been characterized adequately, as described previously, a development plan must be selected. Performance of the reservoir under various exploitation schemes needs to be determined before selecting the final development plan. The modern tools used

by the reservoir engineer to predict the performance of the reservoir are reservoir simulators or mathematical models (see Chap. 48). A general description of the simulation steps and the results from simulation follows.

Simulation Steps

Data Preparation.

1. Select the appropriate simulator to use in the study—i.e., black oil, compositional, 2D, 3D, etc.
2. Divide the reservoir into a number of cells—i.e., establish a grid system for the reservoir.
3. Assign rock properties, geometry, initial fluid distribution, and fluid properties for each cell. The rock properties include permeability, porosity, relative permeability, capillary pressure, etc. The cell geometry includes depth, thickness, and location of wells. Fluid properties are specified by the usual PVT data and phase behavior if required.
4. Assign the production and/or injection schedule for wells and the well constraints that need to be maintained.

Performance Prediction. If no historical data are available, the next step is to make the necessary computer runs to obtain the performance of the wells and the reservoir as a function of time and various plans of development.

If historical data are available, the first step is to match the historical performance. The reservoir performance is calculated and the results are compared with the field-recorded histories of the wells. If the agreement is not satisfactory, adjustments in the data (such as the relative permeability, the specific permeability, the porosity, the aquifer, etc.) are made until a satisfactory match is achieved. The model then is used to predict the performance for alternative plans of operating the reservoir.

In summary, the reservoir engineer obtains from the simulators the reservoir performance for different development plans, including various displacement mechanisms (such as water or gas injection, miscible displacement, etc.), different number and location of wells, and effect of flow rates. The reservoir performance then is used in the appropriate economic analysis to decide on the optimal development plan.

Chapter 37

Solution-Gas-Drive Reservoirs

Roger J. Steffensen, Amoco Production Co.*

Introduction

An oil reservoir is a solution-gas-drive reservoir if it undergoes primary depletion with the main reservoir energy supplied by the release of gas from the oil and the expansion of the in-place fluids as reservoir pressure drops. This excludes reservoirs affected significantly by fluid injection or water influx. Also, reservoirs that have vertical segregation of the gas and oil by gravity drainage merit special analysis. (In combination with appropriate production practices, gravity drainage can increase oil recovery significantly.) Reservoirs with an initial free-gas cap are sometimes included in the category of solution-gas-drive reservoirs; the gas-cap drive (gas expansion) supplements the solution-gas drive.

Solution-gas drive also is called dispersed-gas drive or internal- (as opposed to injected) gas drive because the gas comes out of solution throughout the portion of the oil zone that has a pressure below the bubblepoint. Initially, pore space in a solution-gas-drive reservoir contains interstitial water plus oil that contains gas in solution because of pressure. No free gas is assumed to be present in the oil zone. As reservoir pressure drops below the bubblepoint because of production, the oil shrinks. Part of the pore space is filled by gas that comes out of solution. The water expansion, a much smaller effect, is often neglected. The drive mechanism (gas evolution and expansion) is dispersed or scattered throughout the oil zone.

The evolved gas (less any produced gas) fills the pore space vacated by produced oil and by shrinkage of the remaining oil. The amount of oil recovered depends on the amount of pore space occupied by gas (the gas saturation S_g) and the oil shrinkage (B_o vs. pressure). Gas/oil relative-permeability characteristics and viscosities of oil and gas are important because they determine the flowing GOR at a given S_g (and thus the amount of free gas produced along with the oil).

Abundant literature is available on solution-gas-drive reservoir performance and prediction methods¹⁻²² and on production-rate computations for wells in those reservoirs.²³⁻³⁰ Special methods have been developed for predicting the behavior of volatile oil reservoirs.³¹⁻³⁸

Definitions

Bubblepoint pressure is the saturation pressure of the oil; as pressure drops below bubblepoint, gas starts coming out of solution from the oil. Critical gas saturation is the minimum saturation at which gas starts to flow. Gravity drainage refers to vertical segregation of gas and oil by countercurrent flow because of gravity (i.e., density difference); gas moves up and oil moves down. In differential gas separation, the evolved gas is continuously removed as pressure is lowered, so that the gas does not remain in contact with the liquid. Flash gas separation occurs when the evolved gas remains in contact with the liquid as pressure is lowered.

Typical Performance

Fig. 37.1 shows typical performance for a solution-gas-drive reservoir with an initial pressure above the bubblepoint. During the early production, pressure is above bubblepoint but is dropping rapidly. Gas saturation is zero, and the only gas produced was in solution in the produced oil at reservoir conditions (producing GOR, $R=R_{si}$). The rapid pressure decline is caused by the relatively low compressibility of the system. The only sources of pressure support are fluid and rock expansion.

Once the reservoir pressure reaches bubblepoint, solution-gas drive begins, and pressure declines less rapidly. The additional pressure support is a result of the liberation of gas as pressure declines and the expansion of this gas as it undergoes further pressure reduction.

As pressure drops below bubblepoint, the evolved gas is immobile until the gas saturation exceeds the critical

*Original chapter in 1962 edition was written by Vincent J. Sikora, now retired.

Fig. 37.1—Typical solution-gas-drive reservoir performance.

value, S_{gc} . For this period, there is no free-gas production, and the produced GOR declines because the produced oil now contains less gas in solution (lower R_s). Once S_{gc} is exceeded, free-gas production begins, and the total (free plus solution) produced GOR increases. This ratio rises to a peak much higher than the solution GOR (most of the gas produced at that time is free gas), then drops at low pressures. This drop is caused by insufficient additional gas evolution to sustain the high gas production. Solution-gas-drive reservoir performance is characterized by (1) relatively rapid pressure decline (faster than with fluid injection); (2) low initial producing GOR (equal to solution GOR) rising to a much higher GOR; (3) oil production rates declining because of both 1 and 2; (4) little or no water production; and (5) relatively low oil recovery—typically 15 to 20% of original oil in place (OOIP), but occasionally as low as 5% or as high as 30% OOIP.

A notable exception is that reservoirs benefiting from gravity drainage may have sustained production at a lower GOR and, consequently, a higher oil recovery. This is particularly true if the oil production is taken from the lower part of the oil column where the gas saturation and GOR are lower.

Types of Models Used

Performance prediction methods can be divided into two categories: tank-type models and gridded reservoir models. Tank-type models are simpler; gridded models can consider more details. Each is useful when used appropriately. Tank-type models for solution-gas-drive reservoirs are described in this chapter, and gridded models are discussed in Chap. 48.

Before gridded models were made practical by the introduction of modern computers, the main methods available for reservoir performance calculations were the tank-type models. These treat the reservoir as a single tank or region that is described by the average pressure and average saturations at a given time. This is equivalent to assuming that the reservoir is at equilibrium (i.e., has uniform pressure and saturation). Variations with time are considered, but variations with position are not. The field production rate vs. time for tank-type models is predicted

by calculating the rate for an average or representative well and then multiplying by the number of active wells.

Gridded reservoir models subdivide the reservoir into a number of gridblocks, each having its own PV, pressure, and saturations. Some blocks contain wells. Gridded models enable consideration of such details as reservoir heterogeneity, individual well locations and characteristics, and fluid migration between regions.

Tank-type models are adequate—in certain cases even preferable—for answering some questions, while being simpler and quicker to use than the gridded models. Understanding tank-type models aids the understanding of gridded simulators because both use basic continuity (material balance) principles. Even for reservoirs that ultimately may be studied with a gridded model, the calculated tank-type primary performance can provide useful, quick information and can serve as a reference point for comparison.

Also, a very important use of tank-type models is in interpretation of a reservoir's pressure/production history to determine the OIP and whether the reservoir is volumetric or has water influx. Havlena and Odeh¹⁵ presented particularly useful techniques for doing this with the material-balance equation rearranged as the equation of a straight line. They noted that OIP calculated by this equation is the oil that contributes to the pressure/production history (i.e., is communicating with wells). This may or may not agree with the volumetrically calculated OIP because of uncertainties in volumes and/or incomplete communication.

This chapter focuses on tank-type material balances and their application to solution-gas-drive reservoirs. Gridded simulator studies that are used to evaluate the range of applicability of tank-type models are also discussed. Calculation methods for ordinary (nonvolatile) oils are given first. These are normally adequate for oils having B_o less than roughly 2.0 RB/STB. The last part of the chapter discusses performance prediction methods for volatile oil reservoirs.

Basic Assumptions of Tank-Type Material Balance

1. The reservoir PV is constant (except in some cases where nonzero rock compressibility is considered).
2. The reservoir temperature is constant.
3. The reservoir has uniform porosity and uniform relative-permeability characteristics.
4. Equilibrium conditions exist throughout the reservoir at all times. Pressure is assumed to be uniform throughout the reservoir; consequently, fluid properties at any time (i.e., any pressure) do not vary with position in the reservoir. The effects of pressure drawdown around wells are neglected. The liquid saturation is assumed to be uniform throughout the oil zone. Thus, at a particular time, the value of the gas/oil relative-permeability ratio (k_{rg}/k_{ro}) is regarded as constant throughout the oil zone. This includes the assumption of no gravity segregation. For reservoirs having an initial gas cap, this includes the assumption of no gas coning at wells. Gas cap and oil zone volumes are assumed not to change with time. Any gas leaving the cap because of gas expansion is assumed to be distributed uniformly throughout the oil zone.

5. The PVT properties are representative of reservoir conditions. The fluid sample from which the PVT data are determined is assumed to be representative of the fluid in the reservoir, and the gas liberation mechanism in the reservoir is assumed the same as that used to determine the PVT data. Usually, differential vaporization is assumed to be most representative of conditions in the reservoir. With the possible exception of volatile oils, the fluid properties are assumed to be functions of only pressure—i.e., any effects of composition change are neglected.

6. The recovery is independent of rate.

7. Production is assumed to result entirely from liberation of solution gas and the expansion of the liberated gas of any initial gas cap and of oil as reservoir pressure decreases. This includes assumptions that there is no fluid injection; that water is immobile and there is no water production and no water influx; and that reservoir water and rock compressibility can be neglected (note that this assumption is used only below bubblepoint and that these effects should be considered above the bubblepoint).

8. A relationship is assumed for specifying oil production rate as a function of reservoir pressure and saturation.

9. Reservoir performance data, if used, are assumed to be reliable. This refers, for example, to average pressure vs. cumulative oil production used to determine OIP, and producing GOR vs. pressure used to determine or check the curve of k_{rg}/k_{ro} vs. saturation.

Basic Data Required

OIP

Two sources of OIP data are volumetric calculations and values determined from the reservoir's pressure/production history. Often, only the volumetric estimate is available. When there is enough solution-gas-drive history (reservoir average pressure vs. oil produced), this volumetric value can be checked by a comparison with the history-derived OIP. A convenient method for determining the OIP from pressure/production history is given by Havlena and Odeh¹⁵ and will be described in a later section.

A frequently given rule of thumb is that 5 to 10% of the fluid in place must be produced before the performance history is sufficient for calculation of OIP. For a solution-drive reservoir, this would be a large fraction of the ultimate recovery, which is typically 15 to 20%. While the amount of production is important, good values for average reservoir pressure at a sequence of times (based on well pressure tests) are equally important. If you have a sequence of pressure points that were determined from field measurements, try Havlena and Odeh's method; if several points form an essentially straight line, you probably have enough data to confirm the OIP (even at less than 5% recovery).

PVT

As reservoir pressure drops below the bubblepoint, the first gas liberation is by the flash vaporization process (the gas is not yet mobile and therefore stays in contact with the oil). Once the critical gas saturation is exceeded, some of the gas flows. Thereafter, the gas liberation process is somewhere between differential vaporization (gas is continuously removed from the oil) and flash vaporization.

As the gas saturation increases above critical, the gas mobility increases rapidly, the gas becomes more mobile than the oil, and the gas moves faster than the oil. Because the evolved gas moves ahead of the oil, the process is closer to differential. Overall, the process in the reservoir is approximated more closely by the laboratory differential PVT data than by the laboratory flash data. This is particularly true for high-solubility crudes. Use of the differential PVT data is recommended. Even for the pressure range just below bubblepoint, where flash PVT data are more appropriate, the differential data do not cause significant errors because flash and differential data are almost identical in this pressure range.

If laboratory data are not available, reasonable estimates sometimes may be obtained from published correlations (see Chap. 22).

Gas liberation in the separators is closer to a flash vaporization process and frequently is at a temperature much lower than the reservoir temperature. Because differential PVT data are used in the material-balance computations, the computed recoveries could be adjusted to account for the different process (and particularly the different temperature of gas separation) from bottomhole to stock-tank conditions (see Chap. 22 and Page 64 of Dake³⁹). For typical crudes, however, this adjustment is often within the range of other data and model limitations and consequently not warranted.

Initial Fluid Saturations

Because saturations are assumed to be uniform, a single value is used for initial water saturation, S_{wi} . The initial oil saturation is then $S_{oi} = 1.0 - S_{wi}$. The preferred data are initial fluid saturations obtained from a laboratory analysis of representative cores or from a combination of core analysis and well log analysis. Alternatively, these values can be based on logs or on other reservoirs in the same or similar formations.

Relative-Permeability Data

Generally, laboratory-determined k_g/k_o and k_{ro} data are averaged to obtain a single representative set for the reservoir that is consistent with the interstitial water saturation. If laboratory data are not available, estimates may be based on other reservoirs in the same or similar formations.

For reservoirs having sufficient solution-gas-drive history, the calculated k_g/k_o values vs. saturation can be compared with the averaged laboratory or estimated k_g/k_o data. These values may be calculated¹¹ with Eqs. 1 and 2, and the laboratory data can be adjusted slightly to match more closely the observed history of producing GOR (R) vs. reservoir pressure if necessary.

$$\frac{k_g}{k_o} = (R - R_s) \frac{\mu_g B_g}{\mu_o B_o} \quad (1)$$

$$S_o = \frac{(N - N_p) B_o S_{oi}}{N B_{oi}} \quad (2)$$

Fig. 37.2—Vertical saturation distribution for complete segregation.

where

- k_g = effective permeability to gas, md,
- k_o = effective permeability to oil, md,
- R = producing GOR, scf/STB,
- R_s = solution GOR, scf/STB,
- μ_g = gas viscosity, cp,
- μ_o = oil viscosity, cp,
- B_g = gas formation volume factor, RB/scf,
- B_o = oil formation volume factor, RB/STB,
- B_{oi} = value of B_o at initial pressure, RB/STB,
- S_o = oil saturation, fraction PV,
- S_{oi} = initial oil saturation, fraction PV,
- N_p = cumulative oil production, STB, and
- N = initial OIP, STB.

To use the above equations, you need estimates of the initial OIP (N) and of the current reservoir pressure. The fluid properties (μ_o , μ_g , B_o , and B_g) are evaluated at this pressure.

Pseudo-Relative-Permeability Data for Complete Segregation

This refers to reservoirs that have enough vertical communication for gravity segregation to occur, with evolved gas moving upward and oil draining downward. The literature on tank-type-model predictions includes description of relative-permeability modifications to obtain pseudo-relative-permeability curves to account for complete gravity segregation within the reservoir. Consequently, the suitability of such pseudocurves in the tank-type material-balance computations should be discussed. For reasons given below, this approach is potentially misleading and should be avoided.

The laboratory-measured relative-permeability data apply to an unsegregated situation (no change in saturation with height). This case is most consistent with the basic

Fig. 37.3—Comparison of no-segregation and complete-segregation relative-permeability data.

assumptions of the tank-type model, and the tank-type model is most suitable for it. It is also possible to calculate¹³ pseudo or effective k_g/k_o and k_{ro} data for the case of a reservoir that has complete gravity segregation, as shown in Fig. 37.2, and flow from the total net pay thickness (i.e., assuming wells are completed in the total net pay).

The entire reservoir shown in Fig. 37.2 contains interstitial water saturation. Complete segregation means that the upper part of the reservoir contains gas and immobile oil at residual oil saturation, S_{or} , while the lower part contains oil and immobile gas at the critical gas saturation, S_{gc} . Vertical communication is assumed to be high enough that, as gas evolves in the lower region, any gas saturation above S_{gc} moves upward rapidly and leaves that region, while in the upper region any oil above S_{or} drains downward and moves into the lower region. The flow to wells is assumed to be horizontal and to consist of only gas in the upper region and of only oil in the lower region. On the basis of these assumptions, the effective k_g/k_o and k_{ro} are given by Eqs. 3 and 4.

$$\frac{k_g}{k_o} = \frac{(S_g - S_{gc})(k_{rg})_{or}}{(S_o - S_{or})(k_{ro})_{gc}} \quad \dots \dots \dots (3)$$

$$k_{ro} = \frac{S_o - S_{or}}{1 - S_w - S_{gc} - S_{or}} (k_{ro})_{gc} \quad \dots \dots \dots (4)$$

where

$(k_{rg})_{or}$ = relative permeability to gas at residual oil saturation,

$(k_{ro})_{gc}$ = relative permeability to oil at critical gas saturation,

S_g = gas saturation, fraction PV,

S_{gc} = critical gas saturation, fraction PV,

S_{or} = residual oil saturation, fraction PV, and

S_w = water saturation, fraction PV.

Fig. 37.3 compares ordinary k_r/k_o and k_{ro} curves for an unsegregated reservoir with the adjusted curves for the completely segregated assumption.

Pseudo-relative-permeability data calculated with Eqs. 3 and 4 are consistent with the above assumptions. And one might be tempted to assume that results computed for no segregation (unmodified relative-permeability data) and for complete segregation (the above pseudo-relative-permeability data) bracket the results to be expected for cases with partial segregation. What is wrong with this approach? The problem is that perforating the entire pay thickness is not the best way to operate such a reservoir. Producing gas at high GOR from the upper part of the pay thickness reduces reservoir energy (pressure support). It is much better to produce such a reservoir only from the lower part of the oil column, thereby reducing the producing GOR and maintaining reservoir energy. Consequently, the assumption of production from the entire pay thickness is inappropriate for this case. The tank-type model with pseudorelative permeabilities seriously underestimates the oil recovery compared to a good gravity-drainage project. Results of this model will lead to incorrect conclusions about the benefits of gravity drainage and about how to operate the field.

If a reservoir has enough vertical communication to benefit from gravity drainage, consider use of a gridded model (Chap. 48) for primary performance predictions. With the gridded model, you can study the benefits of selective perforation low in the pay, possible benefits of producing mainly from downdip wells if the reservoir has dip, and possible sensitivity of oil recovery to production rate and to the amount of vertical permeability.

Material-Balance Equation

The material-balance equation keeps inventory on all material entering, leaving, and accumulating within a region. Sometimes called the Schilthuis¹ equation when applied to a reservoir, it states that because reservoir volume is constant, the algebraic sum of volume changes (including production and injection) of the oil, free gas, and water must equal zero. In other words, expansion equals voidage; the net voidage (production minus injection minus influx) must be made up by expansion of the in-place materials. Van Everdingen *et al.*⁴⁰ stated the material balance in reservoir volumes as follows:

“(Cumulative oil produced and its original dissolved gas) + (Cumulative free gas produced) + (Cumulative water produced) – (Cumulative expansion of oil and dissolved gas originally in reservoir) – (Cumulative expansion of free gas originally in reservoir) = (Cumulative water entering original oil and water reservoir).”

Water and gas injection could also be considered in the material balance by replacing cumulative production with cumulative production minus cumulative injection.

For an oil reservoir having an initial gas cap, with m denoting the ratio of gas-cap-volume/oil-zone-volume, the material balance expressed in reservoir volumes is given by Eq. 5.

$$\begin{aligned}
 & N(B_o - B_{oi}) \text{ (expansion of initial oil)} \\
 & + N(R_{si} - R_s)B_g \text{ (volume occupied by liberated solution gas)} \\
 & + mNB_{oi} \left(\frac{B_g - B_{gi}}{B_{gi}} \right) \text{ (gas-cap gas expansion)} \\
 & + \frac{NB_{oi}(1+m)}{1-S_w} S_w c_w (p_{iR} - p_R) \text{ (water expansion)} \\
 & + \frac{NB_{oi}(1+m)}{1-S_w} c_f (p_{iR} - p_R) \text{ (rock expansion)} \\
 & = N_p B_o \text{ (oil production)} \\
 & + (G_{ps} - N_p R_s) B_g \text{ (liberated solution gas production)} \\
 & + G_{pc} B_g \text{ (gas-cap gas production)} \\
 & - G_i B_g \text{ (gas injection)} \\
 & + W_p B_w \text{ (water production)} \\
 & - W_i B_w \text{ (water injection)} \\
 & - W_e B_w \text{ (water influx), } \dots \dots \dots (5)
 \end{aligned}$$

where

R_s = solution GOR, scf/STB,

R_{si} = value of R_s at initial pressure, scf/STB, and

m = PV of gas cap/PV of oil zone, dimensionless.

Solving Eq. 5 for N yields the general material-balance equation for initial OIP:

$$\begin{aligned}
 N = & \frac{N_p B_o + (G_p - N_p R_s) B_g + (W_p - W_i - W_e) B_w - G_i B_g}{(B_o - B_{oi}) + (R_{si} - R_s) B_g + m B_{oi} \left(\frac{B_g - B_{gi}}{B_{gi}} \right) + \frac{B_{oi}}{1-S_w} (1+m) (S_w c_w + c_f) (p_{iR} - p_R)} \\
 & \dots \dots \dots (6)
 \end{aligned}$$

where $G_p = G_{ps} + G_{pc}$ = cumulative gas production, in standard cubic feet.

By considering a case only above bubblepoint or only below bubblepoint, some terms are zero or negligible, and the general equation can be simplified. These cases are discussed in the following sections.

Material Balance Above Bubblepoint

For an undersaturated reservoir (i.e., above bubblepoint), no gas will be released from solution, the produced GOR will remain constant at R_{si} , and there would not be any gas cap. Thus $(R_{si} - R_s) = 0$, $m = 0$, and $(G_p - N_p R_s) = 0$.

With these simplifications and the assumption of no gas injection, Eq. 6 reduces to

$$N = \frac{N_p B_o + (W_p - W_i - W_e) B_w}{B_o - B_{oi} + \frac{B_{oi}}{1 - S_{wi}} (S_w c_w + c_f) (p_{iR} - p_R)} \quad (7)$$

Because for the single-phase oil $B_o - B_{oi} = B_{oi} c_o (p_{iR} - p_R)$, the material-balance equation above bubblepoint becomes

$$N = \frac{N_p B_o + (W_p - W_i - W_e) B_w}{B_{oi} c_e (p_{iR} - p_R)} \quad (8)$$

where the effective compressibility (c_e) is

$$c_e = c_o + \frac{S_w c_w}{1 - S_w} + \frac{c_f}{1 - S_w} \quad (9)$$

Although water and rock compressibility are often neglected below bubblepoint because their effect is small compared with gas evolution and expansion, they should be included above bubblepoint. For example, consider a case with the following data:

$$c_o = 15 \times 10^{-6} \text{ vol/}(\text{vol-psi})$$

$$c_w = 3 \times 10^{-6} \text{ vol/}(\text{vol-psi})$$

$$c_f = 4 \times 10^{-6} \text{ vol/}(\text{PV-psi})$$

and

$$S_w = 0.20.$$

By use of Eq. 9,

$$\begin{aligned} c_e &= 15 \times 10^{-6} + \frac{(0.20)(3 \times 10^{-6})}{1 - 0.2} + \frac{4 \times 10^{-6}}{1 - 0.2} \\ &= 15 \times 10^{-6} + 0.75 \times 10^{-6} + 5 \times 10^{-6} \\ &= 20.75 \times 10^{-6} \text{ vol/}(\text{vol-psi}) \end{aligned}$$

For this example, the water and rock compressibility contribute more than one-fourth of the total compressibility. Their omission would cause the OIP calculated by Eq. 8 to be too high by a factor of $20.75/15 = 1.383$ (i.e., 38% too high). The error would be even greater for larger S_w .

Calculation of Oil Production Above Bubblepoint. For an initially undersaturated reservoir with negligible water production, injection, or influx, rearrangement of Eq. 8 yields the following expression for cumulative oil production:

$$N_p = \frac{N B_{oi} c_e (p_{iR} - p_R)}{B_o} \quad (10)$$

Calculation of oil recovery to bubblepoint is straightforward, with bubblepoint pressure as the value of p_R in Eq. 10. The remaining OIP is then $N - N_p$. This value is often used in computations of the additional recovery below bubblepoint.

Material Balance Below Bubblepoint

Below bubblepoint, the net expansion of hydrocarbons (gas evolution plus gas expansion minus oil shrinkage) is much greater than the expansion of rock and water. Consequently, the rock and water expansion terms can be omitted without serious error. By neglecting these terms and by assuming no water influx, no gas injection, and no net water production, we simplify Eq. 6 to Eq. 11.

$$N = \frac{N_p B_o + (G_p - N_p R_s) B_g}{(B_o - B_{oi}) + (R_{si} - R_s) B_g + m B_{oi} \left(\frac{B_g - B_{gi}}{B_{gi}} \right)} \quad (11)$$

Even if the initial pressure was above bubblepoint, Eq. 11 can be used to compute the performance below bubblepoint. In this case, the value used for N is the OIP at bubblepoint; N_p and G_p are the incremented oil and gas production below bubblepoint; and the "initial" fluid properties B_{oi} and B_{gi} are values at bubblepoint.

Another expression for N , often found in the literature and equivalent to Eq. 11, is given by Eq. 12.

$$N = \frac{N_p [B_i + B_g (R_p - R_{si})]}{B_i - B_{ii} + m B_{oi} \left(\frac{B_g}{B_{gi}} - 1 \right)} \quad (12)$$

where

$$R_p = \text{cumulative produced GOR, scf/STB.}$$

$$R_p = \frac{G_p}{N_p} \quad (13)$$

B_i is the two-phase (i.e., total hydrocarbon) FVF—reservoir barrels occupied by one barrel of stock-tank oil plus the gas that was initially dissolved in that oil at reservoir conditions.

$$B_i = B_o + B_g (R_{si} - R_s) \quad (14)$$

Material Balance as Equation of Straight Line for Determination of OIP and of Gas-Cap Size

Havlena and Odeh¹⁵ show how to use the material-balance equation along with a reservoir's pressure/production history to get information about whether the reservoir is volumetric or has water influx, plus the initial OIP (N) and the ratio of gas-cap-volume/oil-zone-volume (m) for a volumetric reservoir. Water influx is discussed in Chap. 38; only the volumetric case will be considered here.

Fig. 37.4A—Straight-line material balance for reservoir without gas cap. Q_p from Eq. 15 vs. $\Delta B_t = B_t - B_{ti}$.

Havlena and Odeh rearranged Eq. 12 as the equation of a straight line, grouping terms as follows:

$$Q_p = N_p [B_t + B_g (R_p - R_{si})], \quad (15)$$

$$\Delta B_t = B_t - B_{ti}, \quad (16)$$

and

$$\Delta B_g = B_g - B_{gi}, \quad (17)$$

where

Q_p = net fluid production, RB,

ΔB_t = oil expansion per STB of initial OIP.
RB/STB, and

ΔB_g = expansion of initial free gas (the gas cap)
per scf of initial free gas in place,
RB/scf.

Eq. 12 can be rearranged as

$$Q_p = N \Delta B_t + N m \frac{B_{ti}}{B_{gi}} \Delta B_g. \quad (18)$$

A plot of Q_p vs. $\Delta B_t + m(B_{ti}/B_{gi}) \Delta B_g$ should result in a straight line going through the origin. The slope of this line represents N , the initial OIP. Similarly, in the absence of a gas cap, $Q_p = N \Delta B_t$; a plot of Q_p vs. ΔB_t should be a straight line of slope N , going through the origin. This is illustrated by Fig. 37.4A.

When field performance (Q_p vs. ΔB_t) is plotted, if it yields an approximately straight line, the slope indicates the value of the initial OIP (N). The data needed are fluid properties vs. pressure and the reservoir performance data at several times or pressures. The performance data are N_p , G_p , and average reservoir pressure (for determination of fluid properties). If the plot of Q_p vs. ΔB_t is not a straight line, possible reasons include (1) erroneous average pressures and/or fluid properties, (2) water influx (see Chap. 38), (3) gas cap is present and expand-

Fig. 37.4B—Straight-line material balance for reservoir with gas cap.

ing, and (4) gravity drainage that is affecting reservoir performance (R_p lower than for solution-gas drive alone).

For a reservoir with an initial gas cap but no water influx, values of both N and m can be determined from the field performance data, as illustrated in Fig. 37.4B. By trial and error, the value of m yielding a straight line can be determined; N is the slope of this line.

For cases with a gas cap, Havlena and Odeh recommended that a second method also be used as a check, even though the first method (given above) "is a more powerful method" because "it specifies that the line must go through the origin." The second method plots values of $Q_p/\Delta B_t$ on the vertical (y) axis vs. values of $\Delta B_g/\Delta B_t$ on the horizontal (x) axis. If both sides of Eq. 18 are divided by ΔB_t , we can see that the plotted points should approximate a straight line with slope equal to NmB_{ti}/B_{gi} . Also, if this line is extrapolated so that it intercepts the y axis, the y value at that intercept is equal to N . Consequently, the slope and the y intercept of this plot enable calculation of both N and m . Comparison of these values with those determined by the first method is a desirable check, and also may aid selection of the best value of m for use in the first method.

Having values of N and m that are based on reservoir performance and/or on other information or estimates, we are now ready to consider predictions of future performance by solution-gas drive. Techniques for this have been published by Muskat,⁴ Tarner,² and Tracy.⁶ All three methods yield essentially the same results when small enough intervals of pressure or time are used. Because Tracy's method is the most convenient to use, it will be described first.

Material-Balance Calculations Using Tracy's Method

Prediction of solution-gas-drive performance involves the use of a material-balance equation such as Eq. 11, plus enough additional relationships (equation for producing GOR, and for relating saturations to N_p) to enable computation of N_p and G_p vs. pressure. The computations are performed for a sequence of pressure decrements. The

Fig. 37.5A—Oil pressure function Φ_o vs. reservoir pressure.Fig. 37.5B—Gas and water pressure functions Φ_g and Φ_w vs. reservoir pressure.

incremental oil production ΔN_p and the incremental gas production ΔG_p for the pressure decrement from p_{n-1} to p_n are determined by an iterative method, and the cumulative production values are then given by Eqs. 19 and 20.

$$(N_p)_n = (N_p)_{n-1} + \Delta N_p \quad \dots \dots \dots (19)$$

and

$$(G_p)_n = (G_p)_{n-1} + \Delta G_p \quad \dots \dots \dots (20)$$

Tracy simplified the use of Eq. 11 by introducing pressure functions Φ_g and Φ_o :

$$\Phi_g = \frac{1}{\left(\frac{B_o - B_{oi}}{B_g} \right) - (R_s - R_{si}) + mB_{oi} \left(\frac{1}{B_{gi}} - \frac{1}{B_g} \right)} \quad \dots \dots \dots (21)$$

and

$$\Phi_o = \left(\frac{B_o}{B_g} - R_s \right) \Phi_g \quad \dots \dots \dots (22)$$

Actually, Eq. 21 is a slight modification of Tracy's original equation. Tracy gave an example problem that

started at bubblepoint and used B_o at bubblepoint pressure instead of the B_{oi} used in Eq. 21. As discussed in the next section, use of B_{oi} in Eq. 21 makes Tracy's method also applicable above bubblepoint (in which case m is zero). Tracy also used R_s at bubblepoint instead of R_{si} , but these are equivalent because R_s is constant above bubblepoint.

Examples of Φ_g and Φ_o vs. pressure are shown in Figs. 37.5A and 37.5B. At the initial pressure, the denominator in Eq. 21 is zero; consequently, Φ_g and Φ_o are infinite. This, however, does not cause any difficulty because the only Φ values used are the finite values at lower pressures.

With Tracy's Φ functions, Eq. 11 becomes

$$N = N_p \Phi_o + G_p \Phi_g \quad \dots \dots \dots (23)$$

This form of the material-balance equation is particularly convenient because the Φ values are functions only of gas-cap size and of pressure. For each pressure level, the Φ values need to be calculated only once.

Material-Balance Equation 23 is applied to the pressure decrement from p_{n-1} to p_n :

$$\begin{aligned} N &= N_p \Phi_o + G_p \Phi_g \\ &= [(N_p)_{n-1} + \Delta N_p](\Phi_o)_n + [(G_p)_{n-1} + \Delta G_p](\Phi_g)_n, \quad \dots \dots \dots (24) \end{aligned}$$

where the average producing GOR is given by

$$\bar{R} = \frac{\Delta G_p}{\Delta N_p} = \frac{R_{n-1} + R_n}{2} \quad (25)$$

Solving Eq. 24 for ΔN_p ,

$$\Delta N_p = \frac{N - (N_p)_{n-1}(\Phi_o)_n - (G_p)_{n-1}(\Phi_g)_n}{(\Phi_o)_n + \bar{R}(\Phi_g)_n} \quad (26)$$

The producing GOR, R_n , at pressure p_n is the sum of up to three terms: the solution GOR $(R_s)_n$, the flowing (i.e., free) GOR, and the ratio $(R_{gc})_n$ of gas production directly from gas-cap/oil production:

$$R_n = (R_s)_n + \left(\frac{k_g}{k_o}\right)_n \left(\frac{\mu_o B_o}{\mu_g B_g}\right)_n + (R_{gc})_n \quad (27)$$

The term $(\mu_o B_o / \mu_g B_g)_n$ is a function only of pressure and is computed using values at pressure p_n . The value of $(k_g / k_o)_n$ is a function of the total liquid saturation, $S_o + S_w$, in the oil zone. The current oil saturation, $(S_o)_n$, is given by Eq. 28:

$$(S_o)_n = (1.0 - S_w) \frac{[N - (N_p)_n](B_o)_n}{NB_{oi}} \quad (28)$$

If the liquid saturation is known, the value of (k_g / k_o) can be read from a curve or calculated by interpolation in a table of values. The incremental material balance for each pressure step involves iterations to satisfy Eqs. 23 through 28. This determines ΔN_p , ΔG_p , S_o , and R_n .

For this iterative solution, either of two approaches could be used: (1) estimate the incremental oil production, ΔN_p , and solve for the corresponding GOR, R_n , or (2) estimate R_n and solve for ΔN_p . With either approach, the iterations are continued until the calculated results converge to the material-balance solution (i.e., until the value of N calculated using Eq. 23 agrees with the initially specified value of N). Tracy⁶ indicated that the more effective approach is to estimate R_n and to solve for ΔN_p .

Thus, Tracy's method for iterative solution of Material-Balance Equation 24 at each pressure level consists of the following steps.

1. Estimate the average GOR, \bar{R} , for the pressure decrement from p_{n-1} to p_n .
2. Compute estimated ΔN_p from Eq. 26.
3. Compute estimated $(N_p)_n$ by using $(N_p)_n = (N_p)_{n-1} + \Delta N_p$.
4. Compute oil saturation $(S_o)_n$ from Eq. 28.
5. Determine (k_g / k_o) corresponding to the liquid saturation.
6. Compute R_n from Eq. 27.
7. Compute new estimate of \bar{R} from Eq. 25.
8. Compute new estimate of ΔN_p as in Step 2 and of $(N_p)_n$ as in Step 3.
9. Compute $(G_p)_n$ from $(G_p)_n = (G_p)_{n-1} + \bar{R}\Delta N_p$.

10. Compute the estimated OIP (N) from Eq. 23 or 24.

11. To test GOR, check whether the new value of R computed at Step 7 is arbitrarily close to the previous estimate of \bar{R} for this same pressure decrement, denoted \bar{R}_{old} . An adequate test is

$$0.999 \leq \frac{\bar{R}}{\bar{R}_{old}} \leq 1.001.$$

If this criterion is satisfied, go on to Step 12. Otherwise, go back to Step 4 and continue the iterative solution for this pressure level by using the most recently calculated estimate of $(N_p)_n$. Usually, a few iterations suffice.

12. To test material balance, the computed value of N should agree with the initially specified value of N . An adequate test is

$$0.999 \leq \frac{N_c}{N_s} \leq 1.001,$$

where N_c is the computed initial OIP and N_s is the specified initial OIP.

If this is satisfied, an adequate material balance is considered to have been obtained for that pressure. The production for the pressure decrement has been computed with sufficient accuracy. If the above criterion is not satisfied, go back to Step 4 and continue the iterations until a material balance is obtained for this pressure decrement. This material-balance test will almost always be satisfied once the GOR test of Step 11 has been satisfied.

This completes the material-balance computation at the selected pressure p_n . The values computed are the incremental oil and gas production, the oil and gas saturations, and the producing GOR. Rates and time have not been considered because the tank-type material-balance performance was assumed to be independent of rate and time. Computations of rates and time are covered in a later section.

After results for one pressure decrement are obtained, the next pressure decrement is selected and the iterative computations are done for that pressure step. Because of a strong nonlinearity in the k_g / k_o vs. S_g relationship, results are sensitive to the size of the pressure step used (which influences the change in S_g and thus in k_g / k_o and GOR). Typically, until the pressure has dropped to 1,000 psi below bubblepoint, the pressure steps should not exceed 200 psi, and 100 psi is sometimes better. At lower pressures, larger pressure steps can be used. A good practice is to use pressure steps small enough that the GOR does not increase by more than a factor of two in a single step.

Applicability of Tracy's Method Above Bubblepoint

Historically, two reasons were given for not using Tracy's method above bubblepoint pressure: (1) use of Eq. 10 is simpler, and (2) according to the literature, Tracy's method is not applicable above bubblepoint. The purpose of this section is to show how Tracy's method can be used both above and below bubblepoint. Heretofore, the approach for calculating the total oil production N_p for initially undersaturated reservoirs has been to calculate N_p

to the bubblepoint with Eq. 10, to calculate incremental oil production below bubblepoint by Tracy's method or another method, and to add these two produced volumes together to obtain the total oil recovery. The new alternative is to use Tracy's method for the entire pressure range. Existing computer programs that use Tracy's method only below bubblepoint can be applied for the entire pressure range if data are modified as described below.

The literature contends that Tracy's method cannot be used above bubblepoint pressure because the Φ functions are infinite at bubblepoint. This is true for Tracy's equations in Ref. 6 that used B_o at the bubblepoint (Tracy's initial condition) instead of B_{oi} as in Eq. 21. However, if B_{oi} is used in Eq. 21, Tracy's method becomes more general. It can be used for all pressure intervals because the Φ functions (Eqs. 21 and 22) are infinite only at the initial pressure, which does not have to be the bubblepoint. Values of the Φ functions at the initial pressure are not used in Tracy's formulation; only the finite values at lower pressures are used. Consequently, if B_{oi} is used in Eq. 21, Tracy's method can predict performance for the entire pressure range from any initial pressure down to abandonment. When used above bubblepoint, Tracy's method does not require iteration because an accurate initial estimate can be made for R ($R=R_s$). When Tracy's method is used for the full pressure range of an initially undersaturated oil, however, three considerations are pertinent: (1) the computed recovery will be a fraction of the initial OIP, not of the OIP at bubblepoint; (2) bubblepoint pressure should be one of the pressure levels for proper consideration of gas evolution that starts at bubblepoint; and (3) the effects of rock and water compressibility must be considered for realistic computation of pressure decline above bubblepoint. A technique for considering the third point by adjusting the B_o data is given below.

Because rock and water compressibilities are relatively unimportant below bubblepoint, they were not included in the Tracy material-balance formulation. They can be included indirectly, however, by use of pseudovalues of the oil formation volume factor at pressures below the initial pressure. These pseudovalues, B_o^* , are given by Eq. 29.

$$B_o^* = B_o + B_{oi} \left(\frac{S_w c_w + c_f}{1 - S_w} \right) (p_{iR} - p_R). \quad (29)$$

These pseudovalues include the additional pressure support of water and rock compressibilities in the material-balance computations.

Comparison of Tarner's and Tracy's Methods

Tarner² and Tracy⁶ solved the same material-balance equation for a sequence of pressure decrements. Although Tracy's method is more convenient, Tarner's method is often referenced and consequently will be described.

For each pressure in the Tarner method, several estimates are made of the cumulative oil production, N_p . For each N_p , the corresponding cumulative gas production, G_p , is calculated two ways: from Material Balance Equation 11, or on the basis of relative permeability. To calculate G_p from relative permeability, first calculate S_o

(Eq. 28) and determine k_{rg}/k_{ro} . Second, calculate the GOR, R_n (Eq. 27). Third, calculate the incremental gas production ΔG_p (Eq. 25). Then the cumulative gas production is calculated by $G_p = (G_p \text{ at previous pressure}) + \Delta G_p$.

The correct value of N_p is the value at which both methods above yield identical values of G_p . Tarner suggested plotting both sets of calculated G_p values vs. N_p . The intersection of the two curves then yields the correct G_p and N_p .

Tarner's method works if the plotting is done accurately. It should yield the same results as Tracy's method because the same relationships are used. Tarner's method is time-consuming because you have to calculate and plot the two curves of G_p vs. N_p and then determine their intersection. While this graphical interpolation approach can be implemented on digital computers, Tracy's iterative approach is more straightforward to implement and usually converges within a few iterations.

Material-Balance Calculations Using Muskat and Taylor's Method

Muskat and Taylor's method⁴ is applicable to the tank-type depletion performance of a volumetric reservoir with no initial gas cap. It is intended mainly for below-bubblepoint pressure. For a sequence of pressure steps, Δp , the change in oil saturation, ΔS_o , during each step is calculated by use of the following depletion equation in differential form.

$$\frac{\Delta S_o}{\Delta p} = \frac{S_o \frac{B_g}{B_o} \frac{dR_s}{dp_R} + S_g B_g \frac{d(1/B_g)}{dp_R} + \frac{S_o k_{rg} \mu_o}{B_o k_{ro} \mu_g} \frac{dB_o}{dp_R}}{1 + \frac{k_{rg} \mu_o}{k_{ro} \mu_g}} \quad (30)$$

The stepwise solution of this depletion equation yields the reservoir oil saturation, S_o , vs. reservoir pressure, p_R . For each pressure at which S_o has been calculated, the cumulative recovery as a fraction of the original OIP can be calculated by use of Eq. 31.

$$\frac{N_p}{N} = 1 - \left(\frac{S_o}{1 - S_w} \right) \frac{B_{oi}}{B_o} \quad (31)$$

Having the value of S_o , k_{rg}/k_{ro} can be determined from the plot of k_{rg}/k_{ro} vs. S_o or vs. $S_o + S_w$, which is required data. The producing GOR is then

$$R = R_s + \frac{k_{rg}}{k_{ro}} \left(\frac{\mu_o B_o}{\mu_g B_g} \right) \quad (32)$$

Because this method assumes uniform oil saturation throughout the reservoir, it is not applicable when there is appreciable segregation of gas and oil.

Eq. 30 can be solved either explicitly or implicitly. Explicit means each term on the right side of Eq. 30 is evaluated on the basis of the pressure and saturation at the start of the pressure step. Each pressure step must be small so that these values are representative of conditions during the step. While this approach has the advantage of not requiring iteration, it is not self-checking. Significant cumulative errors may occur unless the pressure intervals are sufficiently small. In the implicit (iterative) solution, the terms on the right side of Eq. 30 are evaluated on the basis of estimated conditions (p_R and S_o) at either the middle or the end of the pressure step. This requires making an initial estimate of these conditions, computing the pressure step, checking agreement between estimated and computed values, and, if necessary, recomputing the step with the most recently computed values as the new estimates. This iterative solution involves more work but can handle larger pressure steps suitably.

Comparison With Gridded Simulator Equations

Because Eq. 30 looks rather formidable and mysterious, it may be helpful to show where the terms come from. This will also show the relationship of Eq. 30 to the equations used in gridded multiphase reservoir simulators; tank-type models and gridded models use similar continuity (material-balance) principles. For a two-phase (gas/oil) gridded model omitting gravity and capillary forces, the oil phase partial differential equation that combines Darcy-law flow and continuity is Eq. 33. This equation is in Darcy units.

$$\nabla \cdot \left(\frac{kk_{ro}}{\mu_o B_o} \nabla p \right) = \phi \frac{\partial}{\partial t} \left(\frac{S_o}{B_o} \right) - q_{ov}, \dots \dots \dots (33)$$

where ∇ denotes the gradient,

$$\nabla = \frac{\partial}{\partial x} + \frac{\partial}{\partial y} + \frac{\partial}{\partial z},$$

and $\partial(S_o/B_o)/\partial t$ is the partial derivative of the quantity S_o/B_o with respect to time.

The left side of Eq. 33 represents Darcy-law flow of oil in the reservoir (between blocks in a gridded model) and would be zero for a tank-type (one-block) model. The right-side terms represent oil accumulation and production. The corresponding equation for total (free+solution) gas is Eq. 34.

$$\begin{aligned} \nabla \cdot \left[\left(\frac{kk_{rg}}{\mu_g B_g} + R_s \frac{kk_{ro}}{\mu_o B_o} \right) \nabla p \right] \\ = \phi \frac{\partial}{\partial t} \left(\frac{S_g}{B_g} + R_s \frac{S_o}{B_o} \right) - q_{gv}, \dots \dots \dots (34) \end{aligned}$$

The corresponding equations for a tank-type model are obtained by noting that the left sides of Eqs. 33 and 34 are zero for the tank-type model. Deleting the left side

Fig. 37.6—Reservoir pressure vs. percent oil recovery for several values of m .

Fig. 37.7—Producing GOR vs. percent oil recovery for several values of m .

of each equation, multiplying by the bulk volume, and changing to oilfield units yields

$$V_p \frac{\partial}{\partial t} \left(\frac{S_o}{B_o} \right) = q_o \dots \dots \dots (35)$$

and

$$V_p \frac{\partial}{\partial t} \left(\frac{S_g}{B_g} + R_s \frac{S_o}{B_o} \right) = q_g \dots \dots \dots (36)$$

This total gas rate q_g is the sum of the free-gas production rate and the solution-gas production rate.

Fig. 37.8—Pressure and GOR histories of solution-gas-drive reservoirs producing oil of different viscosities.

Fig. 37.9—Pressure and GOR histories of solution-gas-drive reservoirs producing oil of different gas solubilities and oil viscosities.

Fig. 37.10—Reservoir pressure and GOR histories of gas-drive reservoirs with various ratios of gas-cap volume to oil-zone volume (H = thickness of gas cap/thickness of oil zone).

The producing GOR (R), scf/STB, is given by

$$R = \frac{q_g}{q_o} = \frac{k_g/\mu_g B_g}{k_o/\mu_o B_o} + R_s = \frac{k_g \mu_o B_o}{k_o \mu_g B_g} + R_s \quad (37)$$

The producing GOR can also be expressed by use of q_o from Eq. 35 and q_g from Eq. 36:

$$R = \frac{q_g}{q_o} = \frac{V_p \frac{\partial}{\partial t} \left(\frac{S_g}{B_g} + R_s \frac{S_o}{B_o} \right)}{V_p \frac{\partial}{\partial t} \left(\frac{S_o}{B_o} \right)} \quad (38)$$

From the chain rule for derivatives,

$$\frac{dx}{dt} = \frac{dx}{dp} \frac{dp}{dt}$$

Eq. 38 becomes

$$R = \frac{S_g \frac{d(1/B_g)}{dp_R} + \frac{1}{B_g} \frac{dS_g}{dp_R} + \frac{R_s}{B_o} \frac{dS_o}{dp_R} + \frac{S_o}{B_o} \frac{dR_s}{dp_R} + R_s S_o \frac{d(1/B_o)}{dp_R}}{S_o \frac{d(1/B_o)}{dp_R} + \frac{1}{B_o} \frac{dS_o}{dp_R}} \quad (39)$$

By equating the two expressions for R given by Eqs. 37 and 39, using $dS_g = -dS_o$, and rearranging we obtain Eq. 30. Thus, the Muskat material balance for a tank-type reservoir (Eq. 30) can be derived as a special case of the equations for a gridded multiphase simulator. Because we use compatible equations, the results from a gridded simulator using special data to match the Muskat method (e.g., no flow between gridblocks) should match those obtained by Muskat's method. Even for a gridded simulator with flow between blocks, Ridings *et al.*¹⁴ showed results agreeing with Muskat's method. More information is given in the section entitled Insights from Simulator Studies.

Sensitivity of Material-Balance Results

Several authors have discussed the sensitivity of material-balance results to data variations. Turner² showed the effect of gas-cap size on performance for values of m (gas-cap-volume/oil-reservoir-volume) of 0 (no cap), 0.1, 0.5, and 1.0. Oil recovery vs. pressure is shown in Fig. 37.6; Fig. 37.7 shows GOR vs. oil recovery. Turner discussed applicability of assumptions about the gas initially in the gas cap: (1) the gas cap and the oil zone are each assumed to remain constant in size, and (2) all gas leaving the gas cap is assumed to pass through the oil zone (i.e., no bypassing—such as by gas coning at wells). Turner stated that such assumptions are obviously in error but they in part will compensate each other. The assumption of no bypassing tends to overestimate oil recovery, while the assumption of a constant oil-zone size (corresponding to low gravity drainage) tends to underestimate oil recovery.

Muskat and Taylor³ provided informative results about the sensitivity of oil recovery to oil property variations

Fig. 37.11—Relative-permeability ratio for sands and sandstones vs. liquid saturation.

and to gas-cap size. Fig. 37.8 shows the reduction in oil recovery as oil viscosity is increased. It also shows the higher producing GOR's for cases with higher oil viscosity. Note the large variations in oil recovery, from less than 8% to more than 17%. Fig. 37.9 shows the combined effects of varying oil viscosity and solution GOR. Fig. 37.10 shows performance for several values of the gas-cap-volume/oil-zone-volume ratio, which Muskat and Taylor denoted by H . It can be seen that calculated oil recovery and peak GOR both increase with increasing gas-cap size. Muskat and Taylor emphasized the assumptions that gas-cap size remains constant throughout the production history and that depletion of the cap takes place by gas moving from the cap into the oil zone where it is assumed to be mixed or dispersed throughout the oil zone and produced along with the oil and gas originally in the oil zone.

Arps and Roberts⁸ plotted several sets of sandstone permeability ratio vs. liquid-saturation data and determined the three curves designated maximum, average, and minimum in Fig. 37.11. Maximum means highest oil recovery (lowest k_g/k_o at a given liquid saturation), while minimum means lowest oil recovery (highest k_g/k_o). For each k_g/k_o curve, they computed oil recovery [STB/(acre-ft)(percent porosity)] vs. pressure for several sets of oil fluid properties. Fig. 37.12 is for the minimum recovery (maximum k_g/k_o) case. Do not be confused by

Fig. 37.12—Reservoir pressure vs. recovery factor, STB/acre-ft/percent porosity for sandstone with k_g/k_o giving minimum oil recovery.

the label of minimum k_g/k_o in this figure. Fig. 37.13 is the average case, and Fig. 37.14 shows results for the maximum recovery (minimum k_g/k_o) case. Again the label (maximum k_g/k_o) is misleading. Note the large variation in oil recovery, STB/acre-ft/percent porosity: 2 to 12 for the minimum case, 6 to 18 for the average case, and 9 to 26 for the maximum case. Arps and Roberts⁸ also presented results with limestone k_g/k_o curves. Computed recovery ranges were 1 to 7 for the minimum case, 3 to 16 for the average case, and 13 to 32 for the maximum recovery case.

Fig. 37.15 is the comparison by Sikora¹³ of reservoir performance for no segregation vs. complete segregation. The complete segregation case has a lower calculated oil recovery and a faster rise in producing GOR. This illustrates the adverse effects of assumed segregation on performance calculations in a tank-type model that, among other things, assumes production from the entire pay thickness. For a reservoir with high vertical communication, oil recovery could be increased by selective production from perforations in the lower part of the oil zone. The tank-type prediction with production from the entire pay thickness would be inapplicable and misleading. The limited applicability of the tank-type model to cases with segregation was discussed previously. Performance predictions that consider the selective production would require a more detailed model, such as a gridded simulator.

Fig. 37.13—Reservoir pressure vs. recovery factor, STB/acre-ft/percent porosity for sandstone with average k_g/k_o .

Fig. 37.14—Reservoir pressure vs. recovery factor, STB/acre-ft/percent porosity for sandstone with k_g/k_o giving maximum oil recovery.

Singh and Guerrero¹⁸ showed sensitivity of recovery to variations in gas-cap size (m), interstitial (connate) water saturation, permeability ratio (k_g/k_o), oil reservoir volume factor (B_o), solution GOR (R_s), and initial pressure (p_{iR}). Fluid properties are shown in Table 37.1 and Figs. 37.16 through 37.18. Singh and Guerrero used permeability-ratio data that approximated the sandstone average permeability ratio characteristics given by Arps and Roberts.⁸ Interstitial water saturation was 22%. They calculated performance from bubblepoint pressure of 2,500 psi down to a 100-psi abandonment pressure using 200-psi pressure decrements.

Fig. 37.19 shows oil recovery (below bubblepoint) vs. pressure for three base cases with m values of 0, 0.5, and 0.75. For each of the base cases, performance was computed for $\pm 30\%$ changes in each of the following: B_o , R_s or B_g , p_{iR} , interstitial water saturation, and k_g/k_o or μ_o/μ_g . The percentage change or error in oil recovery resulting from the $\pm 30\%$ change in these data items is shown in Table 37.2. Figs. 37.20 through 37.24 show the sensitivity of calculated performance to these $\pm 30\%$ changes in data values. These figures and Table 37.2 show that oil recovery percentage increased with reductions in B_o , p_{iR} , or k_g/k_o and with increases in R_s and S_{iw} . Table 37.2 shows that the changes in oil recovery were largest for cases with $m=0$ (no gas cap). The presence of a

*"Factor" denotes the type of data changed.

gas cap moderated performance sensitivity. This does not mean that the presence of a gas cap always reduces the overall uncertainty about future performance. For actual reservoirs, there will be additional uncertainties, such as gas-cap size and applicability of the tank-type model (e.g., no gravity drainage and no gas coning at wells).

Production Rate and Time Calculations

Rate and time were not considered in the material-balance computations described in the previous sections because performance (recovery vs. pressure) would be independent of rate and time for the assumed tank-type behavior with pressure equilibrium. Once the material-balance computations are completed, the incremental oil production for each pressure decrement has been calculated. The time required for this production can be calculated if the oil production rate can be determined.

All wells are assumed to have the same oil production rate at a given reservoir pressure (or equivalently an average well is considered). The production rate for the entire reservoir is calculated as the rate per well times the number of wells.

Two different approaches have been used for calculating the oil production rate, q_o , as a function of average reservoir pressure, \bar{p}_R , and well flowing BHP (p_{wf}). The simpler approach assumes a straight-line relationship shown in Fig. 37.25 and given by Eq. 40.

$$q_o = J(\bar{p}_R - p_{wf}) \quad (40)$$

The other approach does not assume a straight-line relationship. Curves that are called the well's inflow performance relationship (IPR) aid in calculation of q_o . Each approach is discussed below.

Rates Based on Productivity Index

Well production rates are often assumed to be directly proportional to the pressure drawdown (difference between reservoir and wellbore pressures), as shown by Eq. 40. The proportionality term is the productivity index, J , which is often based on the equation for pseudosteady-state flow in a bounded system. The generalized form of this equation presented by Odeh²⁷ has a shape factor or constant C_A to enable characterization of both noncircular and circular drainage areas:

$$q_o = \frac{0.00708k_{ro}kh(\bar{p}_R - p_{wf})}{\mu_o B_o \ln(C_A - \frac{3}{4} + s)} \quad (41)$$

For a radial system, the shape factor is $C_A = r_e/r_w$, where r_e is the external radius and r_w is the wellbore radius. The productivity index for a single well is then determined by combining Eqs. 40 and 41:

$$J = \frac{q_o}{\bar{p}_R - p_{wf}} = \frac{0.00708k_{ro}kh}{\mu_o B_o \ln(C_A - \frac{3}{4} + s)} \quad (42)$$

A well's productivity index is sometimes treated as a constant—at least for some limited time or pressure interval—because variations in μ_o , B_o , and k_{ro} are small. For performance predictions over larger pressure ranges, however, it is important to consider these variations.

The initial productivity index, J_i , can be determined two ways: (1) from well pressure and flow-rate tests (see Chap. 32), or (2) by Eq. 42 with $k_{ro} = 1.0$ at initial conditions.

The expression for J_i based on Eq. 42 is

$$J_i = \frac{0.00708kh}{\mu_{oi} B_{oi} \ln(C_A - \frac{3}{4} + s)} \quad (43)$$

No matter how J_i is determined, at a later time (i.e., a lower pressure), J is

$$J = J_i k_{ro} \left(\frac{\mu_{oi} B_{oi}}{\mu_o B_o} \right) \quad (44)$$

where k_{ro} is evaluated at the current liquid saturation and μ_o and B_o are evaluated at the current reservoir pressure. Eq. 44 assumes pseudosteady state flow conditions as the average reservoir pressure declines [i.e., $\partial/\partial t (S_o/B_o)$ is the same at all points]. J from Eq. 44 is used in Eq. 40 to calculate q_o . Consequently, the well's production rate is directly proportional to pressure drawdown ($\bar{p}_R - p_{wf}$), but the proportionality term (J) varies with pressure and saturation.

Rates Based on Inflow Performance Ratio (IPR)

The uniform saturation assumption of tank-type material balances is avoided in rate calculations using the IPR approach. The basic idea is that with increasing drawdown

(lower BHP), gas saturation will not be uniform. More gas will be evolved in the near-well region, causing higher gas saturations and more resistance to oil flow (lower k_{ro}). This increased flow resistance reduces the oil production rate at a given BHP.

The reader may be wondering why we would combine a tank-type material-balance computation that assumes uniform saturation with rate calculations based on a different assumption. Isn't it more consistent to stay with the uniform saturation assumption by using rates based on productivity index values? Although such questions are logical, note that the nonuniformity in near-well saturations tends to affect mainly rates. The overall material-balance results (oil recovery vs. average reservoir pressure) are more a function of average reservoir conditions than of near-well conditions. The IPR approach is also of interest for predicting oilwell productivity in other types of calculations for solution-gas-drive reservoirs.

Vogel²⁴ used a computer program to determine oil production rate (q_o) vs. BHP, p_{wf} , for each of a sequence of declining reservoir pressures. This was done for a circular reservoir with a completely penetrating well at its center using Weller's¹⁶ approximation described in the section entitled Insights from Simulator Studies.

Vogel simulated several circular reservoirs with different oil properties, relative-permeability characteristics, well spacings (i.e., sizes of the circular reservoir), and well skin conditions. His results for one case are shown in Fig. 37.26. Each line shows q_o vs. p_{wf} for a given cumulative oil recovery (or for a given reservoir pressure that is the pressure corresponding to zero q_o). Note that, in contrast to the straight line of Fig. 37.25, the lines in Fig. 37.26 have a downward curvature. This is a result of the greater resistance to oil flow with increasing gas saturation. Vogel pointed out the compatibility of his results with those of Evinger and Muskat,²³ who presented theoretical calculations to show that plots of q_o vs. p_{wf} for two-phase flow result in curved lines rather than straight lines.

Vogel found that in plotting dimensionless IPR curves, as shown in Fig. 37.27, the curves group closely. He approximated this group of curves by a single average or reference curve shown in Fig. 37.28. This curve can be an approximation for all wells. An equation for this curve is

$$\frac{q_o}{(q_o)_{\max}} = 1.0 - 0.2 \frac{p_{wf}}{\bar{p}_R} - 0.8 \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 \quad (45)$$

where $(q_o)_{\max}$ = maximum oil production rate, STB/D.

Vogel did not provide a way to compute q_o given p_{wf} and \bar{p}_R . His approach required knowledge of q_o at some p_{wf} from a well test. Eq. 45 could then be used to calculate the q_o at any other value of p_{wf} . In 1971, Standing²⁶ provided the additional insights necessary to use Vogel's results in performance prediction models.

Standing noted that Eq. 45 can be rearranged to

$$\frac{q_o}{(q_o)_{\max}} = \left(1 - \frac{p_{wf}}{\bar{p}_R} \right) \left(1 + 0.8 \frac{p_{wf}}{\bar{p}_R} \right) \quad (46)$$

Fig. 37.26—Computed inflow performance relationships for a well in a solution-gas-drive reservoir.

Fig. 37.28—Comparison of reference curve with computed IPR curves.

Fig. 37.27—Dimensionless inflow performance relationships for a well in a solution-gas-drive reservoir.

and that the productivity index of a well is defined by

$$J = \frac{q_o}{\bar{p}_R - p_{wf}} \quad (47)$$

Substituting Eq. 47 into Eq. 46 yields

$$J = \frac{(q_o)_{\max}}{\bar{p}_R} \left(1 + 0.8 \frac{p_{wf}}{\bar{p}_R} \right) \quad (48)$$

Standing noted that the physical conditions inherent in Eq. 48 are that reservoir gas and oil saturations, as well as reservoir pressure, vary with distance from the wellbore and that the well's skin factor is zero.

Standing also considered the situation in which fluid saturations are uniform within the reservoir. This would be the case for production with minimal drawdown. The well's productivity under these conditions of essentially uniform saturations and pressure was denoted by J^* . Note that J^* is based on the same conditions assumed for the productivity index, J , in Eq. 42; J^* is identical to the J of Eq. 42 and can be evaluated the same way:

$$J^* = \frac{0.00708 k_{ro} kh}{\mu_o B_o \ln \left(C_A - \frac{3}{4} + s \right)} \quad (49)$$

where k_{ro} is evaluated at the average fluid saturations in the reservoir, and μ_o and B_o are evaluated at the average reservoir pressure \bar{p}_R . Recall that for a radial system the shape factor C_A is simply r_e/r_w .

Standing used J to denote the true (or at least more accurate) value of the well's productivity index. The difference between J and J^* is an indication of the inaccuracy that occurs because J^* is based on uniform conditions.

Standing noted that J^* is the limiting value of J for very small drawdown (i.e., as p_{wf} approaches \bar{p}_R):

$$J^* = \lim_{p_{wf} \rightarrow \bar{p}_R} J = \frac{1.8(q_o)_{\max}}{\bar{p}_R} \quad (50)$$

Combining Eqs. 48 and 50 enables elimination of $(q_o)_{\max}/\bar{p}_R$, yielding

$$J = \frac{J^*}{1.8} \left(1 + 0.8 \frac{p_{wf}}{\bar{p}_R} \right) \quad (51)$$

Eqs. 49 and 51 enable calculation of the well's J once the average fluid saturations, p_{wf} , and p_R are known.

By combining Eqs. 45 and 50, Standing eliminated $(q_o)_{\max}$ and obtained Eq. 52, which is a general relationship for IPR curves at various average reservoir pressures.

$$q_o = \frac{J^* \bar{p}_R}{1.8} \left[1 - 0.2 \left(\frac{p_{wf}}{\bar{p}_R} \right) - 0.8 \left(\frac{p_{wf}}{\bar{p}_R} \right)^2 \right]. \quad (52)$$

Thus, Standing has shown how production rate in a solution-gas-drive performance model can be calculated by use of Vogel's IPR information. Because a value of J^* can be calculated with Eq. 49, all terms in Eq. 52 can be evaluated.

Later, Al-Saadoon²⁸ suggested that a different expression should be used for J . However, Rosbaco²⁹ clarified the situation by noting that although Standing²⁶ and Al-Saadoon²⁸ used different formulas for J and for J/J^* , both yield the same results for q_o vs. p_{wf} . Consequently, it is workable and acceptable to use Standing's equations.

Standing²⁵ discussed application of the IPR approach to damaged wells and Dias-Couto and Golan³⁰ developed a general IPR for wells in solution-gas-drive reservoirs that is applicable to wells with any drainage area shape, any completion flow efficiency, and at any stage of reservoir depletion.

Time Required for Oil Production

At this point, oil recovery vs. reservoir pressure is known from the material-balance calculations. The oil production rate per well, q_o , corresponding to a specified minimum p_{wf} can be calculated by use of either the productivity index approach (Eq. 42) or the IPR approach (Eqs. 49 and 52). This q_o is the calculated rate that the well is capable of producing. The well also may be subject to a scheduling constraint, such as an allowable production rate. Consequently, the well's oil production rate q_n at pressure p_n is the smaller of these two rates:

$$q_n = (q_o)_{\min}, \quad (53)$$

where $(q_o)_{\min}$ = minimum value of calculated and scheduled oil rate, STB/D.

The average oil production rate \bar{q}_o during the pressure decrement from p_{n-1} to p_n is given by Eq. 54.

$$\bar{q}_o = 0.5(q_n + q_{n-1}). \quad (54)$$

This average rate is used in Eq. 55 to calculate the time Δt_n required for the incremental oil production $(\Delta N_p)_n$ from p_{n-1} to p_n .

$$\Delta t_n = \frac{(\Delta N_p)_n}{\bar{q}_o n_w}. \quad (55)$$

The cumulative time, t_n , to reach pressure p_n is given by Eq. 56, with initial time $t_o = 0$.

$$t_n = t_{n-1} + \Delta t_n. \quad (56)$$

Insights from Simulator Studies

Because reservoir simulation is the topic of Chap. 48, we will not discuss it in detail here. For solution-gas-drive reservoirs, several comparisons have been made of gridded simulator results vs. simpler approaches, such as tank-type material balances. These comparisons help to confirm the range of applicability of the simpler approaches. The key questions addressed by these studies are the same questions Vogel²⁴ considered in getting the computed results on which he based the IPR method for well rate calculations. These questions are (1) to what extent is the saturation distribution nonuniform, and (2) how much does this influence performance.

The most informative study was by Ridings *et al.*,¹⁴ who compared laboratory vs. computed solution-gas-drive results for linear systems and obtained close agreement. Also, they used a gridded radial simulator to study the effect of rate and spacing on performance of solution-gas-drive reservoirs. Their conclusions concerning thin, homogeneous, horizontal solution-gas-drive reservoirs included the following.

1. "Ultimate recovery essentially is independent of rate and spacing, and agrees closely with recovery predicted by the conventional Muskat method."

2. "GOR depends somewhat on rate and spacing. For high rates or close spacings, GOR's initially are higher, but later become lower than a Muskat prediction would indicate. At low rates or wide spacings, GOR behavior approaches the Muskat prediction."

3. Computed depletion time agreed closely with conventional analysis (productivity index method) at low pressure drawdowns, but differed more for high drawdowns. This is in qualitative agreement with the results obtained by Vogel.²⁴

4. "Intermittent operation greatly affects instantaneous GOR behavior, but the cumulative GOR is not affected significantly. Also, oil recovery apparently is not affected." This refers to the cumulative oil recovery, not the amount of oil recovered in a given time period.

Note that Conclusions 1 and 2 support the use of tank-type models for predictions of recovery and of GOR (at least for low rates) for solution-gas-drive reservoirs. Although Muskat's method is mentioned, other tank-type approaches, such as Tracy's method, would be equally suitable.

Stone and Garder¹⁷ compared one-dimensional (1D) gridded simulator results vs. pressure and production data measured on a laboratory model produced by solution-gas drive. Computed and measured pressures vs. percent oil recovery were in close agreement.

In 1961, Levine and Prats¹² presented a comparison of solution-gas-drive results for an "exact method" (a 1D radial gridded simulator) vs. an "approximate method." The approximate method was based on assumptions of semisteady state—often called pseudosteady state (i.e., the stock-tank-oil desaturation rate is the same at all locations at any instant)—and "constant GOR," which actually meant uniform GOR (i.e., the total GOR is the same at all points at any instant). Levine and Prats showed close agreement between results of the simulator and the approximate method. These results, for various stages of depletion, were pressure and saturation vs. radius and the corresponding values of producing GOR and of percent

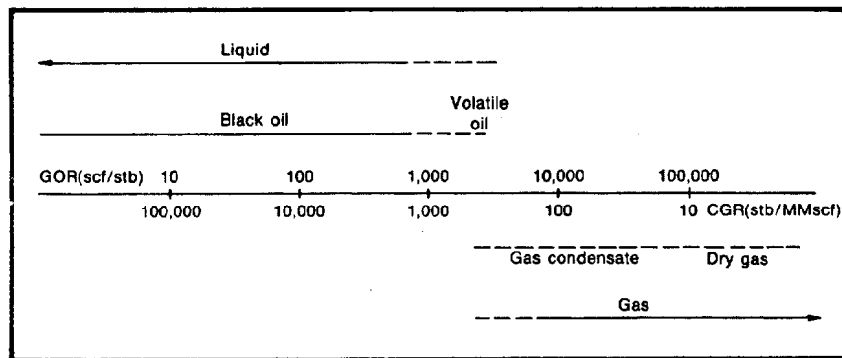

Fig. 37.29—Solution GOR range from black oil to gases. Volatile oils typically are in the range of 1,500 to 3,500 scf/STB.

oil recovery. Only limited information was given about the approximate method. This method would require derivation of additional equations and development of a computer program. Levine and Prats also discussed the extension of results to other sets of fluid and rock properties by use of dimensionless groups.

Later, Weller¹⁶ presented a different approach that retained the semisteady-state assumption but eliminated need for the "constant GOR" assumption. Weller showed that his method matched simulator results more closely than Levine and Prats' constant-GOR method. Weller developed equations for the radial distribution of saturation and pressure based on the combination of a transient period before the effects of a change in producing rate are felt at the drainage boundary with semisteady state (same rate of tank-oil desaturation everywhere) thereafter. Because these equations serve mainly as an alternative to a gridded simulator, details will not be given here (see Ref. 16).

Volatile Oil Reservoir Performance Predictions

Volatile oils are characterized by significant hydrocarbon liquid recovery from their produced reservoir gas. Also, volatile oils evolve gas and develop free-gas saturation in the reservoir more rapidly than normal black oils as pressure declines below the bubblepoint. This causes relatively high GOR's at the wellhead. Thus, performance predictions differ from those discussed for black oils mainly because of the need to account for liquid recovery from the produced gas. Conventional material balances with standard laboratory PVT (black-oil) data underestimate oil recovery. The error increases for increasing oil volatility.

A volatile oil can be defined as hydrocarbon that is liquid-phase oil at initial reservoir conditions but at pressures below bubblepoint evolves gas containing enough heavy components to yield appreciable condensate dropout at the separators. This is in contrast to black oils for which little error is introduced by the assumption that there is negligible hydrocarbon liquid recovery from produced gas.

Cronquist³⁸ used Fig. 37.29 to show the position of volatile oils in the GOR range between black oils and gases. Compared to black oils, volatile oils have higher solution GOR (1,500 to 3,500 scf/STB), generally higher

oil gravities (greater than 40 or 45° API), and higher B_o (above about 2.0 RB/STB). Volatile oils tend to shrink rapidly with pressure decline below bubblepoint. Cronquist used Fig. 37.30 to illustrate this behavior. The curves are made dimensionless (i.e., normalized to maximum values of unity) to facilitate comparisons. The ordinate b_{oD} is the dimensionless shrinkage:

$$b_{oD} = (B_{ob} - B_o) / (B_{ob} - B_{ou}).$$

The abscissa p_{RD} is a special form of dimensionless reservoir pressure:

$$p_{RD} = p_R / p_b,$$

where

p_{RD} = reservoir pressure, dimensionless,

p_R = reservoir pressure, psi, and

p_b = bubblepoint pressure, psi.

The curve labeled BO in Fig. 37.30 represents the typical behavior of a black oil. Shrinkage is almost proportional to pressure reduction below bubblepoint. In contrast, Curves E, F, and G are for progressively more volatile oils and show much greater shrinkage as pressure drops below bubblepoint.

This large shrinkage corresponds to substantial gas evolution (i.e., a large reduction in the solution GOR as pressure drops below bubblepoint). This is illustrated by Fig. 37.31, which shows dimensionless cumulative gas evolved, $R_{pD} = R_{rs} / R_{sb}$, vs. dimensionless pressure. R_{sb} is the solution GOR at bubblepoint, and R_{rs} is the reduction in solution GOR below bubblepoint: $R_{rs} = R_{sb} - R_s$. The trend line in Fig. 37.31 shows typical behavior for a black oil. Gas evolution is almost proportional to pressure reduction below the bubblepoint. Curves E, F, and G, which are for volatile oils, show much more gas evolution as pressure declines below bubblepoint.

Consequently, depletion performance of volatile oil reservoirs below bubblepoint is strongly influenced by the rapid shrinkage of oil and by the large amounts of gas evolved. This results in relatively high gas saturations, high producing GORs, and low to moderate production of reservoir oil. The produced gas can yield a substantial

Fig. 37.30—Dimensionless shrinkage vs. dimensionless pressure. Curves E, F, and G are for progressively more volatile oils. Curve BO is for a black oil. Curve VO is for a volatile oil.

volume of hydrocarbon liquids in the processing equipment. This liquid recovery at the surface can equal or exceed the volume of stock-tank oil produced from the reservoir liquid phase.^{31,33,34,38} Depletion-drive recoveries are often between 15 and 25% of initial OIP. Improved recovery through injection of gas or water is sometimes considered but is beyond the scope of this chapter.

For volatile oil reservoir primary-performance prediction methods, the key requirements are correct handling of the oil shrinkage, gas evolution, gas and oil flow in the reservoir, and liquids recovery at the surface. For oil with a low volatility but a higher shrinkage than a typical black oil, simple corrections to differential shrinkage data are sometimes made.^{33,35,39} For volatile oils, however, it is essential to account for their special behavior more thoroughly. This includes determination of the composition of the gas evolved in the reservoir for a sequence of pressure steps below bubblepoint.

Methods for predicting volatile-oil reservoir-depletion performance that assume tank-type behavior (i.e., ignore pressure gradients) have been published by Cook *et al.*,³¹ Reudelhuber and Hinds,³³ and Jacoby and Berry.³⁴ In Refs. 31 and 33, laboratory data determined fluid compositions, while in Ref. 34, fluid compositions were computed from data for equilibrium constants. Cronquist³⁸ stated that there was no significant advantage of one method over the other two methods because "each method appears to yield acceptable results."

The multicomponent-flash method of Jacoby and Berry³⁴ is particularly appealing because a comparison of predicted vs. actual reservoir performance is available. Sections to follow describe the prediction method³⁴ and discuss a comparison of predicted vs. field performance.³⁶ The description of the multicomponent-flash method is from Sikora.¹³

Fig. 37.31—Dimensionless evolved gas vs. dimensionless pressure. Curves E, F, and G are for progressively more volatile oils. The trend line typifies black-oil behavior.

Multicomponent-Flash Method of Jacoby and Berry

Data required to predict volatile-oil reservoir performance by the multicomponent-flash method include (1) the state and composition of the reservoir fluid at initial pressure; (2) appropriate sets of equilibrium vaporization ratios (K values) for the reservoir pressure range at the reservoir temperature and covering the temperature and pressure of surface separation; (3) some experimental liquid-phase densities at reservoir conditions to check correlations for calculating the required liquid densities during the depletion process; (4) experimental oil-phase viscosity data at reservoir temperature; and (5) relative-permeability-ratio data.

Calculation Procedure. Prediction of reservoir performance by the Multicomponent-Flash Method consists of the following steps, starting at pressure p_1 . For convenience, the calculation is made for a unit of hydrocarbon PV.

1. Select a pressure p_2 that is lower than p_1 .
2. Flash the number of moles of the reservoir composite fluid in the unit pore space at p_1 to the next lower pressure p_2 .
3. Assume a gas saturation at p_2 and calculate the average flowing bottomhole GOR with Eq. 57.

$$\bar{R} = \frac{k_g \mu_o}{k_o \mu_g} \quad (57)$$

4. Calculate the number of moles in each phase of the unit volume, the overall composition, and the number of moles of reservoir composite remaining in the unit volume at p_2 .

5. Determine the difference between the reservoir composite at p_1 and p_2 , which is the total amount and com-

*Original reservoir fluid at its bubblepoint; analysis of bottomhole sample.

position of the produced wellstream for this pressure decrement.

6. Calculate the bottomhole GOR by flashing the wellstream composition from p_1 to the average pressure $(p_1 + p_2)/2$, for this pressure decrement.

7. If the difference between the GOR from Step 6 and the average GOR from Step 3 exceeds the desired tolerance, select a new gas saturation and repeat Steps 3 through 7 to continue iterations for the current pressure decrement. If this difference is within the tolerance, the final answer has been obtained for this pressure decrement. For the next decrement, set $p_1 = p_2$ and select a

p_2 that is lower than the previous p_2 . Repeat Steps 1 through 7.

Example From Jacoby and Berry.³⁴

Reservoir temperature, 246°F

Initial pressure, 5,070 psia

Bubblepoint pressure, 4,836 psia

Initial GOR, 2 Mscf/STB

Oil gravity, 50°API

Conventional B_o , 4.7 RB/STB

Original reservoir fluid composition, Table 37.3 (column 1)

Fig. 37.32—Comparison of oil and gas production for volatile-oil material balance (multicomponent flash method) vs. conventional material balance.

Fig. 37.34—Main Reservoir cumulative oil production vs. reservoir pressure.

Fig. 37.33—Main Reservoir performance history.

Fig. 37.35—Main Reservoir cumulative oil production vs. GOR.

Solution. Results calculated by Jacoby and Berry³⁴ with the above method are given in Tables 37.3 and 37.4 and in Fig. 37.32. Table 37.3 shows the calculated well-stream compositions, and Table 37.4 shows the fluid compositions in the reservoir. The oil and gas production in Fig. 37.32 was obtained by separating the wellstream data in Table 37.3 at separator conditions of 500 psia and 65°F and stock-tank conditions of 14.7 psia and 70°F. Fig. 37.32 also shows the comparison of oil and gas production with conventional performance predictions.⁶

Comparison of Predicted vs. Actual Reservoir Performance

Jacoby and Berry's example was a performance prediction published in 1957 for a volatile-oil reservoir in north Louisiana that was discovered in 1953 and produced from

the Smackover lime.³⁴ The reservoir was believed to be volumetric. The comparison vs. actual performance was published in 1965 by Cordell and Ebert.³⁶ They called this field the Main Reservoir. The field was completely developed with 11 wells on 160-acre spacing by 1956 and was 90% depleted by the time of their publication.

Fig. 37.33 shows performance history for the Main Reservoir.³⁶ Figs. 37.34 and 37.35 compare actual performance (cumulative stock-tank-oil production vs. reservoir pressure) vs. performance predicted by the volatile-oil material balance³⁴ and by conventional material balance.⁶ Cordell and Ebert stated that actual ultimate recovery would be 10% greater than predicted by the volatile-oil material balance and 175% greater than indicated by the conventional (black-oil) material-balance calculation.

Fig. 37.35 illustrates the large errors in applying a conventional black-oil material balance to volatile oils: oil recovery is underestimated, and producing GOR is overestimated. This emphasizes the importance of considering the varying reservoir and wellstream compositions in volatile-oil reservoir-performance predictions by use of a volatile-oil material-balance method.

Nomenclature

b_o = oil shrinkage factor	k_{ro} = relative permeability to oil
b_{oD} = oil shrinkage factor, dimensionless	$(k_{ro})_{gc}$ = relative permeability to oil at critical gas saturation
B_g = gas formation volume factor (gas FVF), RB/scf	K = reservoir vaporization ratio
B_{gi} = initial gas formation volume factor, RB/scf	m = PV of gas cap/PV of oil zone, dimensionless ratio
B_o = oil formation volume factor, RB/STB	n_w = number of wells
B_o^* = pseudovalues for formation volume factor, RB/STB	N = initial OIP, STB
$B_{ou} = B_o$ at atmospheric pressure and reservoir temperature, RB/STB	N_c = computed initial OIP, STB
$B_{ob} = B_o$ at bubblepoint pressure, RB/STB	N_p = cumulative oil production, STB
B_{oi} = initial oil formation volume factor, RB/STB	$(N_p)_n$ = cumulative oil production to pressure n , STB
B_t = two-phase FVF, RB/STB	$(N_p)_{n-1}$ = cumulative oil production to pressure $n-1$, STB
B_{ti} = initial two-phase FVF, RB/STB	ΔN_p = incremental oil production, STB
B_w = water formation volume factor, RB/STB	N_s = specified initial OIP, STB
ΔB_g = expansion of initial free gas in place, RB/scf	p_b = bubblepoint pressure, psi
ΔB_t = expansion of initial OIP, RB/STB	p_{iR} = initial reservoir pressure, psi
c_e = effective compressibility, vol/(vol-psi)	p_n = certain chosen pressure value, psi
c_f = formation compressibility, vol/(vol-psi)	p_{n-1} = pressure value one step below p_n , psi
c_o = oil compressibility, vol/(vol-psi)	p_R = reservoir pressure, psi
c_w = water compressibility, vol/(vol-psi)	\bar{p}_R = average reservoir pressure, psi
C_A = shape factor or constant, dimensionless	p_{RD} = reservoir pressure, dimensionless
G_i = cumulative gas injection, scf	p_{wf} = well flowing BHP, psi
G_p = cumulative gas production, scf	p_1, p_2 = intermediate pressure values in iterative equations, psi
G_{pc} = cumulative production of gas that was initially in the gas cap, scf	q_g = total gas production, scf/D
G_{ps} = cumulative production of gas that was initially solution gas, scf	q_{gv} = gas production rate/unit bulk volume, $\text{cm}^3/(\text{s} \cdot \text{cm}^3)$
$(G_p)_n$ = cumulative gas production to pressure n , scf	q_o = oil production rate, STB/D
$(G_p)_{n-1}$ = cumulative gas production to pressure $n-1$, scf	\bar{q}_o = average production rate, STB/D
ΔG_p = incremental gas production, scf	$(q_o)_{\max}$ = maximum oil production rate, STB/D
H = thickness of gas cap/thickness of oil-zone (Fig. 37.10)	$(q_o)_{\min}$ = minimum oil production rate, STB/D
J = productivity index, STB/D/psi	q_{ov} = oil production rate/unit bulk volume, $\text{cm}^3/(\text{s} \cdot \text{cm}^3)$
J^* = productivity index under conditions of uniform saturation and pressure, STB/D/psi	Q_p = net fluid produced, RB
J_i = initial productivity index, STB/D/psi	r_e = external radius, ft
k = permeability, md	r_w = wellbore radius, ft
k_g = effective permeability to gas, md	R = producing GOR, scf/STB
kh = formation flow capacity, md-ft	\bar{R} = average producing GOR, scf/STB
k_o = effective permeability to oil, md	R_{gc} = ratio of gas production directly from gas cap/oil production, scf/STB
k_{rg} = relative permeability to gas	R_n = producing GOR at pressure p_n , scf/STB
$(k_{rg})_{or}$ = relative permeability to gas at residual oil saturation	R_{old} = previous average producing GOR, scf/STB
	R_p = cumulative produced GOR, scf/STB
	R_{pD} = cumulative produced GOR, R_{sc}/R_{sb} , dimensionless
	R_{rs} = reduction in solution GOR below bubblepoint, $R_{sb} - R_s$, scf/STB
	R_s = solution GOR, scf/STB
	R_{sb} = solution GOR at bubblepoint, scf/STB
	R_{si} = initial solution GOR, scf/STB
	s = skin factor, dimensionless
	S_g = gas saturation, fraction PV
	S_{gc} = critical gas saturation, fraction PV
	S_{iw} = interstitial water saturation, fraction PV
	S_o = oil saturation, fraction PV
	S_{oi} = initial oil saturation, fraction PV

- S_{or} = residual oil saturation, fraction PV
 S_w = water saturation, fraction PV
 S_{wi} = initial water saturation, fraction PV
 t = time, days
 t_i = initial time, days
 t_n = cumulative time to reach pressure n , days
 Δt_n = incremental time for reservoir pressure to decline from p_{n-1} to p_n , days
 V_p = pore volume, RB
 W_e = cumulative water influx, STB
 W_i = cumulative water injected, STB
 W_p = cumulative water produced, STB
 μ_g = gas viscosity, cp
 μ_o = oil viscosity, cp
 μ_{oi} = initial oil viscosity, cp
 ϕ = porosity, fraction
 Φ_g = Tracy's pressure function for gas defined by Eq. 21, dimensionless
 Φ_o = Tracy's pressure function for oil defined by Eq. 22, dimensionless

Chapter 38

Water Drive Oil Reservoirs

Daylon L. Walton, Roebuck-Walton Inc.*

Introduction

Water drive reservoirs are those reservoirs in which a significant portion of volumetric withdrawals is replaced by water influx during the producing life of the reservoir. The total influx, and influx rates, will be governed by the aquifer characteristics together with the pressure-time behavior along the original reservoir/aquifer contact. Ordinarily, few wells are drilled into the aquifer and little or no information concerning the aquifer size, geometry, or rock properties is available. However, if sufficient reservoir pressure and production history is available, the aquifer properties may be inferred from solutions of Eq. 1, the radial form of the diffusivity equation.

$$\frac{\partial^2 p}{\partial r^2} + \frac{1}{r} \frac{\partial p}{\partial r} = \frac{\phi \mu c}{k} \frac{\partial p}{\partial t}, \dots \dots \dots (1)$$

where

- p = pressure,
- r = radius,
- ϕ = porosity,
- μ = viscosity,
- c = compressibility,
- t = time, and
- k = permeability.

These inferred aquifer properties then can be used to calculate the future effect of the aquifer on the reservoir performance.

Definitions

Aquifer Geometry

Radial—boundaries are formed by two concentric cylinders or sectors of cylinders.

Linear—boundaries are formed by two sets of parallel planes.

Nonsymmetrical—neither radial nor linear.

Exterior Boundary Conditions

Infinite—pressure disturbances do not affect the exterior boundary of the system, *during the time of interest*.

Finite closed—no flow occurs across the exterior boundary. Pressure disturbances reach the exterior boundary, *during the time of interest*.

Finite outcropping—aquifer is finite with pressure constant at exterior boundary (i.e., aquifer outcrops into lake, gulf, or other surface water source).

Basic Conditions and Assumptions

1. The reservoir is at the equilibrium average pressure at all times.
2. The water/oil (WOC) or water/gas contact (WGC) is an equipotential line.
3. The hydrocarbons behind the front are immobile.
4. The effects of gravity are negligible.
5. The difference between the average reservoir pressure and the pressure at the original WOC or WGC will be assumed to be zero if unknown.

Mathematical Analysis

Basic Equations

Van Everdingen and Hurst¹ obtained a general solution to Eq. 1 for two cases: (1) a constant water-influx rate (constant-terminal-rate case) and (2) a constant pressure drop (constant-terminal-pressure case). By using the principle of superposition, van Everdingen and Hurst extended these solutions to include variable water-influx rates and pressure drops. Mortada² further extended the solutions to include interference effects in homogeneous infinite radial aquifers.

Constant-Terminal-Rate Case. If time is divided into a finite number of intervals (Fig. 38.1), the average water influx in each interval can be used in Eq. 2 to calculate the pressure drop at the interior aquifer boundary. Eq. 2 shows that the relationship between the pressures and

* Author of the original chapter on this topic in the 1962 edition was Vincent J. Sikora.

Fig. 38.1—Water influx rates—constant terminal rate case.

Fig. 38.2—Pressure drops—constant terminal pressure case.

water-influx rates is a function of a constant m_r and a variable p_D . The constant m_r is a function of the aquifer properties, whereas p_D is a function of aquifer properties and time.

$$\Delta p_{w_n} = m_r \sum_{j=1}^n [e_{w(n+1-j)} - e_{w(n-j)}] p_{D_j}, \quad \dots \quad (2)$$

where

p_{w_n} = cumulative pressure drop to the end of interval n ,

$e_{w(n+1-j)}$ = water-influx rate at interval $n+1-j$,

$$m_r = \frac{\mu_w}{0.001127kh\alpha} \quad \dots \quad (3)$$

for radial aquifers,

$$m_r = \frac{\mu_w}{0.001127kh} \quad \dots \quad (4)$$

for infinite linear aquifers,

$$m_r = \frac{\mu_w L}{0.001127khb} \quad \dots \quad (5)$$

for finite linear aquifers,

p_D = dimensionless pressure term,
 e_w = water influx rate, RB/D,
 p_w = pressure at the original WOC, psi,
 k = permeability, md,
 h = aquifer thickness, ft,
 b = aquifer width, ft,
 L = aquifer length, ft,
 μ_w = water viscosity, cp, and
 α = angle subtended by reservoir, radians.

For calculation convenience it is recommended that time be divided into equal intervals and Eq. 6 be used.

$$\Delta p_{w_n} = m_r \sum_{j=1}^n e_{w(n+1-j)} \Delta p_{D_j} \quad \dots \quad (6)$$

$$= m_r [e_{w_n} \Delta p_{D_1} + e_{w_{n-1}} \Delta p_{D_2} \dots$$

$$e_{w_2} \Delta p_{D_{(n-1)}} + e_{w_1} \Delta p_{D_n}], \quad \dots \quad (7)$$

where $\Delta p_{D_j} = p_{D_j} - p_{D_{j-1}}$.

Constant-Terminal-Pressure Case. If time is divided into a finite number of intervals (Fig. 38.2), Eq. 8 can be used to calculate the cumulative water influx for a given pressure history, using average pressure drops in each time interval.

$$W_{e_n} = m_p \sum_{j=1}^n \Delta \bar{p}_{(n+1-j)} W_{eD_j}, \quad \dots \quad (8)$$

where

W_{e_n} = cumulative water influx to end of interval,

$$m_p = 0.17811 \phi c_{wt} h \alpha r_w^2 \quad \dots \quad (9)$$

for radial aquifers,

$$m_p = 0.17811 \phi c_{wt} h b^2 \quad \dots \quad (10)$$

for infinite linear aquifers,

$\Delta \bar{p}_{(n+1-j)}$ = average pressure drop in interval $n+1-j$,

W_{eD} = dimensionless water-influx term,

r_w = field radius, ft, and

c_{wt} = total aquifer compressibility, psi^{-1} .

The solution of Eq. 8 requires the use of superposition, in a manner similar to that shown by the expansion of Eq. 6. A modification presented by Carter and Tracy³ permits calculations of W_e that approximate the values

obtained from Eq. 8 but does not require the use of superposition. This method is advantageous when the calculations are to be made manually, since fewer terms are required.

Using Carter and Tracy's method, Eq. 11, the cumulative water influx at time t_n is calculated directly from the previous value obtained at t_{n-1} .

$$W_{e_n} = W_{e_{(n-1)}} + \frac{[m_p \Delta p_n t_{D_n} - W_{e_{(n-1)}} p'_{D_n}] [t_{D_n} - t_{D_{(n-1)}}]}{p_{D_n} - t_{D_{(n-1)}} p'_{D_n}}, \quad (11)$$

where

$$p'_{D_n} = \frac{p_{D_n} - p_{D_{(n-1)}}}{t_{D_n} - t_{D_{(n-1)}}} \quad (12)$$

and

$$\Delta p_n = p_i - p_n \quad (13)$$

Reservoir Interference. Where two or more reservoirs² are in a common aquifer, it is possible to calculate the change in pressure at Reservoir A, for example, caused by water influx into another reservoir, B, using Eq. 14 or 15. These are Eqs. 2 and 3 with modified subscripts.

For unequal time intervals,

$$\Delta p_{o(A,B)_n} = m_r \sum_{j=1}^n [e_{wB_{(n+1-j)}} - e_{wB_{(n-j)}}] p_{D(A,B)_j}, \quad (14)$$

and for equal time intervals,

$$\Delta p_{o(A,B)_n} = m_r \sum_{j=1}^n e_{wB_{(n+1-j)}} \Delta p_{D(A,B)_j}, \quad (15)$$

where

$p_{D(A,B)}$ = dimensionless pressure term for Reservoir B with respect to Reservoir A,

$\Delta p_{o(A,B)}$ = pressure drop at Reservoir A caused by Reservoir B, and

e_{wB} = water influx rate at Reservoir B.

The total pressure drop at Reservoir A at any given time is the sum of the pressure drops caused by all reservoirs in the common aquifer, or

$$\Delta p_{oA_n} = \Delta p_{o(A,A)_n} + \Delta p_{o(A,B)_n} + \Delta p_{o(A,C)_n} + \dots \quad (16)$$

Since dimensionless pressure differences are available only for homogeneous infinite radial aquifers, pressure-interference calculations are limited at the present time to aquifers that can be approximated by a uniform, infinite, radial system.

Fig. 38.3—Infinite aquifer bounded on one side by a fault.

Hicks *et al.*⁴ used the past pressure and production history in an analog computer to obtain influence-function curves for each pool in a multipool aquifer. The influence function $F(t)$ can be defined as the product of m_r and p_D ,

$$F(t) = m_r p_D, \quad (17)$$

and can be substituted in Eqs. 59 and 60 to calculate the future performance.

Nonsymmetrical Aquifers. By use of the images method,² the procedure for calculating reservoir interference can be extended to the case where one boundary of an infinite aquifer is a fault. For example, Fig. 38.3 shows Reservoir A located in this type of aquifer. To calculate the pressure performance at Reservoir A, first locate the mirror-image Reservoir A' across the fault. The water-influx history for the mirror-image Reservoir A' will be taken to be the same as Reservoir A. Next, assume that the fault does not exist so that there are two identical reservoirs in a single infinite aquifer, with Reservoir A' causing interference at Reservoir A. The pressure drop at Reservoir A now can be calculated by use of Eq. 19 (for equal time intervals).

$$\Delta p_{oA_n} = m_r \sum_{j=1}^n [e_{wA_{(n+1-j)}} \Delta p_{D_i}] + m_r \sum_{j=1}^n [e_{wA'_{(n+1-j)}} \Delta p_{D(A,A')_j}], \quad (18)$$

Because $e_{wA} = e_{wA'}$,

$$\Delta p_{oA_n} = m_r \sum_{j=1}^n e_{wA_{(n+1-j)}} [\Delta p_{D_j} - \Delta p_{D(A,A')_j}], \quad (19)$$

If other reservoirs in the aquifer also are causing reservoir interference at Reservoir A, each mirror image will cause reservoir interference at Reservoir A. The total pressure drop at Reservoir A, therefore, will be the sum of the pressure drops caused by each reservoir and each mirror image (see Fig. 38.4).

Nonsymmetrical aquifers will be discussed further under Methods of Analysis, Method 2.

Fig. 38.4—Dimensionless pressure drop for infinite aquifer system for constant flow rate.^{3,8}

p_D and W_{eD} Values. Values of p_D , $p_{D(A,B)}$, and W_{eD} are functions of dimensionless time t_D (Eq. 20), aquifer geometry, and aquifer size (t_D for radial aquifers).

Table 38.1 gives the substitution for d in Eq. 20 to calculate t_D and the table, graph, or equation to obtain p_D , $p_{D(A,B)}$, or W_{eD} for various types of aquifers. The following equations are used in conjunction with Table 38.1.

$$t_D = \frac{0.006328kt}{\phi C_w \mu_w d^2}, \quad (20)$$

$$p_D = 1.1284\sqrt{t_D}, \quad (21)$$

$$p_D = 0.5(\ln t_D + 0.80907), \quad (22)$$

$$p_D = \ln r_D, \quad (23)$$

$$W_{eD} = 0.5(r_D^2 - 1), \quad (24)$$

$$\Delta p_D = \frac{2}{r_D^2} \Delta t_D, \quad (25)$$

and

$$p_D = t_D + 0.33333, \quad (26)$$

where

t_D = dimensionless time,

r_D = dimensionless radius = r_a/r_w ,

r_a = aquifer radius, ft,

r_w = field radius, ft, and

d = a geometry term obtained from Table 38.1.

Methods of Analysis

Reservoir Volume Known. Rigorous Methods. There are two methods for obtaining the coefficient m_r and Δp_D in Eq. 6 from the past pressures and the water-influx rates from a material balance on the reservoir. Method 1* is used whenever the aquifer can be approximated by a uniform linear or radial system; therefore, published values of p_D are used. If the aquifer can be approximated by a homogeneous, infinite, radial system, the method can be extended to handle reservoir interference. In Method 2,⁵ the product of m_r and p_D is replaced by Z (the resistance function).

$$\Delta p_{w_n} = \sum_{j=1}^n e_{w(n+1-j)} \Delta Z_j, \quad (27)$$

where $\Delta Z_j = Z_i - Z_{j-1}$.

Method 2 is not limited to homogeneous linear or radial aquifers because the final Z is obtained by adjusting previous approximations to Z . Techniques for applying Method 2 to the case where reservoir interference exists are not available at this time, except for unusual circumstances.

*Personal communication from Atlantic Refining Co.

15	3,900	949	2.921	3.873	949	946

The procedure for both methods can be illustrated best by an application to a single-pool aquifer. Assume that a reservoir has produced for 15 quarters and that Cols. 2 and 3 in Table 38.2 are, respectively, the pressures at the end of each quarter and the average water-influx rates obtained by material balance for each quarter.

Example Problem 1. Method 1. From the following assumed best set of aquifer properties, check Table 38.1 for the substitution of d in Eq. 20.

$$\begin{aligned}
 c_{wt} &= 5.5 \times 10^{-6} \text{ psi}^{-1}, \\
 \mu_w &= 0.6 \text{ cp}, \\
 h &= 50 \text{ ft}, \\
 \alpha &= 2\pi \text{ radians}, \\
 k &= 76 \text{ md}, \\
 \phi &= 0.16, \\
 r_w &= 3,270 \text{ ft},
 \end{aligned}$$

and the aquifer geometry is infinite radial.

Calculate a convenient value (to minimize interpolation) of dimensionless time interval (Δt_D) for the quarterly interval ($\Delta t = 91.25$ days) by varying the permeability (if necessary) in Eq. 20. In this case, $\Delta t_D = 10$, corresponding to $k = 91$ md, was selected. A check of Table 38.1 shows that p_D is to be obtained from Table 38.3 (also tabulated in Table 38.2, Col. 4).

$$m_{r_n} = \frac{\Delta p_{f_n}}{\sum_{j=1}^n e_{w_{n+1-j}} \Delta p_{D_j}}, \dots (28)$$

where Δp_D is the known field pressure drop at original WOC.

Calculate Δp_D as a function of interval number. Then calculate m_r as a function of interval number using Eq. 28 and plot m_r as a function of n (Curve 1, Fig. 38.5). Fig. 38.6 shows an example of the calculation procedure for $n=5$ using equal time intervals.

If the Δt_D selected is the correct value, m_r as a function of n will be constant. Variations from a constant can result from (1) incorrect Δt_D , (2) production and pressure errors, (3) incorrect aquifer size or shape, or (4) aquifer inhomogeneities. An examination of the m_r plot will aid in the analysis of the cause.

Value of m_r	Possible Remedy
increase with n	decrease with Δt_D
decrease with n	increase Δt_D
constant, then increasing	finite-closed aquifer
constant, then decreasing	finite-outcropping aquifer

For a finite-closed aquifer or finite-outcropping aquifer, Eq. 29 or 30 is used to find r_D .

$$r_D = 2.3(N_{it}\Delta t_D)^{0.518} \dots (29)$$

for $N_{it}\Delta t_D \leq 3.4$, and

$$r_D = 3(N_{it}\Delta t_D)^{0.301} \dots (30)$$

for $N_{it}\Delta t_D \leq 3.4$, where N_{it} is the time interval number where m_r vs. n increases from a constant value.

In this example, m_r increased with n (Fig. 38.5, $\Delta t_D = 10$). Therefore, Δt_D was decreased from 10 to 1 (large changes are recommended) and m_r for $\Delta t_D = 1$ was calculated (Curve 2). Now m_r is constant until about Interval 9 and then increases, indicating the possibility of a finite-closed aquifer. Using $N_{it} = 9$ and $\Delta t_D = 1$ in Eq. 29 gives a first approximation of 7 (rounded from 7.2) for r_D . The m_r calculated for $\Delta t_D = 1$ and $r_D = 7$ is reduced after Interval 9 (Curve 3) but is still too high and therefore indicates that the aquifer is still too large. An r_D of 6 is taken for the next approximation, and this results in a constant value of m_r (Curve 4). This shows that the past field behavior (Col. 3, Table 38.2) can be duplicated by assuming a finite-closed aquifer where $\Delta t_D = 1$ and $r_D = 6$ (Col. 6, Table 38.2). Because these aquifer properties gave the best match to the past field performance, they should be taken as the best set for predicting the future performance.

If an infinite aquifer had been indicated, it may be desirable in some cases to predict the future performance assuming first an infinite aquifer and then a finite-closed aquifer having a calculated r_D based on the best estimate of Δt_D and setting N_{ii} equal to the last interval number in Eq. 20 or 30.

Note that, in general, the plot of m_r will not be a smooth plot because of errors in basic data. The first few values are particularly sensitive to errors and generally may be ignored.

If it is possible to obtain a relatively constant value of m_r , check the production and pressure data for errors. If the production and pressure data are correct, try Method

2. If it appears that the production and/or pressure data may be in error, refer to the following discussion of Errors in Basic Data.

Example Problem 2. Method 2. This method is based on the following principles: (1) the slope of Z (m_r times p_D) as a function of time is always positive and never increases; (2) a constant slope of Z vs. time indicates a finite aquifer (see Eqs. 25 and 26) and therefore the extrapolated slope is constant; and (3) a constant slope of Z vs. log time indicates an infinite radial aquifer (Eq. 22). Extrapolation of this constant slope continues to simulate an infinite aquifer.

Fig. 38.5—Estimation of m_r , Δt_D , and r_{Dp} for data in Table 38.2 (Method 1).

As in the first procedure, time is divided into equal intervals. The first approximation to Z can be obtained as in Method 1 or by arbitrarily using the square root of the interval number (Col. 5, Table 38.2, and Trial 1, Fig. 38.7). A fitting factor m is calculated as a function of time for Trial 1 in exactly the same manner used to calculate m_r in Method 1.

$$m_n = \frac{\Delta p_{fn}}{\sum_{j=1}^n e_{w(n+1-j)} \Delta p_{Dj}} \quad (31)$$

However, instead of m being plotted, m is used to calculate the next approximation of Z by use of Eq. 32.

$$\text{New } Z_n = m_n(\text{old } Z_n) \quad (32)$$

The new values of Z are plotted as a function of n (Trial 2, Fig. 38.7), and a smooth curve is drawn through the points, making certain the slope is positive and never increases (Principle 1). This procedure is repeated with values of Z from this smoothed curve until the fitting factors are relatively constant and equal to 1 (Trial 3, Fig. 38.7).

The final Z curve then is extrapolated to calculate the future performance as follows.

1. If the final slope of Z as a function of time is constant, extrapolate Z at a constant slope (Principle 2).

2. If the final slope is not constant as a function of time but is constant as a function of log time, first assume that the aquifer is an infinite radial system and will continue to behave as such (Principle 3) and extrapolate Z as a straight line as a function of log time; then assume that the aquifer is immediately bounded and extrapolate Z as a straight line on a linear plot of time using the last known slope (Principle 2).

3. If the final slope is not constant for either time or log time, extrapolate Z as a straight line using half the last known slope.

Fig. 38.6—Sample pressure-drop calculation.

Fig. 38.7 shows that three trials were needed to obtain a constant value of 1 for m . Col. 7, Table 38.2, shows that the final Z 's will duplicate the past pressure performance and therefore may be used to predict the future performance. Because Z becomes a straight line as a function of n , a finite-closed aquifer is indicated (Principle 2). Therefore, Z can be extrapolated as a straight line to calculate the future performance.

Errors in Basic Data. Good results were obtained for both methods, since accurate water influx and pressure data were used. In many cases a solution for m_r and Δp_D in Method 1 or Z in Method 2 is impossible because of errors in basic data. In these cases the errors may be eliminated by smoothing the basic data or may be adjusted somewhat by using Eqs. 33 and 34.⁵

$$\delta \Delta p_{fn} = -0.1 \frac{m_n - \bar{m}}{m_n} \Delta p_{fn} \quad (33)$$

Fig. 38.7—Estimation of Z for data in Table 38.2 (Method 2).

Fig. 38.8—Estimation of m_F and F function for approximate water drive analysis of data in Table 38.2.

and

$$\delta e_{w_f} = 0.4 \frac{m_n - \bar{m}}{m_n \bar{m} \Delta Z_1} \Delta p_{f_n} - \frac{1}{\Delta Z_1} \sum_{j=2}^n \delta e_{w_{(n+1-j)}} \Delta Z_j, \dots (34)$$

where

$$\begin{aligned} \delta p_{f_n} &= \text{correction to } \Delta p_{f_n}, \\ \delta e_{w_n} &= \text{correction to } e_{w_n}, \text{ and} \\ \bar{m} &= \text{average value of } m. \end{aligned}$$

In applying Eqs. 33 and 34 to Method 1, replace m by m_r and ΔZ by Δp_D . Note that, since Eqs. 33 and 34 imply that the last values of Z (or Δp_D) are reasonably correct, some judgment must be exercised when making these adjustments.

Approximate Methods. If the water influx rate is constant for a sufficiently long period of time, the following equations can be used to estimate water drive behavior roughly.

$$\Delta p_{wt_n} = m_F e_{wt_n} F \dots (35)$$

and

$$W_{e(t_1-t_2)} = \frac{1}{m_F} \int_1^2 \frac{\Delta p_{wt}}{F}, \dots (36)$$

where F is an approximation to p_D and a function of the type of aquifer and m_F is a proportionality factor. See Table 38.4 for function and aquifer type.

TABLE 38.4—WATER DRIVE BEHAVIOR EQUATIONS

Type Aquifer	F	Basis
Infinite radial	$\log t$	Eq. 22
Infinite linear	\sqrt{t}	Eq. 21
Finite outcropping	L	Eq. 23
Finite closed	t	Eq. 25 or 26

The equations for the infinite-radial and finite-outcropping aquifers are commonly referred to in the literature as the "simplified Hurst" and "Schilthuis" water drive equations.

The procedure consists of calculating m_F for the past history using Eq. 35 or 36, plotting m_F as a function of time, and extrapolating m_F to predict the future water drive performance. Since the method assumes a constant water influx rate, the use of these equations should be limited to short-term rough approximations of future water drive behavior. Large errors may be obtained if the method is used to predict the behavior for large changes in reservoir withdrawal rates.

Fig. 38.8 shows a comparison of m_F as a function of time for various values of F and the data in Table 38.2. These curves seem indicative of either an infinite linear or radial aquifer (the curves for these assumptions more nearly approach a constant value), whereas the more rigorous analyses indicated a finite aquifer. The selection of the best curve to use in predicting the future performance is difficult because of the fluctuations in the curves caused by variations in water influx rates. Note that this difficulty would be compounded if there were errors in the production and pressure data.

Fetkovitch⁷ presented a simplified approach that is based on the concept of a "stabilized" or pseudosteady-state aquifer productivity index and an aquifer material balance relating average aquifer pressure to cumulative water influx. This method is best suited for smaller aquifers, which may approach a pseudosteady condition quickly and in which the aquifer geometry and physical properties are known.

In a manner similar to single-well performance, the rate of water influx is expressed by Eq. 37.

$$e_w = J_a (\bar{p}_a - p_w), \dots (37)$$

where

$$\begin{aligned} e_w &= \text{water influx rate, B/D,} \\ J_a &= \text{aquifer productivity index, B/D-psi,} \\ \bar{p}_a &= \text{average aquifer pressure, psi, and} \\ p_w &= \text{pressure at the original WOC, psi.} \end{aligned}$$

Combining Eq. 37 with a material-balance equation for the aquifer, the increment of influx over a time interval $t_n - t_{n-1}$ is given by Eq. 38.

$$\Delta W_e = \frac{W_{ei} [\bar{p}_{a(n-1)} - \bar{p}_{wn} [1 - e^{(-J_a \Delta t_n)/(c_{wt} V_{wi})}]]}{P_{ai}}, \dots (38)$$

where

$W_{et} = W_{cwt} p_{ai}$, total aquifer expansion capacity, bbl,

V_{wi} = initial water volume in the aquifer, bbl,

p_{ai} = initial aquifer pressure, psi, and

c_{wt} = total aquifer compressibility, psi^{-1} .

$$\bar{p}_{a(n-1)} = p_{ai} \left[1 - \frac{w_{e(n-1)}}{W_{et}} \right], \dots\dots\dots (39)$$

$$J_a = \frac{7.08 \times 10^{-3} kh}{\mu_w (\ln r_D - 0.75)} \dots\dots\dots (40)$$

for a closed radial system, and

$$J_a = \frac{3(1.127 \times 10^{-3})kbh}{\mu_w L} \dots\dots\dots (41)$$

for a closed linear system.

Original Oil in Place (OOIP)

Occasionally, it may be necessary to estimate the OOIP and to make a water drive analysis simultaneously. In general, the methods available are very sensitive to errors in basic data so that it is necessary to have a large amount of accurate data. Also, since the expansion of the reservoir above the bubblepoint is relatively small, generally only the data obtained after the reservoir has passed through the bubblepoint will be significant in defining the OOIP. In the three methods to be discussed, the aquifer will be assumed to be infinite and radial.

Brownscombe-Collins Method. This method⁸ assumes that the OOIP and the aquifer permeability are unknown and that the reservoir and aquifer properties other than permeability are known.

The pressure performance and the variance are calculated using Eqs. 7 and 42 for a given assumed aquifer permeability and various estimates. The minimum variance from a plot of variance vs. OOIP (Fig. 38.9) will be the best estimate of OOIP for the selected permeability.

$$\sigma^2 = \frac{1}{n} \sum_{j=1}^n (\Delta p_{f_j} - \Delta p_{w_j}), \dots\dots\dots (42)$$

This procedure is repeated for various estimates of permeability until it is possible to obtain a minimum of the minimums. The permeability and the OOIP associated with this minimum should be the best estimates for the assumptions made.

It is possible to calculate the best estimate of OOIP for each selected permeability by the following procedure. Using the best available estimate of OOIP, calculate the reservoir voidage and expansion rates as a function of time. Select an aquifer permeability and use these rates in place of the water influx rates in Eq. 6 to calculate pressure drops Δp_{v_n} and Δp_{E_n} . The estimated OOIP mul-

Fig. 38.9—Estimation of reservoir volume and water drive (Brownscombe-Collins method).

tiplied by the factor X calculated by Eq. 43 gives the best estimate of OOIP for the selected permeability. Eq. 44 gives the minimum variance for this permeability.

$$X = \frac{\sum_{j=1}^n (\Delta p_{v_j} - \Delta p_{f_j}) \Delta p_{E_j}}{\sum_{j=1}^n (\Delta p_{E_j})^2} \dots\dots\dots (43)$$

and

$$\sigma^2 = \frac{1}{n} \sum_{j=1}^n (\Delta p_{f_j} - \Delta p_{v_j} - X \Delta p_{E_j})^2, \dots\dots\dots (44)$$

where

Δp_f = total pressure drop at original WOC (field data), psi,

Δp_v = total pressure drop at WOC (calculated using reservoir voidage rates), psi, and

Δp_E = total pressure drop at WOC (calculated using reservoir expansion rates), psi.

van Everdingen, Timmerman, and McMahon Method.

This method⁹ assumes that the OOIP, aquifer conductivity $kh\alpha/\mu$, and diffusivity $k/(\phi\mu c)$ are unknown. Combination of the material-balance equation and Eq. 8 and solving for the OOIP yields Eq. 45.

$$N = A + m_p F(t), \dots\dots\dots (45)$$

where

$$A = \frac{1}{(F_V - 1)B_{oi}} [N_p F_V B_o + N_p (R_p - R_s) B_g + W_p], \dots\dots\dots (46)$$

$$F(t) = \frac{1}{(F_V - 1)B_{oi}} \left[\sum_{j=1}^n \Delta p_{(n+1-j)} W_{ed_j} \right], \dots\dots (47)$$

$$F_V = \frac{p_b - p}{pY} + 1, \dots\dots\dots (48)$$

and

$$Y = \frac{p_b - p}{p(F_V - 1)} \quad (49)$$

F_V = ratio of volume of oil and its dissolved original gas at a given pressure to its volume at initial pressure.

N = OOIP, STB,

N_p = cumulative oil produced, STB,

W_p = cumulative water produced, bbl,

R_p = cumulative produced GOR, scf/STB,

B_o = oil FVF, bbl/STB,

B_g = gas FVF, bbl/scf, and

p_b = bubblepoint pressure, psia.

Generally, Y is calculated with laboratory-determined values of $F_V - 1$. Because Y vs. p is generally a straight line, smoothed values of Y can be calculated with Eq. 50:

$$Y = b + m, \quad (50)$$

where b = intercept and m = slope.

The equations for obtaining the least-squares fit to Eqs. 46 and 47 for a given dimensionless time interval, Δt_D , and n data points are

$$nN = \sum_{j=1}^n A_j - m_p \sum_{j=1}^n F(t)_j \quad (51)$$

and

$$N \sum_{j=1}^n F(t)_j = \sum_{j=1}^n A_j [F(t)]_j - m_p \sum_{j=1}^n [F(t)]_j^2. \quad (52)$$

The variance of this fit from field data can be calculated by Eq. 53.

$$\sigma^2 = \frac{1}{n} \sum_{j=1}^n \{A_j - N + m_p [F(t)]_j\}^2. \quad (53)$$

The minimum in a plot of variance vs. various assumed values of Δt_D will be the best estimate of Δt_D and can be used in Eqs. 51 and 52 to solve for the best estimate of N and m_p (see Fig. 38.10).

Fig. 38.10—Estimation of reservoir volume and water drive (van Everdingen-Timmerman-McMahon method).

Havlena-Odeh Method. In this method,¹⁰ the material-balance equation is written as the equation of a straight line containing two unknown constants, N and m_p . Combination of the material-balance equation and Eq. 8 yields Eq. 54. (See Fig. 38.10.)

$$\frac{V_{R_n}}{E_{N_n}} = \frac{N + m_p \sum_{j=1}^n \Delta p_{(n-1-j)} W_{ed_j}}{E_{N_n}}, \dots \dots (54)$$

where

$$V_{R_n} = N_p [B_t + B_g(R_p - R_{si})] + (W_p - W_i)B_w - G_i B_{g_i},$$

$$E_{N_n} = B_t - B_{t_i} + \frac{B_{t_i}}{1 - S_w} (c_f + S_w c_w) (p_i - p_n) + m \frac{B_{t_i}}{B_{g_i}} (B_g - B_{g_i}),$$

V_{R_n} = cumulative voidage at the end of interval n , RB,

E_N = cumulative expansion per stock-tank barrel OOIP, RB,

B_t = two-phase FVF, bbl/STB,

W_p = cumulative water produced, STB,

W_i = cumulative water injected, STB,

G_i = cumulative gas injected, scf,

B_w = water FVF, bbl/STB,

c_f = formation compressibility, psi^{-1} ,

c_w = formation water compressibility, psi^{-1} ,

S_w = formation water saturation, fraction, and

m = fitting factor.

Eq. 54 is the equation of a straight line with a slope of m_p and a y intercept of N .

Estimates of r_D and Δt_D are made and the appropriate values of W_{ed} are obtained from Table 38.3 or 38.5, according to system geometry. The summation terms in Eq. 54 then may be calculated and a graph plotted, as shown in Fig. 38.11. If a straight line results, the values of m_p and N are obtained from the slope and intercept of the resulting graph. An increasing slope indicates that the summation terms are too small, while a decreasing slope indicates that the summation terms are too large. The procedure is repeated, using different estimates of r_D and/or Δt_D until a straight-line plot is obtained. It should be noted that more than one combination of r_D and Δt_D may yield a reasonable straight line—i.e., a straight-line result does not necessarily determine a unique solution for N and m_p .

Future Performance

The future field performance must be obtained from a simultaneous solution of the material-balance and water drive equations. If the reservoir is above saturation pressure, a direct solution is possible; however, if the reservoir is below saturation pressure, a trial-and-error procedure is necessary.

There are several methods of solution because there are several possible combinations of the various material-balance and water drive equations. However, only one combination will be used to illustrate the general application to (1) a reservoir above the bubblepoint pressure, and (2) a reservoir below the bubblepoint pressure. In either case, it will be necessary to know (1) the saturations behind the front from laboratory core data or other sources, (2) the water production as a function of frontal advance, and (3) the pressure gradient in the flooded portion of the reservoir.

Pressure Gradient Between New and Original Front Positions. Eq. 55 shows that the difference between the average reservoir pressure and the pressure at the original WOC is a function of water-influx rate, aquifer fluid and formation properties, and aquifer geometry.

$$\Delta p_{o_n} - \Delta p_{w_n} = \frac{\mu_w e_{w_n}}{k_w} F_G = p_{w_n} - p_{o_n}, \dots (55)$$

where F_G is the reservoir geometry factor. The linear frontal advance is given by

$$F_G = \frac{L_f}{0.001127hb} \dots (56)$$

and the radial frontal advance is given by

$$F_G = \frac{2\pi \ln(r_w/r_f)}{0.00708h\alpha}, \dots (57)$$

where

L_f = linear penetration of water front into reservoir, ft,

r_f = radius to water front after penetration, ft, and

α = angle subtended by reservoir, radians.

Note that F_G is a function of distance traveled by the front so that, if the pressure gradients between the reservoir and the original reservoir boundary are known for the past history, F_G may be evaluated as a function of frontal advance. Future values of F_G then can be obtained by extrapolating F_G as a function of frontal advance on some convenient plot (linear, semilog, etc.)

Reservoir Above Bubblepoint Pressure. Above the bubblepoint pressure the total compressibility can be assumed to be constant; so the material-balance equation

$$\Delta p_{on} = \frac{(q_{tn} - e_{wn}) \Delta t}{V_p c_{ot}} + \Delta p_{on-1}, \dots \dots \dots (58)$$

where

Δp_{on} = total reservoir pressure drop from initial pressure at end of interval n ,

q_{tn} = total production rate, RB/D,

V_p = total reservoir PV, bbl, and

c_{ot} = total reservoir compressibility, psi^{-1} ,

can be combined with Eqs. 6 and 55 and solved for the water-influx rate:

$$e_{wn} = \frac{\Delta p_{on-1} + (\Delta t q_{tn} / V_p c_{ot}) - m_r \sum_{j=2}^n e_{w(n+1-j)} \Delta p_{Dj}}{m_r \Delta p_{Dj} + (\Delta t / V_p c_{ot}) + (\mu_w F_g / k_w)} \dots \dots \dots (59)$$

The calculated water-influx rate now can be used in Eq. 58 to calculate Δp_{on} and the whole procedure is repeated for the next time interval. If Eq. 27 is used instead of Eq. 6, $m_r = 1$ and Δp_D is replaced by ΔZ in Eq. 59.

Reservoir Below Bubblepoint Pressure. To simplify the calculation procedure, it was assumed that (1) uniform saturations exist ahead of and behind the front, (2) the saturations do not change as any portion of the reservoir is bypassed, and (3) the changes in pressure are selected small enough that the changes in oil FVF's are very small. Fig. 38.12 shows the saturation changes as the front advances into the unflooded reservoir volume V_{n-1} during time interval n .

The following equations will be used in this method. Water influx rate:

$$e_{wn} = \frac{\Delta p_{on-1} - m_r \sum_{j=2}^n e_{w(n+1-j)} \Delta p_{Dj}}{m_r \Delta p_{Dj} - (\mu_w F_g / k_w)} \dots \dots \dots (60)$$

GOR (relative permeability):

$$R_n = \left(\frac{k_{rg} \mu_o}{k_{ro} \mu_g} \frac{\bar{B}_o}{\bar{B}_g} \right)_n + \bar{R}_{s_n} \quad (65)$$

GOR (production):

$$R_n = \frac{\Delta G_n}{q_{o_n} \Delta t_n} \quad (66)$$

For these equations,

- f_R = fraction of reservoir swept,
- S_o = oil saturation, fraction,
- S_g = gas saturation, fraction,
- S_w = water saturation, fraction, and
- S_{iw} = interstitial water saturation, fraction.

One method for solutions using equal time intervals is as follows.

1. Estimate the pressure drop during the next time interval.
2. Calculate the water-influx rate with Eq. 60.
3. Calculate ΔV_n and V_n with Eqs. 61 and 62.
4. Calculate the oil saturation in V_n for the predicted oil production during Interval n with Eq. 63.
5. Calculate gas production with Eq. 64.

6. Calculate the GOR with Eq. 65.

7. Calculate the GOR with Eq. 66 for average values of pressure and saturation.

8. Compare the GOR's obtained in Steps 6 and 7 and, if they agree, proceed to the next interval. If they do not agree, estimate a new pressure drop and repeat Steps 2 through 8.

If the water drive equation for unequal time intervals is used, the need for re-evaluating the pressure functions for each trial in a given interval can be eliminated. This procedure calls for selecting a given pressure drop and estimating the length of the next time interval in Steps 1 and 8 and this program. The remaining steps are unchanged.

Reservoir Simulation Models. The capability of mathematical simulation models to calculate pressure and fluid flow in nonhomogeneous and nonsymmetrical reservoir/aquifer systems has been thoroughly described in the literature since the early 1960's. Widespread availability of computers and models throughout the industry has helped to remove many of the idealizations and restrictions regarding geometry and/or homogeneity that are a practical requirement for analysis by traditional methods. These models have the capability to analyze performance for virtually any desired description of the physical system, including multipool aquifers. See Chap. 48 for more information.

Nomenclature

A = constant described by Eq. 46	J_a = aquifer productivity index, B/D-psi
b = intercept	k = permeability, md
B_g = gas FVF, bbl/STB	L = aquifer length, ft
B_o = oil FVF, bbl/STB	L_f = linear penetration of water front into reservoir, ft
B_t = two-phase FVF, bbl/STB	m = fitting factor (see Page 38-7); ratio of initial reservoir free-gas volume to initial reservoir oil volume; slope
B_w = water FVF, bbl/STB	m_F = proportionality factor
c_f = formation compressibility, psi^{-1}	m_p = influx constant, bbl/psi (see Eqs. 9 and 10)
c_{ot} = total reservoir compressibility, psi^{-1}	m_r = rate constant, $\text{psi}/\text{bbl-D}$ (see Eqs. 3 through 5)
c_w = formation water compressibility, psi^{-1}	n = interval
c_{wt} = total aquifer compressibility, psi^{-1}	N = OOIP, STB
d = geometry term obtained from Table 38.1	N_{it} = time interval number
e_w = water influx rate, B/D	N_p = cumulative oil produced, STB
e_{wB} = water influx rate at Reservoir B, B/D	\bar{p}_a = average aquifer pressure, psi
$e_{w(n+1-j)}$ = water-influx rate at interval $n+1-j$, B/D	p_{a_i} = initial aquifer pressure, psi
e_{wt_n} = total water influx rate at interval n , B/D	p_b = bubblepoint pressure, psi
E_N = cumulative expansion per stock-tank barrel OOIP, bbl	p_D = dimensionless pressure term
f_R = fraction of reservoir swept	$p_{D(A,B)}$ = dimensionless pressure term for Reservoir B with respect to Reservoir A
F = approximation to p_D and a function of type of aquifer	p_w = pressure at original WOC, psi
F_G = reservoir geometry factor	p_{w_n} = cumulative pressure drop at the end of interval n , psi
$F(t)$ = influence function	Δp_D = known dimensionless field pressure drop at original WOC
F_V = ratio of volume of oil and its dissolved original gas at a given pressure to its volume at initial pressure	Δp_{D_i} = dimensionless pressure drop to time period i
G_i = cumulative gas injected, scf	
h = aquifer thickness, ft	
j = summation of time period $1 + o_n$

Δp_{Dj} = dimensionless pressure drop to time period j

Δp_E = total pressure drop at WOC (calculated using reservoir expansion rates), psi

Δp_f = total pressure drop at original WOC (field data), psi

$\Delta \bar{p}_{(n+1-j)}$ = average pressure drop in interval, psi

$\Delta p_{o(A,B)}$ = pressure drop at Reservoir A caused by Reservoir B, psi

Δp_{oA_n} = total pressure drop at Reservoir A at end of interval n , psi

Δp_v = total pressure drop at WOC (calculated using reservoir voidage rates), psi

q_{on} = total oil production rate at end of interval n , B/D

q_{tn} = total production rate, B/D

r_a = aquifer radius, ft

r_D = dimensionless radius = r_a/r_w

r_f = radius to water front after penetration, ft

r_w = field radius, ft

R_p = cumulative produced GOR, scf/STB

R_{s_n} = average solution GOR at end of interval n , scf/STB

S_g = gas saturation, fraction

S_{iw} = interstitial water saturation, fraction

S_o = oil saturation, fraction

S_{or_n} = residual oil saturation at end of interval n , fraction

S_w = formation water saturation, fraction

t_D = dimensionless time

Δt_D = dimensionless time interval

V_p = total reservoir PV, bbl

V_R = cumulative voidage, bbl

V_{w_i} = initial water volume in the aquifer, bbl

w = aquifer width, ft

W_{eD} = dimensionless water-influx term

W_{e_n} = cumulative water influx at end of interval n , bbl

$W_{et} = W_{c_w} p_{ai}$, total aquifer expansion capacity, bbl

W_i = cumulative water injected, bbl

W_p = cumulative water produced, bbl

Y = constant described by Eqs. 49 and 50

Z = resistance function

Z_n = new values of Z

α = angle subtended by reservoir, radians

δe_{w_n} = correction to e_{w_n}

δp_{f_n} = correction to Δp_{f_n}

μ_w = water viscosity, cp

σ^2 = variance

ϕ = porosity, fraction

Key Equations With SI Units

The equations in this chapter may be used directly with practical SI units without conversion factors, except for certain equations containing numerical constants. These equations are repeated here with appropriate constants for SI units.

$$m_r = \frac{\mu_w}{8.527 \times 10^{-5} kh\alpha}, \quad (3)$$

$$m_r = \frac{\mu_w}{8.527 \times 10^{-5} kh}, \quad (4)$$

$$m_r = \frac{\mu_w L}{8.527 \times 10^{-5} khb}, \quad (5)$$

$$m_p = (1)\phi c_{wt} h\alpha r_w^2, \quad (9)$$

$$m_p = (1)\phi c_{wt} hb^2, \quad (10)$$

$$t_D = \frac{8.527 \times 10^{-5} kt}{\phi c_{wt} \mu_w d^2}, \quad (20)$$

$$J_a = \frac{5.36 \times 10^{-4} kh}{\mu_w (\ln r_D - 0.75)}, \quad (40)$$

$$J_a = \frac{3(8.527 \times 10^{-5})kbh}{\mu_w L}, \quad (41)$$

$$F_G = \frac{L_f}{8.527 \times 10^{-5} hb}, \quad (56)$$

and

$$F_G = \frac{2\pi \ln(r_w/r_f)}{5.36 \times 10^{-4} h\alpha}, \quad (57)$$

where

k is in md,

h is in m,

b is in m,

L is in m,

r_D is dimensionless,

r_w is in m,

μ_w is in mPa·s,

c_{wt} is in kPa⁻¹,

J_a is in m³/d·kPa,

m_r is in kPa/m³·d,

m_p is in m³/kPa,

F_G is in m⁻¹, and

α is in radians.

Chapter 39

Gas-Condensate Reservoirs

Phillip L. Moses, Core Laboratories Inc.*
Charles W. Donohoe, Core Laboratories Inc.

Introduction

The importance of gas-condensate reservoirs has grown continuously since the late 1930's. Development and operation of these reservoirs for maximum recovery require engineering and operating methods significantly different from crude-oil or dry-gas reservoirs. The single most striking factor about gas-condensate systems (fluids) is that they exist either wholly or preponderantly as vapor phase in the reservoir at the time of discovery (the critical temperature of the system is lower than the reservoir temperature). This key fact nearly always governs the development and operating programs for recovery of hydrocarbons from such reservoirs; the properties of the fluids determine the best program in each case. A thorough understanding of fluid properties together with a good understanding of the special economics involved is therefore required for optimum engineering of gas-condensate reservoirs. Other important aspects include geologic conditions, rock properties, well deliverability, well costs and spacing, well-pattern geometry, and plant costs.

Engineers have a wealth of literature on gas-condensate reservoirs available for reference. From this mass of material, Refs. 1 through 5 are especially recommended for fundamental background, and Refs. 6 through 8 are recommended for information on properties of pure compounds and their simple mixtures related to gas-condensate systems. For information regarding reservoir engineering processes and data, Refs. 5 and 9 through 16 are recommended.

The best single bibliography on gas-condensate reservoirs is that of Katz and Rzasa¹⁷; however, later pertinent literature listings will be found in Refs. 6 through 14. The collection of references in Refs. 11 and 12 is particularly recommended for case histories of various gas-condensate operations. Petroleum production papers pub-

lished by SPE (AIME)¹⁸ and API¹⁹ have been indexed separately through the years 1985 and 1953, respectively.

The practicing field engineers should have the following minimum library on gas-condensate systems available for their use: either Ref. 1, 2, or 3; Refs. 5, 9, 13, and 15; and selected volumes of Refs. 11 and 12.

Properties and Behavior of Gas-Condensate Fluids

Sloan²⁰ described the general occurrence of petroleum in the earth: "...think of all the hydrocarbons, beginning with the lightest, methane, to the heaviest asphaltic substances as a series of compounds of the same family, consisting of carbon and hydrogen in a limitless number of proportions. A hydrocarbon reservoir then, is a porous section of the sedimentary crust of the earth containing a group of hydrocarbons, which is probably unique and whose overall properties such as reservoir phase, gas/oil ratio, gasoline content, viscosity, etc., is the direct result of this composition, together with the temperature and pressure that happen to exist in this particular spot in the porous sediment.

"It is now easy to conceive of any possible combination of these hydrocarbons in a given reservoir, and it is also easy to visualize a reservoir fluid whose physical state may range from a completely dry gas in the reservoir, shading gradually through the wet gas, the condensate, the critical mixture, the highly compressible volatile liquid, the more stable light crude oil whose color is beginning to darken, the heavier crudes with decreasing solution gas, and ending with the semisolid asphalts and waxes with no measurable solution gas.

"The condensate reservoir that is the topic under discussion is therefore first a hydrocarbon reservoir. Due to the composition and proportion of the individual hydrocarbons in the mixtures, the content is gas phase at the temperature and pressure of the reservoir."

*Original chapter in 1962 edition was written by T.A. Pollard and Howard B. Bradley.

TABLE 39.1—HYDROCARBON ANALYSES AND PROPERTIES OF EXAMPLE CRUDE OILS AND GAS CONDENSATES

Component	Mole Fraction				
	Crude Oil A*	Crude Oil B*	Condensate 843**	Condensate 944**	Condensate 1143**
Carbon dioxide	—	—	0.00794	0.00130	0.00695

Composition Ranges of Gas-Condensate Systems

Approximate composition indices for gas-condensate systems are the gas/liquid ratio of produced fluids (sometimes called the GOR) or its reciprocal, the liquid/gas ratio, and the gravity of the tank liquid separated out under various surface conditions. These two indices vary widely; they do not necessarily prove whether a hydrocarbon system is in the vapor phase in the reservoir.

Eilerts *et al.*² (Vol. 1, Chaps. 1 and 8) show in a survey that the liquid/gas ratios of gas-condensate systems can vary from more than 500 (very "rich") to less than 10 bbl/MMscf; tank condensate produced from the wells varied from less than 30 to more than 80°API, and more than 85% was within the range of 45 to 65°API. Eilerts *et al.*² (Vol. 1) also quote a rule of thumb that a gas-condensate system exists when the gas/liquid ratio exceeds 5,000 cu ft/bbl (200 bbl/MMscf and less) and the liquid is lighter than 50°API. This appears to be on the conservative side because there is evidence that systems exist as single-phase vapor in the reservoir when the surface gas/liquid ratio is less than 4,000 cu ft/bbl (more than 250 bbl/MMscf) and the API gravity of the liquid in the stock tanks is lower than 40°API.

A more accurate representation of the composition of gas-condensate fluids is provided by fractional analyses of the well streams coming from the reservoirs. The contrast of the fluid composition with the total stream coming from crude-oil reservoirs is fairly large for the relative amounts of the lighter vs. heavier ends of the paraffin-hydrocarbon series. For example, Eilerts *et al.*² (Vol. 1, Table 8.8) report a methane content from about 75 to 90 mol% for several gas-condensate systems, whereas Dodson and Standing²¹ report 44 and 53 mol%, respectively, for two crude-oil systems (see Table 39.1). The table, however, shows much lower heptanes-and-heavier content for the gas-condensate systems than for the crude oil. These are the two outstanding composition features of gas-condensate systems.

Pressure and Temperature Ranges of Gas-Condensate Reservoirs

Gas-condensate reservoirs may occur at pressures below 2,000 psi and temperatures below 100°F²⁰ and probably can occur at any higher fluid pressures and temperatures within reach of the drill. Most known retrograde gas-condensate reservoirs are in the range of 3,000 to 8,000 psi and 200 to 400°F. These pressure and temperature ranges, together with wide composition ranges, provide a great variety of conditions for the physical behavior of gas-condensate deposits. This emphasizes the need for very meticulous engineering studies of each gas-condensate reservoir to arrive at the best mode of development and operation.

Phase and Equilibrium Behavior

An understanding of the behavior of pure paraffin hydrocarbons and simple two-component or three-component systems (involving such compounds as methane, pentane, and decane) is of considerable benefit to the engineer working with gas-condensate reservoir problems. Excellent coverage is given this subject by Sage and Lacey¹ and a more condensed discussion by Burcik.³ Occasional review of such material will assist the engineer concerned with more complex hydrocarbon mixtures.

Chap. 23 describes the phase and equilibrium behavior of complex (multicomponent) hydrocarbon mixtures (see Fig. 23.14 and the accompanying discussion). Note that the critical state (critical point) is that state or condition at which the composition and all other intensive properties of the gas phase and the liquid phase become identical—i.e., the phases are indistinguishable. In gas-condensate reservoirs, the portion of the phase diagram to the left of and above the critical point will not be involved.

Fig. 39.1—Phase diagram of Eilerts' Fluid 843.

Fig. 39.2—Phase diagram of Eilerts' Fluid 1143.

The term “retrograde condensation” (discussed in Chap. 23) is used more loosely than implied by its rigorous definition.¹ In field practice, the term may imply any process where the amount of condensing liquid phase passes through a maximum, whether the process is isothermal or not.

While Fig. 23.14 provides a simplified picture of the phase diagram, reservoir engineers will find that very few quantitative phase diagrams on naturally occurring gas-condensate mixtures have been published. Figs. 39.1 through 39.3 come from extensive work² and represent quantitative measurements on the flow streams from wells in the Chapel Hill, Carthage, and Seeligson fields in Texas. The critical points are not shown because they are at temperatures below those of interest to field operations. This emphasizes that the compositions of gas-condensate systems vary widely and strongly affect the form of the phase diagrams encountered in actual gas-condensate reservoirs. These three phase diagrams represent a reasonable spread in the properties of gas-condensate systems, from a gas/liquid ratio of about 18,000 to 69,000 cu ft/bbl (56 to 14.5 bbl/MMscf). This does not mean, however, that all other gas-condensate systems would fall inside the limits of the properties suggested by these three phase diagrams.

The three cases in Figs. 39.1 through 39.3 imply that the dewpoint boundary approaches zero pressure at a relatively high temperature. Other condensate systems are believed to approximate the qualitative picture shown in Fig. 23.14 more closely. Note that all three systems exhibit both cricondentherm and cricondenbar points (maximum temperature and pressure, respectively, beyond which there is no liquid present in the vapor); the critical temperatures all fall to the left of each diagram at lower temperatures and pressures than the maxima for the dewpoint boundaries.

Liquid-content lines on phase diagrams can be represented by a number of different units. Figs. 39.1 through 39.3 use gallons per thousand cubic feet of separator gas.

The approximate behavior of condensate fluids while being produced from the reservoir into surface vessels can be represented advantageously on phase diagrams. In Fig. 39.2, for example, Line FT shows a flow path for fluids that starts at formation conditions (outside the dewpoint boundary, indicating that the formation fluids were all in vapor phase); proceeds to sandface pressure, Point S_1 , at the well; declines as the fluid rises from the bottom of the hole to the wellhead, Point WH; passes through the choke to separator conditions, Point S_2 ; and reaches Point T, representing tank conditions. The phase diagram is thus helpful to the engineer in visualizing what happens to gas-condensate fluids as they flow from the formation to the wellbore and from there to surface equipment.

Fig. 39.3—Phase diagram of Eilerts' Fluid 944.

Methods have been proposed by Organick²² and Eilerts *et al.*² for predicting the critical temperatures and pressures of hydrocarbon mixtures and for computing the phase diagrams (including dewpoint curves) of gas-condensate fluids. The dependability of these methods for a wide range of gas-condensate compositions has not yet been established. For reservoir engineering work, direct laboratory measurements of phase diagrams or of pressure-depletion behavior are necessary because of the large recoveries at stake. Laboratory work may not be required for other problems.

Gas/Liquid Ratios and Liquid Contents of Gas-Condensate Systems

As discussed earlier, it is difficult to specify whether a hydrocarbon system is in the vapor phase in the reservoir from measurements of field gas/liquid ratio and tank-oil gravity. Fluid production with tank-oil gravities as low as 30° API and gas/liquid ratios as low as 3,000 cu ft/bbl may be from true gas-condensate systems; this possibility should always be checked by laboratory measurements of phase behavior for these and intermediate values.

"Liquid content" and "gas/liquid ratio" can be direct reciprocals, depending on the type of problem considered. The terms must be carefully defined in each case because gas-condensate systems in the field frequently undergo different types of separating procedures that involve several stages before the final liquid phase ("liquid" means hydrocarbon liquid unless otherwise specified) reaches the tanks at atmospheric pressure. To study the properties of gas-condensate fluids at reservoir conditions, it is convenient to define gas/liquid ratios and liquid contents on the basis of the gas and liquid outputs of the first-stage separator through which the fluids pass. These two output streams then represent the total composition of the gas-condensate fluid in the reservoir if sampling, producing, and measuring conditions have been properly set and maintained. Other gas/liquid ratios may be reported, however, including the total gas output of all stages of separation divided by the tank-liquid volumes corresponding to the gas output; note that the total gas output would include a measurement of tank vapors as well as separator gas to represent the full composition of the wellstream.

The gas/liquid ratio at stock-tank conditions may be roughly approximated when field facilities are not available for measurements. The gas and liquid flow rates from the high-stage separator are observed and a liquid sample collected from the separator in a stainless-steel cylinder of known volume. If all the cylinder contents are bled into a calibrated graduate at atmospheric pressure and the volume of the resultant liquid phase is compared with the original liquid volume, an approximate value of the liquid-phase shrinkage may be determined. From this, the high-stage gas/liquid ratio may be converted to stock-tank conditions. This procedure ignores the volume of gas liberated between high-stage separator and stock-tank conditions. This volume can be approximated by using a calibrated glass separator with gas meter attached in place of the graduate. Ignoring this gas volume adds further errors to those resulting from not simulating the existing field stage separation conditions. The higher the first-stage separation pressure, the greater the error in total gas volume of the gas/liquid ratio. This is only an approx-

imate method that may be used when there are no intermediate separator stages and stock tanks for individual well measurements and when the atmospheric temperature and pressure do not vary appreciably from stock-tank conditions.

Gas/liquid ratios usually are reported in cubic feet per barrel of liquid (or thousands of cubic feet per barrel) and liquid contents or liquid/gas ratios in barrels of liquid per million standard cubic feet of gas. The separator streams used in the ratio must be specified.

Properties of Separated Phases

The properties of both liquid and gas phases separated from gas-condensate streams can vary considerably. One of the dominant properties of the gas is high methane content. Eilerts *et al.*² (Vol. 1, Chap. 8) list the compositions of the gas and liquid phases of eight gas-condensate systems. Methane contents of the gas phases (simulated from field separators) varied from about 0.83 to 0.92 mole fraction; the hexanes and heavier ("hexanes plus") varied from 0.004 to about 0.008 mole fraction. The liquid phases varied from about 0.1 to nearly 0.3 mole fraction methane; hexanes plus varied from about 0.4 to 0.7 mole fraction.

In the absence of measured data, properties of the separated phases of gas-condensate systems (including volumetric and density behavior) can be approximated by methods described in Chaps. 20 through 23, especially Chaps. 20 and 22 (see also Refs. 9 and 14).

Viscosities of Gas-Condensate Systems

The viscosity of a gas-condensate system is of interest in various reservoir calculations, particularly with respect to cycling operations and the representation of such reservoirs in computer models. Whenever possible, viscosity of the vapor phase at reservoir conditions should be measured directly. Carr *et al.*²³ presented a method to estimate the viscosities of gas systems from a knowledge of compositions or specific gravities (see also Chap. 20 and Ref. 14).

Viscosities of separate gas and liquid phases at the surface conditions usually encountered can be obtained by direct measurement or by the use of the correlations for gas previously mentioned and the correlation of Chew and Connally²⁴ for liquid (see also Chap. 22). Viscosity information on separated materials is needed mainly for separator or plant residue gases to be injected during cycling and for some types of reservoir calculations.

Gas-Condensate Well Tests and Sampling

Proper testing of gas-condensate wells is essential to ascertain the state of the hydrocarbon system at reservoir conditions and to plan the best production and recovery program for the reservoir. Without proper well tests and samples, it would be impossible to determine the phase conditions of the reservoir contents at reservoir temperature and pressure accurately and to estimate the amount of hydrocarbon materials in place accurately.

Tests are made on gas-condensate wells for a number of specific purposes: to obtain representative samples for laboratory analysis to identify the composition and properties of the reservoir fluids; to make field determinations on gas and liquid properties; and to determine formation

and well characteristics, including productivity, producibility, and injectivity. The first consideration for selecting wells for gas-condensate fluid samples is that they be far enough from the "black-oil ring" (if present) to minimize any chance that the liquid oil phase will enter the well during the test period. A second and highly important consideration is the selection of wells with as high productivities as possible so that minimum pressure draw-down will be suffered when the reservoir fluid samples are acquired.

Well Conditioning

Proper well conditioning is essential to obtain representative samples from the reservoir. The best production rates before and during the sampling procedure have to be considered individually for each reservoir and for each well. Usually the best procedure is to use the lowest rate that results in smooth well operation and the most dependable measurements of surface products. Minimum draw-down of bottomhole pressure during the conditioning period is desirable and the produced gas/liquid ratio should remain constant (within about 2%) for several days; the less-permeable reservoirs require longer periods. The farther the well deviates from constant produced gas/liquid ratio, the greater the likelihood that the samples will not be representative.

Recombined separator samples from gas-condensate wells are considered more representative of the original reservoir fluid than subsurface samples.

Accurate measurements of hydrocarbon gas and liquid production rates during the well-conditioning and well-sampling tests are necessary because the laboratory tests will later be based on fluid compositions recombined in the same ratios as the hydrocarbon streams measured in the field. The original reservoir fluid cannot be simulated in the laboratory unless accurate field measurements of all the separator streams are taken. (Gas/liquid ratios may be reported and used in several different forms, as discussed previously.) If the produced gas/condensate (gas/liquid) ratio from field measurements is in error by as little as 5%, the dewpoint pressure determined in the laboratory may be in error by as much as 100 psi. Water production rates should be measured separately and produced water excluded as much as possible from hydrocarbon samples sent to the laboratory.

Separator pressure and temperatures should remain as constant as possible during the well-conditioning period; this will help maintain constancy of the stream rates and thus of the observed hydrocarbon gas/liquid ratio. If the well is being prepared during a period when atmospheric temperatures vary considerably from night to day, reasonably consistent average temperatures and pressures on the several vessels during the conditioning period should be adequate.

Field Sampling and Test Procedures

After the conditioning period has proceeded long enough to show that producing conditions are steady, exacting measurement methods must be used to obtain representative samples. The mechanics of well sampling is partially covered in Chaps. 12 through 14, 16, and 17. The help of experienced laboratory personnel is advisable in

acquiring gas and condensate-liquid samples. Certain minimum items of information in addition to all stream rates are essential, including regular readings of the pressures and temperatures of all vessels sampled, and of tubing heads and casing heads where available, and a recorded history of the well conditions before and during sampling, along with the actual mechanics of the sampling steps. Other information acquired during the sampling period that would help to explain reservoir and well conditions should also be recorded because it is useful in interpreting the results of the tests.

Care must be taken that the compositions of gas and liquid samples obtained are representative and are properly preserved for laboratory analyses. API RP 44²⁵ outlines appropriate sampling methods.

For cases when the liquid-phase sample is obtained at a low temperature (from low-temperature separation equipment), triethylene-glycol/water mixtures are convenient for collecting the samples. Ten percent or more of the cylinder volume for liquid-phase samples should be gas to prevent excessive pressure that could result from temperature rise during subsequent shipment. This 10% "gas cap" can be effected by closing the cylinder sample-inlet valve when 90% of the glycol/water mixture has been displaced and then carefully withdrawing nearly all the remaining mixture from the bottom of the cylinder without losing the oil phase.

The volumes of fluids requested for laboratory testing should be acquired during the sampling period, plus a reasonable amount (25% or more) of extra sample materials in separate containers for emergency use should some of the main samples be lost by leakage or other adversity between the field site and the laboratory.

At the end of actual sampling mechanics in the field, the well should remain on stream for a reasonable period of time, and its producing rate, gas/liquid ratio, and various pressures and temperatures should be observed to confirm that they are consistent with the information developed before and during the sampling period. Any radical changes should be analyzed carefully to decide whether resampling may be necessary to ensure accuracy of the samples and well statistics obtained during the sampling period.

Equipment is available for making some determinations of gas-condensate properties in the field.² Among these properties are the gas/liquid ratios of several vessels simulating various separation conditions (numbers of stages, pressures and temperatures of the stages, and other conditions) and the "gasoline content" of the overhead gas at each stage. If hydrogen sulfide and carbon dioxide are present in the production streams, special sampling procedures should be used and the samples should be taken in stainless-steel cylinders. These corrosive gases could react with the sample cylinders during shipment.

Field determinations of the hydrocarbon compositions of streams from gas-condensate wells can be made with appropriate fractionation equipment in mobile laboratories. Eilerts *et al.*² described such equipment and the test procedures for determining the effect of individual hydrocarbons on liquid/gas ratios at different separation pressures and temperatures. These tests can assist in determining optimum field separation conditions for given production objectives. They require special equipment and experienced personnel.

Measurements of gas-condensate well productivity, producibility, and injectivity are of considerable importance for planning overall field operations and size of plants for either gasoline recovery or condensate-liquids recovery and cycling, as bases for contracts for deliverability from a reservoir for pipeline purposes, and for various other needs. This topic is discussed more fully later; test procedures are described in Chap. 33 and in several published standards and regulations.²⁶⁻²⁹

Sample Collection and Evaluation

In taking samples for recombination to evaluate a gas-condensate reservoir, the samples of gas and samples of liquid usually are taken from the first stage of separation. A representative portion of all the hydrocarbons produced from the well will be contained in these two samples. The first step in the laboratory study is to evaluate the samples taken. The first test is to measure the bubblepoint of the separator liquid. The bubblepoint should correspond to the separator pressure at separator temperature at the time the samples were taken.

The hydrocarbon composition of the separator samples should then be determined by chromatography or low-temperature fractional distillation or a combination of both. An example of the composition of typical separator products are shown in Table 39.2. These compositions may be evaluated by calculation of the equilibrium ratio for each component (see Chap. 23). The equilibrium ratio for a component is the mole percent of that component in the vapor phase divided by the mole percent of the same component in the liquid phase. As an example, the equilibrium ratio for methane in Table 39.2 is calculated by the equation

$$K_1 = y_1/x_1 = 83.01/10.76 = 7.71,$$

where

- K_1 = the equilibrium ratio for methane,
 y_1 = methane in the vapor phase, mol%, and
 x_1 = methane in the liquid phase, mol%.

The experimental equilibrium ratio for methane is 7.71 for the temperature and pressure existing in the field separator at the time of sampling.

The equilibrium ratios for each of the hydrocarbons methane through hexane are calculated in a similar manner. These data can then be compared with equilibrium ratios, such as those published in Ref. 16. If the equilibrium ratios compare favorably, then the samples are in equilibrium and the study should continue. If they do not compare well, then new samples should be obtained before proceeding.

Recombination of Separator Samples

The samples are now ready to be recombined in the same ratio that they were produced. Because we have samples of first-stage separator gas and first-stage separator liquid, we must have the produced gas/liquid ratio in the same form. If the producing gas/liquid ratio was measured in the field in this form, then we can proceed directly with the recombination. If the ratio was measured in the field in the form of primary-separator gas per barrel of second-stage separator liquid or per barrel of stock-tank liquid, then a laboratory shrinkage test must be run to simulate field separation conditions. The shrinkage obtained can then be used to convert the field-measured ratio to the form necessary for the recombination. Once the separator products have been recombined, the composition can be measured and compared with the calculated composition. This will check the accuracy of the physical recombination.

TABLE 39.2—HYDROCARBON ANALYSES OF SEPARATOR PRODUCTS AND CALCULATED WELL STREAM

Component	Separator Liquid (mol %)	Separator Gas		Well Stream	
		mol %	gal/1,000 cf gas	mol %	gal/1,000 cf gas
Hydrogen sulfide	0.00	0.00		0.00	
Carbon dioxide	0.00	0.01		0.01	
Nitrogen	0.01	0.13		0.11	
Methane	10.76	83.01		68.93

Dewpoint and Pressure/Volume Relations

The laboratory personnel will next measure the pressure/volume relations of the reservoir fluid at reservoir temperature with a visual cell. This is a constant-composition expansion and furnishes the dewpoint of the reservoir fluid at reservoir temperature and the total volume of the reservoir fluid as a function of pressure. The volume of liquid at pressures below the dewpoint as a percent of the total volume may also be measured. Phase diagrams can be developed by measuring the liquid volumes at several other temperatures. Table 39.3 is an example of the dewpoint determination and pressure/volume relations of a gas-condensate reservoir fluid.

Simulated Pressure Depletion

Pressure depletion of gas-condensate reservoirs may be simulated in the laboratory by use of high-pressure visual cells. In these depletion studies made in the laboratory, the assumption is that the retrograde liquid that condenses in the reservoir rock will not achieve a sufficiently high saturation to become mobile. This assumption appears to be valid except for very rich gas-condensate reservoirs. For very rich gas-condensate reservoirs where the retrograde liquid may achieve a high enough saturation to migrate to producing wells, the gas/liquid relative permeability data should be measured for the reservoir rock system. These data can then be used to adjust the predicted recovery from the reservoir.

Table 39.4 is an example of a depletion study on a gas-condensate reservoir fluid. Note from Table 39.4 that the dewpoint pressure of this reservoir fluid is 6,010 psig. The composition listed in the 6,010-psig-pressure column in Table 39.4 is the composition of the reservoir fluid at the dewpoint and exists in the reservoir in the gaseous state.

Fig. 39.4—Deviation factor, z , of well stream during depletion at 256°F.

Fig. 39.5—Retrograde condensation during depletion.

The depletion study is performed by expanding the reservoir fluid in the cell by withdrawing mercury from the cell until the first depletion pressure is reached; this is 5,000 psig in the example. The fluid in the cell is brought to equilibrium and the volume of retrograde liquid is measured. The mercury is then reinjected into the cell and, at the same time, gas is removed from the top of the cell so that a constant pressure is maintained. Mercury is injected into the cell until the hydrocarbon or reservoir volume of the cell is the same as the volume when the test was begun at the dewpoint pressure. The gas volume removed from the cell is measured at the depletion pressure and reservoir temperature. The gas removed is charged to analytical equipment where its composition is determined and its volume is measured at atmospheric pressure and temperature. The composition determined is that listed in Table 39.4 under the heading 5,000 psig. The volume of gas produced in this manner is then divided by the standard volume of gas in the cell at the dewpoint pressure. The produced volume is presented in Table 39.4 as cumulative well stream produced.

As mentioned earlier, as the gas is removed from the top of the cell, its volume is measured at the depletion pressure and reservoir temperature. From this volume, the "ideal volume" of this displaced volume may be calculated with the ideal-gas law. When the ideal volume is divided by the actual volume of the gas produced at standard conditions, we get the deviation factor, z , for the produced gas. This is listed in Table 39.4 under

"Deviation Factor z , equilibrium gas" and plotted in Fig. 39.4. The actual volume of gas remaining in the cell at this point is the gas originally in the cell at the dewpoint pressure minus the gas produced at the first depletion level. If we divide the actual volume remaining in the cell into the calculated ideal volume remaining in the cell at this first depletion pressure, we obtain the two-phase deviation factor shown in Table 39.4. We call this value a two-phase deviation factor because the material remaining in the cell after the first depletion level is actually gas and retrograde liquid and the actual gas volume we calculated above is the gas volume plus the vapor equivalent of the retrograde liquid. The two-phase z factor is significant in that it is the z factor of all the hydrocarbon material remaining in the reservoir. It is the two-phase z factor that should be used when a p/z -vs.-cumulative-production plot is made in evaluating gas-condensate production.

This series of expansions and constant-pressure displacements is repeated at each depletion pressure until an arbitrary abandonment pressure is reached. The abandonment pressure is considered arbitrary because no engineering or economic calculations have been made to determine this pressure for the purpose of the reservoir-fluid study.

In addition to the composition of the produced well stream at the final depletion pressure, the composition of the retrograde liquid was also measured. These data are included as a control composition in the event the study is used for compositional material-balance purposes.

The volume of retrograde liquid measured during the course of the depletion study is shown in Fig. 39.5 and Table 39.5. The data are shown as a percent of hydrocarbon pore space. These are the data that should be used in conjunction with relative permeability data and water saturation data to determine the extent of retrograde liquid mobility. As mentioned earlier, this is a significant factor only with extremely rich gas-condensate reservoirs.

Also obtained from the reservoir fluid study is Table 39.6. This table was calculated with the results of the laboratory depletion study described previously applied to a unit-volume reservoir. The unit volume chosen was 1,000 Mscf in place at the dewpoint pressure (note the 1,000 Mscf in Table 39.6 in the first column of numbers). Equilibrium ratios were then used to calculate the amount of stock-tank liquid, primary-separator gas, second-stage gas, and stock-tank gas contained in the unit-volume reservoir. The equilibrium ratios used were for the separator conditions listed at the bottom of Table 39.6. The separator conditions used for these calculations should be the conditions in use in the field or those conditions anticipated for the field. The relative amounts of gas and liquid produced will be a function of the surface separation conditions, among other things. These calculations may be made at a variety of conditions to determine optimum separator pressures and temperatures. For the purpose of this table, production was begun at the dewpoint pressure. The amount of total well effluent (well stream) produced from this unit-volume reservoir as a function of pressure is listed in the table. The amount of stock-tank liquid produced as a function of pressure is also listed. The primary-separator gas, second-stage gas, and stock-tank gas are presented in a similar manner. Various other factors associated with the production of the gas and condensate from this reservoir are also presented in the table.

**First depletion level.

Table 39.6 shows the initial stock-tank liquid in place to be 181.74 bbl for this unit-volume reservoir. After production to 700 psig, 51.91 bbl had been produced. The difference between these two numbers (181.74 - 51.91), 129.83 bbl, is the amount of retrograde loss or liquid still unproduced at 700 psig expressed in terms of stock-tank barrels. The value of 181.74 bbl may be considered the recovery by pressure maintenance, assuming 100% conformance and 100% displacement efficiency.

Table 39.7 furnishes the gravity of the stock-tank liquid that may be expected to be produced as a function of reservoir pressure. Also reported are the instantaneous gas/liquid ratios as a function of reservoir pressure.

*Primary separator at 450 psig and 75°F; second-stage separator at 100 psig and 75°F, stock tank at 75°F.

These data may be calculated without the benefit of rock properties or interstitial water values. The assumption is that the retrograde liquid does not achieve significant mobility. Because only one phase is flowing, water and hydrocarbon liquid saturations do not enter into the calculations. The assumption that the retrograde liquid does not flow in the reservoir except in the drawdown area immediately around the wellbore appears to be good. Only with very rich reservoirs does movement of retrograde liquid add significantly to well production.

It was mentioned earlier that the most popular form of material balance on a gas-condensate reservoir is the p/z -vs.-cumulative-production curve. It was stated that the z factor to be used must be the two-phase z factor. The cumulative production must be the total production from the well. This includes, in most instances, the first-stage separator gas, second-stage separator gas, tank vapors, and the vapor equivalent of the stock-tank liquid. The most accurate production figures from a gas-condensate field are usually the sales-gas volumes. This usually includes the first- and second-stage separator gas. To make the p/z -vs.-cumulative plot, the tank vapors and the vapor equivalent of the stock liquid must be accounted for. Without the benefit of laboratory data, the tank vapors must be estimated and the vapor equivalent of the stock-tank liquid calculated with an average or estimated number.

Table 39.7 furnishes the data to make these calculations. If sales gas is the primary- and second-stage gas, and the average reservoir pressure is 5,000 psig, then the total well-stream volume can be calculated by dividing the sales volume by 0.83704. This factor accounts for the tank vapors and the vapor equivalent of the tank liquid. If the sales gas is only the first-stage gas, then the appropriate factor would be 0.80285.

Operation by Pressure Depletion

Pressure-depletion gas-condensate reservoir behavior can be predicted from the laboratory data described previously, or if necessary, by various correlation and computation procedures that provide similar information (with less ac-

curacy) on the basis of the composition of the gas-condensate system. Whenever possible, the predictions should be made with actual laboratory data because the better accuracy obtained at the reservoir conditions is justified by the large gas and liquid reserves involved in reservoir calculations.

Predictions With Laboratory-Derived Data and Hydrocarbon Analysis

With the assumption that the liquid condensate in the reservoir during a pressure-depletion operation stays in place (does not build up sufficiently to provide liquid-phase permeability for flow), reservoir behavior can be predicted from the laboratory constant-composition depletion study discussed previously. Pertinent information is shown in Tables 39.3 through 39.6 and Figs. 39.4 and 39.5.

Liquid-phase change in the reservoir is shown in Fig. 39.5 derived from Table 39.5. Note that the amount of liquid remaining in the reservoir passes through a maximum but does not return to zero, indicating that pressure-depletion operations leave some liquid hydrocarbons behind at abandonment pressure. Economic analyses of pressure-depletion operations are necessary for estimating the magnitude of this loss and its effect on development and operating policy for the reservoir.

The ultimate recoveries by pressure depletion of wet gas, condensate, and plant products can be calculated for the reservoir described in Table 39.8 by use of the data given in Table 39.6.

Gas in place at original pressure:

$$(500 \times 10^6)(1.545)(178.1) = 137,582 \text{ MMscf.}$$

Gas in place at dewpoint pressure:

$$(500 \times 10^6)(1.471)(178.1) = 130,992 \text{ MMscf.}$$

Wet gas produced to dewpoint pressure:

$$137,582 - 130,992 = 6,590 \text{ MMscf.}$$

TABLE 39.7—CALCULATED INSTANTANEOUS RECOVERY DURING DEPLETION

* Primary separator at 450 psig and 75°F; second-stage separator at 100 psig and 75°F; stock tank at 75°F.

Wet gas produced from dewpoint pressure to abandonment:

$$(130,992)(0.77902) = 102,045 \text{ MMscf.}$$

Total wet gas produced:

$$6,590 + 102,045 = 108,635 \text{ MMscf.}$$

Condensate produced to dewpoint pressure:

$$(6,590)(181.74) = 1,197,667 \text{ bbl.}$$

Condensate produced from dewpoint pressure to abandonment:

$$(130,992)(51.91) = 6,799,795$$

Total condensate produced:

$$1,197,667 + 6,799,795 = 7,997,462$$

Percent recoveries by pressure depletion from dewpoint pressure to abandonment:

$$\text{Wet gas} = \frac{102,045}{130,992} \times 100 = 77.9\%;$$

$$\text{Condensate} = \frac{6,799,795}{181.74 \times 130,992} \times 100 = 28.6\%.$$

The total plant products can be calculated in a similar manner, depending on the flow streams to be processed and the recovery efficiencies anticipated.

Predictions With Vapor/Liquid Equilibrium Calculation and Correlations

In the absence of direct laboratory data on a specific gas-condensate system, pressure-depletion behavior can be estimated with vapor/liquid equilibrium ratios (i.e., equilibrium constants, equilibrium factors or K values) to compute the phase behavior when the composition of the total gas-condensate system is known. Correlations for estimating phase volumes must also be available.

When multicomponent hydrocarbon gases and liquids exist together under pressure, part of the lighter hydrocarbons (light ends) are dissolved in the liquid phase, and part of the heavier hydrocarbons (heavy ends) are vaporized in the gas phase. A convenient concept to describe the behavior of specific components quantitatively is the equilibrium ratio. The ratios vary considerably with the pressure, temperature, and composition of the system involved.

The equilibrium ratio is defined as the mole fraction of a given constituent in the vapor phase divided by the mole fraction of the same constituent in the liquid phase, the two phases existing in equilibrium with each other. The equilibrium ratio is designated as K . The basis for this definition is discussed in Chap. 23 and by Standing.⁹ Fig. 23.21 illustrates the behavior of equilibrium ratios for a particular system and shows the rather wide variation possible for a given constituent at different pressures. The

TABLE 39.8—FORMATION AND FLUID DATA FOR A GAS-CONDENSATE RESERVOIR

Original reservoir pressure, psig	7,000

Gas expansion factor (B_g) of produced fluid at original pressure, Mscf/bbl	1.545
Gas expansion factor (B_g) of produced fluid at dewpoint, Mscf/bbl	1.471

figure shows a tendency of the equilibrium ratios to converge isothermally to a value of $K=1$ at a specific pressure. The pressure is properly called the "apparent convergence pressure."⁹ The selection of equilibrium-ratio values for calculations usually is based on the system's apparent convergence pressure, which can change in a pressure-depletion process because of changing system composition with pressure decline.

Large inaccuracies can occur in pressure-depletion calculations with equilibrium ratios when the heavier hydrocarbons (e.g., heptanes and heavier) are not adequately described. To obtain satisfactory results in calculating pressure-depletion behavior of a gas-condensate system, an extended analysis of the C_{7+} fraction should be made. A determination of the molar distribution of C_{7+} through at least C_{25} is recommended. As can be observed in Table 39.4, the C_{7+} component of the subject gas-condensate fluid exhibited a change in molecular weight from 158 at a pressure of 6,010 psig to 109 at a pressure of 700 psig. The change in density of the C_{7+} component was from 0.827 to 0.778 over the same pressure range. Table 39.4 also shows that at 700 psig, the molecular weight of the C_{7+} in the liquid phase is 174, compared to 109 in the gas phase, and the density is 0.837 in the liquid phase, compared to 0.778 in the gas phase. This change in composition of the C_{7+} fraction with pressure reduction leads to large errors in the vapor/liquid split of the C_{7+} fraction when equilibrium ratios are used and in the resultant molecular weight and density of the calculated gas and liquid volumes.

Should such an extended analysis of the C_{7+} component not be available, then a statistical split should be made that maintains the integrity of the average molecular weight and density of the C_{7+} component. Once the C_{7+} component has been divided into multiple pseudocomponents, the physical properties required to make reservoir flash calculations must be developed.

Whitson³⁰ presents a method for determining the molar distribution of single-carbon-number (SCN) groups that are defined by their boiling points as a function of each group's molecular weight. To make the distribution, a three-parameter gamma probability function is used. Whitson also presents equations for calculating the required physical properties with the Watson³¹ characterization factor. This method can be easily programmed for a personal computer and permits rapid development of molar distribution and physical properties. A statistical expansion of the C_{7+} component of the gas-condensate fluid presented in Table 39.2 has been made with the technique Whitson described. The results of this expansion

are presented in Table 39.9. The ability to calculate accurately the pressure-depletion performance of a gas-condensate reservoir depends on proper characterization of the vapor/liquid equilibrium ratios (K values) of the hydrocarbon system.

Equilibrium ratios for nonhydrocarbon components and hydrocarbons C_1 through C_{10} can be found in the *Engineering Data Book*.¹⁶ Hoffman *et al.*³² and Cook *et al.*³³ have presented methods for developing K values for the pseudocomponents. Hoffman *et al.*'s procedure can be programmed easily for a personal computer for rapid development of equilibrium ratios. An alternative method is to plot the methane and normal pentane K values as a function of their boiling points on a semilog graph for each depletion pressure to be calculated. An equation can be determined for a straight line connecting these two points. The K value for each of the other components and pseudocomponents can then be calculated for each pressure point with their individual boiling points. This method of obtaining K values was used in the earlier example calculation. There are some limitations on the accuracy of the data derived by these methods unless some measured data on similar hydrocarbon systems are available. However, the data should be usable for the quick, rough approximations often needed in the preliminary reservoir evaluation stage. The C_1 through C_6 composition of the gas-condensate fluid presented in Table 39.2 was used to develop a K -value relationship for the extended C_{7+} compositions. The resultant relationship is presented in Fig. 39.6.

Chap. 23 describes the general techniques of the use of vapor/liquid equilibrium ratios to compute the phase compositions and magnitudes of hydrocarbon gas/liquid mixtures. Standing⁹ also has an excellent presentation of this usage, including a discussion of the serious errors that can result in calculating the phase behavior of gas-condensate systems. When these methods are used to estimate the pressure-depletion behavior of a gas-condensate reservoir, the following procedure is used.

1. Assume that the original (known) composition flashes from original pressure (and volume) to a lower pressure, at which the compositions and amounts (in moles) of the liquid and gas phases are computed with the best K values available.

2. Estimate the volume of each phase with the methods discussed below.

3. Assume that enough vapor-phase volume is removed (produced) at constant pressure to cause the remaining gas plus all the liquid to conform to the reservoir's original constant volume.

Fig. 39.6— K -value correlation for Condensate 7 depletion.

4. Subtract the number of moles of each component in the vapor represented by this gas removal from the original system composition.

5. With the new total composition from Step 4, consider the system flashed to the next lower pressure step and repeat the procedure. Removal of vapor phase alone is required by the assumption that fluid flowing into the wells will not be accompanied by any liquid phase at any step of the process.

As indicated previously, the calculations require knowledge of the volume occupied by each phase at each pressure step. Methods to estimate these volumes are described in Chaps. 20 and 22 and also by Standing.⁹ To estimate phase volumes, smoothed values should be used from curves drawn through the points computed from properties of the phase at each known composition.

These calculations are intended to approximate the experimental procedure used in the PVT cell during a laboratory pressure-depletion study. The number of pressure steps used in making such calculations is arbitrary but probably should conform to about 500-psi intervals, with points usually closer together at the start and at the end of the calculations. The calculated depletion performance of Condensate 7 is presented in Table 39.10. The dewpoint pressure of 5,277 psig was calculated with an empirical relationship Nemeth and Kennedy³⁴ presented. The best method to determine the dewpoint pressure is by direct measurement, as in the laboratory PVT analysis. If these data are not available, then one must resort to estimation by empirical methods, such as that used in this example, or by gas/liquid production performance. In the latter choice, one must deplete the reservoir to a pressure below the dewpoint. In Table 39.10 a comparison of wet gas and condensate recoveries is made between the laboratory-measured and calculated depletion performance. As can be seen from the comparison, large errors are possible in the calculated data resulting from estimation of the dewpoint pressure and the physical properties of the reservoir fluid.

Hydrocarbon/Liquid Condensation; Effect on Gas-Condensate Behavior

For some gas-condensate systems, large amounts of liquid can be condensed during pressure depletion, resulting in high liquid saturations in the formation pores. When this probability is indicated by either laboratory tests or calculations, the possibility of hydrocarbon/liquid flow through and out of the reservoir must be examined. Relative permeability information (usually curves showing k_{rg}/k_{ro} vs. liquid saturation in the formation) should be combined with viscosity data (μ_o/μ_g) to estimate the volumetric proportion of liquid in the flowing stream (thus removed from the reservoir), thereby affecting the remaining reservoir phase compositions at each of the depletion steps. The best $k_{rg}\mu_o/k_{ro}\mu_g$ data to use are those determined in the laboratory with actual samples of the reservoir rock and hydrocarbon system in question. In the absence of such information, k_{rg}/k_{ro} can be estimated by the methods explained in Chap. 28; viscosity approximations may be made by the methods described by Carr *et al.*²³ After the amount of gas and liquid removed at each step has been estimated, the calculation procedures can be adjusted to obtain the desired behavior predictions.

Pressure Drawdown at Wells; Effect on Well Productivity and Recovery

The previous discussion has taken liquid condensation in the formation into account as though it occurred uniformly throughout the reservoir (uniform pressure at any instant of time). In low-permeability formations, however, there can be appreciable pressure drawdown at the producing wells because the pressures near the wellbores are much lower than in the main part of the reservoir. This tends to increase the early condensation of liquids around the wells considerably, thus decreasing the gas permeability and affecting the phase behavior of the system near the wells. This is important from at least two standpoints: (1) composition history of fluids produced from the reservoir may diverge from that predicted by assuming uniform pressure in the reservoir at any instant of time and

(2) adverse effects on the ability of the wells to produce may occur, potentially affecting the optimum well spacing and the rate of gas-condensate recovery from the zone as pressures decline.

The effects of well-pressure drawdown on the composition history (and ultimate liquid recoveries) of gas-condensate reservoir production have had little discussion in the literature. The general expectation would be that in lower-pressure areas around the wells, liquid hydrocarbons are precipitated earlier and in greater amounts than in the main volume of the reservoir. The main factors involved in this phenomenon are the richness of the gas condensate, the retrograde characteristics of the reservoir fluid, and the permeability of the reservoir rock. Normally, the area around the wellbore that is affected will be small and the condition will stabilize. Normal operating practices to restrict the pressure drawdown to reasonable values will alleviate the problem. In those reservoirs that exhibit extremely low permeability and contain fluids exhibiting condensable liquids of more than 200 bbl/MMscf, the problem can be severe. When separator samples are taken for the laboratory, the analysis procedure discussed previously should be followed to minimize the drawdown effect on the gas and liquid compositions.

The effects on well productivity of precipitated liquid in the vicinity of the wellbore theoretically can be appreciable. Normally, estimates of future well productivity ignore the drawdown effects of production on liquid-phase distribution in the reservoir. The greater liquid accumulations and lower gas permeabilities near the wells thus are ignored in theoretical predictions of well productivity (or extrapolations from early tests); these predictions then tend to show minimum decline rates. The operating engineer should be alert to this possibility whenever calculated well or reservoir rates approach undesirably close to the minimum necessary for the operating objectives of the project. Well productivity is discussed later.

Relative Merits of Measured vs. Calculated Pressure-Depletion Behavior

This chapter has emphasized that for purposes of reservoir analysis and prediction, measured properties and observed behavior of gas-condensate systems are much superior to the use of correlations or approximations. This applies in particular to the use of equilibrium ratios for simulating or predicting the pressure-depletion behavior of a reservoir. The problem is discussed and illustrated by Standing⁹ in his Vapor Liquid Equilibria and Gas-Condensate Systems chapters. In particular, Standing's Fig. 36 shows that serious errors (in excess of 40%) can be incurred in the computation of the liquid volume of a gas-condensate system from errors of less than 10% in the equilibrium ratios for heptanes-plus and methane.

The literature contains reports on the use of equilibrium ratios for calculating the reservoir behavior of gas-condensate systems. Allen and Roe³⁵ computed the pressure-depletion behavior of a gas-condensate reservoir and observed certain discrepancies with the actual behavior. These authors did not report laboratory-measured equilibrium ratios for the specific fluids involved, however; consequently, there were no means to compare computed fluid behavior with actual fluid behavior. All the observed discrepancies were assigned arbitrarily by Allen

and Roe to factors other than the possible inaccuracies of equilibrium ratios from correlations compared with actual measured ratios for the particular system composition and reservoir conditions involved. Some of these discrepancies were probably attributable to the equilibrium ratios used.

Berryman³⁶ compared calculated gas-condensate fluid performance with that actually obtained in the laboratory; however, he made observations on actual vapor/liquid equilibrium in the laboratory cell and adjusted the literature equilibrium ratios to conform to this actual behavior. With the adjusted vapor/liquid equilibrium ratios, the calculated performance was found to match actual reservoir performance during early life satisfactorily.

Rodgers *et al.*³⁷ provided detailed laboratory data, vapor/liquid equilibrium calculations, and actual reservoir performance for a small gas-condensate reservoir in Utah. The pressure range involved was moderate compared with most cases. Even at these moderate pressures, however, the literature-derived equilibrium ratios for heptanes-plus did not agree favorably with measured values for the system. The authors commented that the "appearance of the data . . . clearly shows the need for improved techniques in establishing proper equilibrium data."

On the basis of this experience and for the reasons Standing stated, it would appear desirable to use measured values of phase and volumetric behavior for a gas-condensate system in predicting the pressure-depletion behavior of a gas-condensate reservoir. As more data are obtained and better correlating methods developed, it is possible that equilibrium ratios may achieve suitable accuracy for reservoir-type calculations in the future. Numerous equation-of-state (EOS) calculation techniques have been developed that produce phase equilibrium data that can be used to perform depletion calculations for gas-condensate reservoirs. Many are discussed in Refs. 38 through 40. The use of EOS methods, while more flexible and in many cases more accurate, requires sophisticated computer programs that may or may not be available or warranted. Continued improvement in techniques using EOS's may enhance the accuracy of calculated pressure-depletion performance.

Operation by Pressure Maintenance or Cycling

Pressure maintenance of a gas-condensate reservoir can exist by virtue of (1) an active water drive after moderate reduction of pressure from early production, (2) pressure maintenance through water injection operations, (3) injection of gas, or (4) combinations of all of these. From time to time, certain reservoirs may be encountered that have fluids near their critical points and that thereby may be candidates for special recovery methods, such as the injection of specially tailored gas compositions to provide miscibility and phase-change processes that could improve recovery efficiency. These usually are not regarded as gas-condensate cases.

Water Drive and Water Injection Pressure Maintenance

Very few cases of gas-condensate reservoirs operated under natural water drive have been reported in the litera-

ture. To be attractive economically, a water drive would have to be sufficiently strong to maintain pressure high enough to minimize condensed hydrocarbon losses in the formation. Under these conditions, expenditures for cycling or other pressure-maintenance operations might not be justified; a careful engineering and economic analysis should be made if this possibility seems imminent. The analysis should include a geologic review of conditions surrounding the reservoir to estimate whether any indicated early water drive is apt to last for the life of the operation. There are also other considerations to be studied carefully, including the expenses of dewatering or working over invaded producing wells, the displacement efficiency of water moving gas, and the potential bypassing and loss of condensate fluids when wells become watered-out prematurely through permeable stringers [invasion efficiency (see Pages 39-17 and 39-18) of the natural flood]. Should this last possibility exist, use of a natural water drive would be of doubtful value if the amount of hydrocarbons in place is large. In any case, predictions of recovery by natural water drive should take into account the factors for water injection discussed below.

The injection of water into a gas-condensate reservoir to maintain pressure is sometimes considered. A number of factors must be weighed carefully before a decision is reached. The mobility ratio (mobility of driving fluid over mobility of the driven fluid, water/gas) in this case is favorably low because of the very high mobility of the gas, thus tending to provide high areal sweep and pattern ($h\phi S$ -weighted) efficiencies. There is strong evidence, however, that displacement efficiency by the water is not high. While Buckley *et al.*⁴¹ indicated that the displacement efficiency of water driving out gas can be as high as 80 to 85%, experiments and field observations by Geffen *et al.*⁴² indicate that it may be as low as 50%. This is offset to some extent by the improved areal sweep efficiency enjoyed at a low mobility ratio. All things considered, the recovery of gas condensate in the vapor phase by water injection is likely to be appreciably lower than by cycling, and any consideration of water injection for gas-condensate recovery should be accompanied by detailed experimental work on cores from the specific reservoir involved. This will help to determine whether the water can, in fact, accomplish a high enough displacement efficiency to justify its use.

Should water injection be decided on, gas and liquid recovery predictions for the reservoir can be made by combining the pattern ($h\phi S$ -weighted), invasion, and displacement efficiencies with a knowledge of the condensable-liquids content of the gas-condensate system at the pressure chosen for pressure maintenance. As an example, an areal sweep efficiency of 90% (based on an extremely low mobility ratio for water displacing gas) might be applied to the case cited on Page 39-24. Taking into account the thickness variations of the reservoir, this might provide a pattern ($h\phi S$ -weighted) efficiency of about 95%. With an assumed invasion efficiency of 65% within the invaded volume, water injection for this case would have swept out about 55% (product of the above three efficiencies) of the vapor phase in place at the start of injection. This compares with the actual recovery of more than 86% of the wet vapor by cycling operations, as discussed on Page 39-22.

These estimates of possible gas recoveries by either a natural water drive or water injection can be affected materially by the permeability distribution in the reservoir. The presence of large differences in permeability will result in premature water breakthrough. Flowing gas wells tend to "load up" when producing water and, depending on the vertical flow velocity and bottomhole flowing pressure, may cease to flow. This inability to flow results from sufficient water dropping out in the tubing to form a hydrostatic water column that exerts a pressure equal to the bottomhole pressure. It is difficult to obtain economical flow rates by artificial lift. This loss of productivity may result in premature abandonment of the project. The problems would be particularly serious for deeper reservoirs where the cost of removing water would be a significant factor. Yuster⁴³ discusses possible remedial methods for drowned gas wells. Bennett and Auvenshine⁴⁴ discuss dewatering gas wells. Dunning and Eakin⁴⁵ describe an inexpensive method to remove water from drowned gas wells with foaming agents.

Generally, the use of water injection for maintaining pressure in a gas-condensate reservoir is unlikely to be attractive where a wide range of permeabilities exists in a layered reservoir and selective breakthrough of water into producing wells might be expected before an appreciable fraction of the gas condensate in place could be recovered.

Reservoir Cycling, Gas Injection

Dry-Gas Injection. Comparative economics determines whether a gas-condensate reservoir should be produced by pressure depletion or by pressure maintenance.

The objective of using dry-gas injection in gas-condensate reservoirs is to maintain the reservoir pressure high enough (usually above or near the dewpoint) to minimize the amount of retrograde liquid condensation. Dry field gases are miscible with nearly all reservoir gas-condensate systems; methane normally is the primary constituent of dry field gas. Dry-gas cycling of gas-condensate reservoirs is a special case of miscible-phase displacement of hydrocarbon fluids for improving recovery. Experimentation has shown that the displacement of one fluid by another that is miscible with it is highly efficient on a microscopic scale; usually the efficiency is considered 100% or very nearly so. This is one of the factors that explain the effectiveness and attractiveness of cycling. Another advantage of cycling is that it provides a means to obtain liquid recoveries from reservoirs at economical rates while at the same time avoiding waste of the produced gas when a market for that gas is not available; the operation provides at its termination a reservoir of dry gas with a potentially greater economic value.

Inert-Gas Injection. The demand for dry gas as a marketable commodity varies, and the economic aspects of retaining dry cycled gas in reservoirs for future use have a changing significance. Most conservation laws in the U.S. still provide for minimizing waste of condensable liquids that would result if gas-condensate reservoirs were depleted through the retrograde range in a manner that left large liquid volumes unrecoverable.

The use of inert gas to replace voidage during cycling of gas-condensate reservoirs can be an economical alternative to dry natural gas. One of the first successful inert-

gas injection projects was in 1949 at Elk Basin, WY,⁴⁶ where stack gas from steam boilers was used for injection. In 1959, the first successful use of internal combustion engine exhaust was seen in a Louisiana oil field.⁴⁷ The first use of pure cryogenic produced nitrogen to prevent the retrograde loss of liquids from a gas-condensate fluid was in the Wilcox 5 sand in the Fordoche field located in Pointe Coupee Parish, LA.⁴⁸ In the Fordoche field, the nitrogen was used as makeup gas. The nitrogen amounted to about 30% of the natural-gas/nitrogen mixture injected.

Moses and Wilson's⁴⁹ studies confirmed that the mixing of nitrogen with a gas-condensate fluid elevated the dewpoint pressure. Moses and Wilson also presented data to show that the mixing of a lean gas with a rich-gas condensate would also result in a fluid with a higher dewpoint pressure. The increase in dewpoint pressure was greater with nitrogen than with the lean gas. In the same study, results are presented from slim-tube displacement tests of the same gas-condensate fluid both by pure nitrogen and by a lean gas. In both displacements, more than 98% recovery of reservoir liquid was achieved. These test results were also observed by Peterson,⁵⁰ who used gas-cap gas material from the Painter field located in southwest Wyoming. The authors concluded that the observed results were obtained because of multiple-contact miscibility.

Cryogenic-produced nitrogen possesses many desirable physical properties.⁵¹ Those that make nitrogen most useful for a cycling fluid are that it is totally inert (non-corrosive) and that it has a higher compressibility factor than lean gas (requires less volume). The latter advantage is partially offset by increased compression requirements when compared with lean gas.

Until the mid 1970's, most inert-gas injection consisted of injection of combustion or boiler gas into oil zones. The need for an alternative source of gas for gas-condensate-cycling projects emerged because of the high cost of hydrocarbon gas needed to replace reservoir voidage. The combustion and boiler gas that had been used to displace oil miscibly contains byproducts (CO , O_2 , H_2O , and NO_x) that are highly corrosive⁵² and decrease cost effectiveness.

Economic parameters used to evaluate any process are by their nature representative only under the general economic conditions during which they are prepared. Therefore, there will be no attempt here to present representative economic data. However, one should be cognizant of and take into account those variables peculiar to a particular process when applying current economic parameters to compare different processes.

Many factors affect the economics of a gas-cycling project. The major factors are product prices, makeup gas costs, liquid content of reservoir gas, and degree of reservoir heterogeneity. When inert-gas injection is considered, some important additional factors should also be considered. Donohoe and Buchanan⁵³ and Wilson⁵² have discussed these factors.

The use of inert gas as a cycling fluid offers both advantages and disadvantages. The major advantages are that it permits early sale of residue gas and liquids, resulting in greater discounted net income and that a higher recovery of total hydrocarbons is achieved because the reservoir contains large volumes of nitrogen rather than hydrocarbon gas at abandonment.

Offsetting these advantages are some disadvantages: production problems and increased operating costs caused by corrosion if combustion or flue gas is used as cycling fluid; possible additional capital investments to remove the inert gas from the sales gas, to pretreat before compression, and/or to fund reinjection facilities; and early breakthrough of inert gas caused by high degrees of heterogeneity in the reservoir, resulting in excessive operating costs to obtain marketable sales gas.

All these factors should be evaluated properly when the depletion method is selected.

Calculation of Cycling Performance. Methods of calculating reservoir performance under gas-cycling operations generally fall into one of two categories: feasibility and/or sensitivity analysis or detailed design and evaluation. The calculation method selected usually is determined after consideration of the quality and quantity of data available and the ultimate use of the engineering study.

When the potential of a gas-condensate reservoir for cycling is first considered, it is generally desirable to make calculations that require the use of some reasonably simplifying assumptions. In this manner, relatively rapid and inexpensive results can be obtained that define the approximate cycling rate, cycling life, ultimate recovery, and profitability. If, at the conclusion of these studies, it appears that gas cycling is feasible, more detailed and exacting studies can be made with mathematical simulators to evaluate the earlier results and to design the most advantageous distribution of injection and producing wells.

Efficiency and Effectiveness of Cycling. The principal factors determining reservoir cycling efficiency have been used with interchangeable labels and definitions in the literature. It is therefore necessary to define the various efficiencies clearly. The engineer should define and explain terms carefully when reporting estimates on gas-condensate reservoir behavior.

Reservoir Cycling Efficiency. E_R is defined as the reservoir wet hydrocarbons recovered during cycling divided by the reservoir wet hydrocarbons in place in the productive volume of the reservoir at the start of cycling. Both figures must be computed at the same pressure and temperature; e.g., at reservoir conditions or at standard conditions. The reservoir cycling efficiency can be visualized as the product of three other efficiencies: pattern ($h\phi S$ -weighted), invasion, and displacement. A fourth efficiency factor, areal sweep, can be evaluated for various injection patterns using analog or mathematical models. All efficiency terms used (except "displacement efficiency") must be identified as to time—i.e., time of dry-gas breakthrough into first producing well, time of breakthrough into last well, end of cycling, or other suitable designation.

Areal Sweep Efficiency. E_A is the area enclosed by the leading edge of the dry-gas front (outer limit of injected gas) divided by the total area of reservoir that was productive at the start of cycling. (Black oil, if present, is usually excluded from these areas.) Area of sweep can be estimated closely from analog or mathematical model studies (discussed later) or by observing the locations of wells developing dry-gas content during actual operations. The areal sweep efficiency depends primarily on the injection and production well patterns and rates and the lateral

homogeneity of the formations from a permeability and porosity standpoint. Lesser factors affecting areal sweep efficiency include variations in water content of the pores; time of operation of the compression plant in relation to the input capacities of the wells and their locations in the reservoir; the activity, if any, of a natural water drive; and the presence and handling of black-oil wells if an oil ring exists in the reservoir. Mathematical model techniques (Chap. 48) provide a useful means for predicting the areal sweep efficiencies of gas-condensate reservoirs and, simultaneously, the rate of frontal advance of the injected dry gas. For such studies, a reasonable amount of subsurface data is needed on sand characteristics, reservoir fluid properties, properties of injected fluid, and geologic description.

Pattern ($h\phi S$ -Weighted) Efficiency. E_p is the hydrocarbon pore space enclosed by the projection (through full reservoir thickness) of the leading edge of the dry-gas front divided by the total productive hydrocarbon pore space of the reservoir at start of cycling. (Black oil, if present, is usually excluded from these volumes.) The hydrocarbon volume contained within the dry-gas-front projection can be determined by outlining the farthest-advanced position of the front (from model studies or field observations) on a hydrocarbon isovol map (isovol maps are developed from data on sand thickness, porosity, and interstitial water content), determining the hydrocarbon volume enclosed by this line, and comparing the volume with total reservoir productive hydrocarbon pore space. Note that the definition specifies "projection of the leading edge" and avoids stating whether either the entire gross or entire microscopic PV's are invaded or displaced by the injected gas. For the special cases in which productive thickness, porosity, interstitial water content, and effective permeability are each uniform, the pattern ($h\phi S$ -weighted) and areal sweep efficiencies are the same. The pattern ($h\phi S$ -weighted) efficiency in general depends on the same factors discussed for areal sweep efficiency. Expected pattern ($h\phi S$ -weighted) efficiencies of nearly 95% have been predicted under favorable conditions.⁵⁴

Invasion Efficiency. E_I is the hydrocarbon pore space invaded (contacted or affected) by the injected gas divided by the hydrocarbon pore space enclosed by the projection (through full reservoir thickness) of the leading edge of the dry-gas front. (Sometimes volumetric sweep efficiency, $E_v = E_p \times E_I$, is used.) The definition says nothing about the effectiveness of the invading fluid in forcing original fluid out of the pores contacted. The term "vertical sweep efficiency" has sometimes been used in the sense of invasion efficiency. This is misleading in that it uses a one-dimensional term ("vertical") when dealing with a three-dimensional problem. Invasion efficiencies can be as high as 90% under favorable conditions.⁵⁵ However, invasion is affected significantly by large variations in reservoir flow properties. These might be strictly lateral variations in horizontal permeability (and to a lesser extent in porosity and interstitial water content) of a single-bed reservoir that does not have any variations vertically at any location; strictly layering effects by which the reservoir may comprise several strata, each relatively uniform in properties but differing appreciably in permeability from all the others; or combinations of these extreme cases. Performance of cycling operations can vary ap-

TABLE 39.11—EFFICIENCY TERMS USED IN RESERVOIR CYCLING OPERATIONS

	Areal Sweep Efficiency	Pattern ($h\phi S$ -weighted) Efficiency	Invasion Efficiency	Displacement Efficiency	Reservoir Cycling Efficiency
Definitions	Area enclosed by leading edge of injected-gas (dry-gas) front divided by total area of reservoir productive at start of cycling.	Hydrocarbon pore space enclosed by the projection (through full reservoir thickness) of leading edge of dry-gas front divided by total productive hydrocarbon pore space of reservoir at start of cycling.	Hydrocarbon pore space invaded by (contacted or affected by) dry gas divided by hydrocarbon pore space enclosed by the projection (through full reservoir thickness) of leading edge of dry-gas front.	Wet hydrocarbon volume swept out of individual pores or small groups of pores divided by hydrocarbon volume in same pores at start of cycling (both volumes calculated at same temperature and pressure).	Reservoir wet hydrocarbons recovered during cycling divided by reservoir wet hydrocarbons in place at start of cycling (calculated at same temperature and pressure).
	$E_A = E_P$ for uniform thickness, porosity, interstitial water content, and effective permeability.		E_I is 100% for uniform effective permeability in a gas-condensate reservoir.	E_D is usually assumed 100% for gas-condensate cycling operations.*	$E_P \times E_I \times E_D$

 **Arbitrarily defined as occurring at the time invading fluid first reaches the producing wells; first breakthrough.

preciably according to what combination of the two extremes may exist for a given reservoir. Mathematical models can handle reservoir heterogeneities, both horizontally and vertically, if the data are available. Maximum use of core analysis data, pressure buildup and drawdown analysis, and detailed analysis of downhole logs is required to ensure an accurate evaluation of a reservoir's potential as a cycling project.

Displacement Efficiency. E_D is the volume of wet hydrocarbons swept out of individual pores or small groups of pores divided by the volume of hydrocarbons in the same pores at the start of cycling; note that both volumes must be calculated at the same conditions of pressure and temperature. This term is used here because it has received wide acceptance in the literature (on immiscible as well as miscible processes) for the microscopic displacement of fluids. Displacement efficiency is controlled mainly by the miscibility of the driving and driven fluids and their mobilities. For a cycling operation in which the pressure is being maintained at or above the dewpoint, the displacement efficiency resulting from action of the dry gas against the wet-gas phase in the individual pores will be virtually 100% because of near-complete miscibility and the near-identical mobility ratios of the two fluids. If the pressure is well below the dewpoint, the displacement efficiency will be less than 100% because of the immobility of the condensed liquid and incompleteness of revaporization of the dry gas. Evaluation

of a case of this type requires trial calculations of vapor/liquid equilibrium to estimate the extent to which dry gas coming into contact with the condensed liquid would revaporize some of the components and carry them toward the producing wells.

Thus the reservoir cycling efficiency is the product of the pattern ($h\phi S$ -weighted), invasion, and displacement efficiencies, as summarized in Table 39.11, along with the previous discussion, and usage of terms appearing in some of the literature.

Permeability Distribution. Permeability variation, both laterally and vertically, can have a strong influence on recoveries by cycling. Vertical stratification of horizontal permeability is probably the primary factor controlling invasion efficiency. In reservoirs containing layers or regions of contrasting permeabilities, the leading edge of the dry-gas front (used in calculating invasion efficiency) is at a different position for each layer. Field observations usually establish the front on the basis of breakthrough in the most-permeable layer, whereas mathematical model studies may have been based on an average permeability of layers or a discrete number of layers, thus predicting later breakthrough. This possibility should be understood when model predictions of breakthrough time are compared with field observations. Detailed reservoir analysis is required in developing a mathematical model to ensure that the model used adequately reflects the properties of the reservoir.

There can be several sources of comparative permeability information for reservoir layers, including direct measurements of permeabilities on cores removed from wells, formation tests during drilling and completion, comparative transmissibilities from carefully run injection profiles, and flow, drawdown, and buildup tests on wells completed in different layers. If different kinds of information are to be used together, they should all be adjusted to the same units for calculating the effects of permeability variation on gas-condensate reservoir performance.

Much discussion has been published regarding the effects of permeability variation on the recoveries of hydrocarbons from reservoirs. Discussions with particular reference to gas-condensate reservoirs have been provided by Muskat,^{5,64} Standing *et al.*,⁶⁵ Miller and Lents,⁶⁶ and others.⁶⁷⁻⁷⁰ Generally, the proposals to account for the effect of permeability variations on gas-condensate reservoir performance use two different methods of well-to-well averaging of horizontal permeabilities. The first method averages all high permeabilities from all wells together (irrespective of vertical positions of the high-permeability samples in the section) and all low permeabilities from all wells in another group, with intermediate permeabilities classified into one or more subgroups. Each of the average permeabilities is regarded as a single stratum continuous throughout the reservoir. This type of averaging would appear to give maximum probability of computed early breakthroughs of dry gas to producing wells. In the second method, permeabilities are averaged from well to well according to vertical position in the sec-

tion. For example, permeabilities in the top 10% of each well's productive section might all be averaged together, the next 10% together, and so on to the bottom. This procedure maintains layers in their relative vertical positions in the reservoir, and thus, by averaging laterally, the effects of any individual high-permeability samples tend to be damped out unless high-permeability streaks are actually persistent in one or more layers of the section.

Either of these methods can be used in solutions presented by Muskat,^{5,64} who used the "stratification ratio" to develop mathematical means of evaluating the effects of vertical variation of permeability on cycling. "Stratification ratio" is the ratio of the permeability of the most-permeable recognizable layer in the section to that of the least-permeable layer in the same section (these permeabilities are the layer average in each case, determined by whatever means, rather than individual high or low permeabilities from single plugs or cores from the layer). The Muskat development also assumes simple parallel superposition of layers of different horizontal permeabilities with no crossflow between. The resultant correlations are presented graphically in the references.

Miller and Lents⁶⁶ used the second type of lateral permeability averaging in their analysis of the Cotton Valley Bodcaw reservoir. Their work should be reviewed for an understanding of the detailed procedure used. The table of permeabilities they developed (rearranged in descending order of magnitude) for illustrating the calculation of dilution behavior of the subject reservoir with time is shown here as Table 39.12. The calculation assumes no

Fig. 39.7—Boundary of invaded area predicted by early potentiometric model studies.

crossflow, and the reservoir is treated as though it were composed of alternating layers of variable porosity and permeability. It is also assumed that parallel flow occurs simultaneously in the various layers with the same potential distribution throughout the layers. The injection wells are treated as a line source, and the producing wells as a "line sink." Hence, the calculations in the table predict the percentage of original reservoir hydrocarbon volume at constant pressure produced at the instant each layer has been displaced and the percentage of dry gas (and wet gas) in the producing stream as more and more layers are displaced (breakthrough). The recovery to any stage of dilution in the produced gas can then be predicted; the recovery Miller and Lents calculated (supported by later production history, as shown by Brinkley's⁵⁵ Fig. 7) is in good agreement with predictions from Muskat's correlations.

Very little has been published comparing the actual behavior and final recoveries of gas-condensate reservoirs with those predicted with the different methods of accounting for permeability variation. Stelzer⁶³ reports on the performance of the Paluxy gas-condensate reservoir of the Chapel Hill field, TX, the cycling behavior of which had been predicted earlier by Marshall and Oliver.⁵⁸ This analysis is discussed further later. In a discussion of Stelzer's paper, Hurst takes the position that permeability variation or stratification in a reservoir can be of minor significance in controlling the ultimate recovery by cycling:

The lithological nature of a reservoir is such that with the interspersing of shale throughout, it can virtually reproduce the configuration of a uniform sand if the

sweep is sufficiently great in length. . . Few reservoirs conform to a parallel deposition of lens, each of different uniform permeability, unless one wishes to subscribe to the worst possible consequences for cycling, which can condemn the application of such a program in a rich gas-condensate field.

Such unpublished information as has come to our attention tends to substantiate the belief that most reservoirs are not composed of continuous layers of contrasting permeabilities (with no crossflow) that would tend to produce quick breakthrough during injection operations. Hurst's viewpoint should therefore be considered seriously by the engineer predicting the behavior of cycling projects, because overemphasis on the permeability variation within a reservoir could produce too pessimistic a view of possible recoveries and thereby condemn cycling in gas-condensate reservoirs that might, in fact, yield profitable cycling performance.

The second method for lateral averaging of permeabilities is recommended, whether the Miller and Lents⁶⁶ analysis or other techniques are applied to the handling of permeability variation in gas-condensate reservoirs. Proper consideration for pattern ($h\phi S$ -weighted) efficiency must be given in each case.

Prediction of Cycling Operations with Model Studies—

Analog Techniques. The steady-state flow of fluids through porous media, when governed by Darcy's law, is analogous to the flow of current through an electrical conductor governed by Ohm's law. Thus steady-state electrical-model studies have been used quite successfully in the prediction of gas-condensate cycling operations.

The fundamental analogy between an electrical model of a gas-condensate reservoir and the flow system of the reservoir depends on the equivalence of electrical charge to reservoir fluid, current flow to fluid flow, specific conductivity to fluid mobility, and potential (voltage) distribution in the model to a function Φ_g (not to pressure distribution in the reservoir, as in an oil/water system) defined by Muskat⁴ as

$$\Phi_g = \frac{\rho_g}{\mu_g} dp,$$

where

ρ_g = gas density,

μ_g = gas viscosity, and

p = pressure.

This analogy holds, provided the sources, sinks, and boundary conditions are made equivalent in shape and distribution.

Steady-state models can be divided into two general classes: electronic and electrolytic. The former depends on the movement of electrons through resistive solids, such as metal sheets, carbon paper, and graphite-impregnated cloth or rubber sheeting. Electrons are introduced at one boundary and move into the model to displace free electrons throughout the entire body of the model. The electrons moving out of the model at the other boundary produce a current that causes a potential drop in the solid resistive medium in accordance with Ohm's

law. As a result, the movement of the equivalent fluid interface can be traced. In the case of a graphite-impregnated cloth model, the reservoir is represented by layers of cloth, the number of layers of which are some function of the permeability/net-thickness product (kh) of the producing strata. The shape of each layer of cloth conforms to the shape of the kh range it represents. Copper electrodes are fixed in the cloth model at positions corresponding to the wells in the reservoir and direct currents are passed through these electrodes in proportion to the well flow rates. The electrodes are not usually scaled to the actual well diameters.

Electrolytic models depend on the mobility of the ions in the medium. Because the velocity of an ion in an electrolyte system is proportional to the potential gradient, just as the velocity of a liquid particle in a porous medium is proportional to the pressure gradient, an electrolytic model can be set up that provides a good analogy to single-phase flow in a porous system. The ions are moved into the model across one or more boundaries and displace ions throughout the entire medium, causing ions to leave through other boundaries. The flowing current and potential drop are established in exactly the same way as in the electronic models.

Electrolytic models can be divided into three major types: gel, blotter, and liquid. Although the first two types can be used to determine the areal sweep patterns in two-dimensional uniform media, the potentiometric model that uses a liquid electrolyte is the most flexible and accurate. In this type, the fluid conductivity of the porous medium is usually represented by an open container that has its bottom shaped to produce electrolyte depths proportional to the kh of the producing strata and its sides shaped to conform to the productive limits of the strata. This construction implies that there is no vertical variation in permeability and no bedding at any location in the reservoir, as represented by the model. Copper electrodes (not scaled to well diameter) are fixed in the model at positions corresponding to the locations of the wells in the reservoir, and alternating currents of proper phase are passed through these electrodes. The magnitudes of these currents are made proportional to the production and injection rates to be used in the reservoir. The direction of current flow at every point in the model is considered analogous to the direction taken by the flowing fluid in the reservoir.

The general assumptions applicable to steady-state analog techniques are that (1) a vertical and discrete interface exists between the displacing and the displaced phases; (2) because the history of advance of only one front can be traced at any one time, if two interfaces or fronts are present (such as gas/gas and gas/water), one is considered a stationary boundary; (3) average reservoir pressure is constant regardless of the injection or production schedule (this avoids compressibility effects in the model study); and (4) gravitational effects are neglected. In addition, if the mobility ratio of the system is not (near) unity or infinity, the necessary procedures become tedious and costly.

An example case history by Marshall and Oliver⁵⁸ reported results of a potentiometric model study of the Paluxy sand reservoir of the Chapel Hill field, Smith County, TX. This gas-condensate reservoir is bounded on the north by a gas/water contact, on the west by a fault, and on the south and east by a pinchout. It was assumed

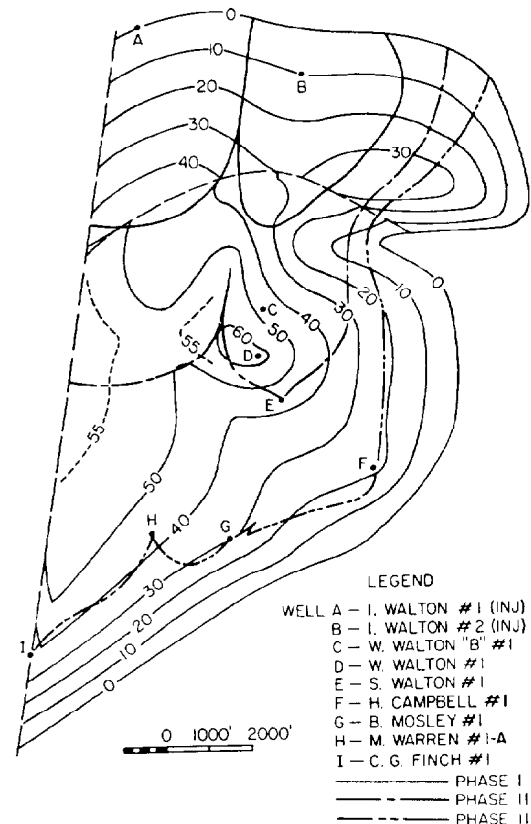

Fig. 39.8—Boundaries of invaded areas predicted by later potentiometric model studies.

that the gas/water contact was a fixed impermeable boundary; that the permeability, porosity, and interstitial water content were each uniform throughout the producing zone; that the reservoir volume rate of dry-gas injection was equal to the corresponding rate of gas-condensate production; and that gravity effects were negligible. Fig. 39.7 shows the final dry-gas/wet-gas interface position at time of breakthrough into Well 1 (determined after several trials of well arrangement and production- and injection-rate schedules) that yielded an optimum pattern ($h\phi S$ -weighted) efficiency prediction of 83%. Injection was into Wells 1 and A with production from Wells 2 through 4 and B as indicated in Fig. 39.7. This program provided a sustained capacity of 35 MMscf/D for the life of the operation.

Stelzer⁶³ reported a comparison of model study predictions with actual performance for this reservoir. Actual gas injection was begun in accordance with the north/south sweep indicated by the model study. During the initial period (first 15 months after cycling began) the production- and injection-rate program predicted by the initial model study was followed quite closely. New structural data revealed in the drilling of additional wells, however, required some changes in the isopach map of the Paluxy sand. The results from a second model study, which incorporated these changes plus injection into only Wells A and B, are shown in Fig. 39.8. Three interface boundaries (dry-gas fronts) are shown for three

Fig. 39.9—Comparison of predicted with actual times of first dry-gas breakthrough, Paluxy gas-condensate reservoir, Chapel Hill field, TX.

production- and injection-rate schedules. The first schedule was maintained for the first 15 months of cycling; the second was continued until breakthrough of dry gas into Well E; the final schedule was maintained until first breakthrough at Well I. There was close agreement between the model rates used and actual reservoir rates.

The second model study indicated a pattern ($h\phi S$ -weighted) efficiency of 88%, a 5% increase over that obtained by the initial study. Stelzer estimated the amount of reservoir gas in place at start of cycling to be 78.4 Bscf. The new model study thus implies an additional 4 Bscf of predicted recoverable gas as a result of better reservoir definition and better operating schedules.

The data in Fig. 39.9 compare model (predicted) breakthrough times with the actual times to dry-gas appearance in corresponding field wells. (Phases 1, 2, and 3 of actual behavior correspond to Schedules 1, 2, and 3 of the model study.) Field data on breakthrough were taken from breaks in content curves of isobutanes-plus; the dashed line shows the cumulative well-by-well breakthrough behavior of the dry-gas flood. Because predicted and actual injection and production rates were nearly equal and constant during the period shown (except for Phase 1, which was adjusted to the same average rates), times on the plot are directly proportional to cumulative reservoir volumes of gas. Therefore, the lower light line represents a hypothetical invasion efficiency of 100% that would prevail if actual breakthrough times coincided with those predicted by the model [and the areal and pattern ($h\phi S$ -weighted) sweeps were identical with model predictions]. The upper light line represents an arbitrary invasion efficiency of 80% [assuming that predicted and actual pattern ($h\phi S$ -weighted) efficiencies are identical]. The straight heavy line from the origin through the last well to experience breakthrough

indicates an invasion efficiency a little greater than 90% and implies that more complete invasion of low-permeability regions behind the dry-gas front was accomplished during the later stages of cycling. The agreement of predicted breakthrough times within 10% of actual breakthrough times illustrates the great utility of potentiometric models in planning cycling operations. Small further improvement in the pattern ($h\phi S$ -weighted) and invasion efficiencies was to be expected before abandonment of the reservoir in this case.

Stelzer's⁶³ figures (at the start of cycling) of 78.4 Bscf of gas in place and 74 bbl of condensable liquids in the vapor phase of the reservoir per 1 MMscf of gas indicate that 5,800,000 bbl of condensable liquids is in the reservoir vapor phase at the start of cycling. Using the model-derived pattern ($h\phi S$ -weighted) efficiency of 88% (end of Schedule 3), 5,100,000 bbl of liquids was subject to removal by dry-gas invasion. Stelzer's Fig. 5 shows that about 4,640,000 bbl of liquid products were recovered between the start of cycling and the breakthrough of gas at Well 1. This provides an invasion efficiency of 91% at that time, based on 100% displacement efficiency. Thus the product of the pattern ($h\phi S$ -weighted) and invasion efficiencies represents a reservoir cycling efficiency of 80% at the time of breakthrough into Well 1. In addition, later operations increased the cumulative recovery during cycling to more than 5 million bbl of condensable liquids, thus bringing final reservoir cycling efficiency to more than 86%. This is considered very good.

Prediction of Cycling Operations With Mathematical Reservoir Simulators. The use of mathematical reservoir simulators to calculate reservoir performance during gas-cycling operations yields results superior to those obtained by the more simplified calculation procedures. Use of these simulators removes the necessity of making the assumptions required in an analog model. Some assumptions are required, however, which should be understood to perform a reservoir simulation study properly. The theory of reservoir simulation is presented in Chap. 48. Coats⁷¹ presents a good discussion of reservoir simulation studies of gas-condensate reservoirs. One must keep in mind that the results from a mathematical reservoir simulator depend on the quality of the data used to prepare the reservoir model. If good data are not available, one should consider whether the expense and time required to perform a mathematical reservoir simulation are justified.

Data Requirements for Gas-Condensate Cycling Study.

To evaluate properly the potential of cycling a gas-condensate reservoir, the following data are required.

1. Geologic data—maps and cross sections showing net effective sand thickness, structural contours on the top and base of the productive formation, location of gas/water interface originally and at the date the model study begins, and location of dry-gas/wet-gas interface at the start of study—and general information on lithology and lenticularity of the productive strata, such as extent of fissures, fractures, caverns, and other special conditions. If a black-oil ring is present, its size and extent should be shown.

2. Physical properties of the reservoir rock—isoporosity map (or average porosity), effective or specific isopermeability map (or average values), and interstitial water content.

3. Fluid characteristics (produced, and injected where applicable)—fluid composition, retrograde dewpoint pressure of reservoir fluids, gas FVF or specific volume vs. pressure, deviation factor, condensate content of reservoir fluid, viscosity, and densities of liquid and gas phases, all from original reservoir pressure through the range of interest (usually to abandonment conditions).

4. Amount of original fluids in place (derivable from data in Points 1 through 3).

5. Reservoir pressure history (volumetrically weighted) from discovery to present. If this is not available, isobaric contour maps at the various pressure survey dates should be supplied.

6. Condensate, gas, and water production data, from the date of discovery.

7. Proposed future production rates.

8. Gas- and/or water-injection data, past and future projections.

9. Productivity, injectivity, and backpressure test data on wells.

Ultimate Recovery of Gas and Condensate Liquids by Cycling. The same reservoir for which pressure-depletion calculations were made previously can be used to illustrate the effectiveness of a cycling operation. Table 39.8 lists the basic data for predicting the ultimate recoveries of wet gas, condensate, and plant products during cycling at original reservoir pressure (to avoid serious drawdown effects) followed by pressure depletion to abandonment pressure. Productive thickness, porosity, and interstitial water content are each assumed uniform. Consequently, the 79.0% areal sweep efficiency obtained by a potentiometric model study is also the pattern ($h\phi S$ -weighted) efficiency. The invasion efficiency is assumed to be 90% because permeability variations are moderate. Because a dry-gas/wet-gas cycling operation is a miscible flood, the displacement efficiency is essentially 100%. Therefore, the reservoir cycling efficiency would be 71.1%. To simplify the example, it is assumed that after cycling, the unswept pore space both inside and outside the dry-gas front will pressure deplete in the same manner as predicted previously for the noncycling case; it will also be assumed economical to recover the butanes-plus from the gas produced.

Reservoir wet gas produced during cycling period (original reservoir composition):

$$130,992 \times 0.711 = 93,135 \text{ MMscf.}$$

Reservoir wet gas produced by pressure depletion after cycling (changing composition, as shown in pressure-depletion example):

$$102,045 \times (1,000 - 0.711) = 29,491 \text{ MMscf.}$$

Reservoir wet gas produced at abandonment pressure, 700 psig:

$$93,135 + 29,491 = 122,626 \text{ MMscf.}$$

Total separator gas produced (see Table 39.6):
During cycling,

$$\frac{777.15 + 38.52 + 38.45}{1,000} \times 93,135$$

$$= 0.85412 \times 93,135 = 79,548 \text{ MMscf.}$$

During depletion,

$$\frac{696.75 + 14.99 + 18.05}{1,000} \times 29,491$$

$$= 0.72979 \times 29,491 = 21,522 \text{ MMscf.}$$

Total:

$$79,548 + 21,522 = 101,070 \text{ MMscf.}$$

Total condensate produced:
During cycling,

$$181.74 \times 93,135 = 16,926,355 \text{ bbl.}$$

During depletion,

$$51.91 \times 29,491 = 1,530,878 \text{ bbl.}$$

Total:

$$16,926,355 + 1,530,878 = 18,457,233 \text{ bbl.}$$

These figures represent a significant improvement over the recoveries previously estimated for pressure-depletion alone.

Noninjection-Gas Requirements in Cycling Operations.

The noninjection-gas requirements for cycling can affect the amount of gas available for injection. The amount of gas to be cycled is determined by the optimum pressure level to be maintained and the efficiency of reservoir fluid recovery to be achieved; the amount of gas readily available, including sources and costs; and the design and operating programs for surface facilities. The amount of gas that is economical to cycle through a gas-condensate reservoir varies with many factors, including richness of the vapor at reservoir cycling pressure, size and cost of the plant, and the price of the field products and of dry gas. Miller and Lents⁶⁶ expected to cycle the equivalent of about 115% of the gas in place to recover some 85% of the wet-gas reserve of the Cotton Valley Bodcaw reservoir. While Brinkley⁵⁵ indicated cycling-gas volumes of as much as 130% of original wet gas in place for various reservoirs, no general correlation has been presented on the amount of gas that is economically sound to cycle; this should be the subject of a detailed engineering analysis in each case. The makeup gas needed for constant-pressure cycling is mainly the volume required to replace shrinkage by liquid recovery and the amount consumed

for various fuel needs. For some composition, temperature, and pressure ranges, the removal of high-molecular-weight constituents from the produced wet gas may result in a higher compressibility factor for the injected dry gas; hence, the greater volume per mole injected may require little or no makeup gas for constant-pressure cycling.

The amount of gas not available for injection because of consumption for operating needs should be taken into account in determining makeup gas requirements if pressure is to be maintained. The amount of fuel for compression and treatment plants depends mainly on the total amount of gas to be returned to the reservoir and the discharge pressure for the plant. Discharge pressure, in turn, depends on the total rate of injection demanded and the number of injection wells and their intake capacities throughout the life of the operation. Other factors affecting the amount of gas required for overall operations are type of plant, type of liquid-recovery system used, and auxiliary field requirements (such as for drilling, completion, and well testing; camp fuel and power for maintenance shops, general service facilities, employee housing; and other factors that vary from one case to another).

Moore⁵⁴ reports that gas fuel consumption for the compression plant alone varies from 7 to 12 cu ft/bhp-hr; this is probably for gases with heat values of about 1,000 Btu/cu ft. Horsepower requirements per million standard cubic feet of gas compressed per day are correlated in Ref. 16 (Compressor section).

An example based on Refs. 16 and 52 shows that, with 8 cu ft/bhp-hr, a compression ratio of 15.0 (compressing from, say, 461 to 7,000 psia) requiring three stages of compression with a ratio per stage of 2.47, and a specific-heat ratio of 1.25, the cubic feet of compressor fuel used per million cubic feet of gas compressed can be calculated as follows.

For a gas of 0.65 specific gravity and a stage compression ratio of 2.5, the chart in Ref. 16 reads 22 bhp. The allowance factor for interstage pressure drop (three compression stages) is 1.1.

Fuel used per million cubic feet of gas compressed = bhp × cu ft of fuel/bhp-hr × ratio/stage × number of stages × allowance factor. Or compressor fuel consumption is

$$m_c = 22 \times 8 \times 24 \times 2.47 \times 3 \times 1.1 = 34.4 \text{ Mscf/MMscf.}$$

This compares favorably with the factor presented in Moore's⁵⁴ Fig. 8. For an example reservoir originally containing 130,992 MMscf of wet gas, which might be cycled the equivalent of 1 1/4 times, the approximate compressor fuel consumption would be

$$130,992 \times 1.25 \times 34.4 = 5.633 \text{ MMscf.}$$

This is approximately 3% of the gas handled through the plant.

Treatment plant fuel and other plant needs added to compressor fuel bring the range of consumption inside the plant fence to 3 to 7% of the gas handled by a cycling plant. In addition to these needs and others mentioned earlier, possible gas losses can occur in a cycling operation: gas used in "blowing down" wells, should this be necessary for cleaning or treating purposes; small gas leaks at compressor plants and in field lines; and gas leaks

resulting from imperfect seals or corrosion in well tubings, casings, and cement jobs. Remedial workover operations should be planned immediately when there is evidence of appreciable loss of gas between the compression plant and the reservoir sandface or between the outflow-well sandface and the plant intake.

Combination Recovery Procedures

Partial water drive—conditions of natural water influx at rates too low to maintain pressure completely at the desired production rates—can exist for gas-condensate reservoirs. In such cases, operation may be by partial water drive and depletion, supplemental water injection, or partial water drive and cycling.

Prediction of reservoir behavior and recovery under these conditions requires knowledge or assumptions about the aquifer and the water drive it supplies. This information can be deduced from a study of geologic conditions and early producing history of the reservoir; sometimes the deductions are accurate, sometimes not. Projections of water drive magnitude into the future at selected reservoir pressure levels can be made by methods developed in Refs. 72 and 73. If sufficient early producing history of a reservoir is available, it can usually be matched (simulated) by a mathematical reservoir simulation study. The future behavior of the reservoir can then be predicted under the following producing methods: (1) producing history and ultimate recovery of gas and liquids under partial water drive and pressure depletion at the selected production rate; (2) amount of supplemental water injection required to maintain reservoir pressure fully at the selected pressure level and production rate; and (3) size of cycling plant required to maintain pressure at the selected pressure level and production rate.

General Operating Problems: Well Characteristics and Requirements

As with any complex operation, gas-condensate recovery projects have many operating problems. Those pertaining to the plant, lines, and other surface facilities are best left to experienced plant and maintenance personnel, except as they affect reservoir operation (e.g., compressor-oil or corrosion-products carry-over into wells). Operating difficulties occurring at and below the wellhead are often concerns of the reservoir engineer and have an important bearing on the effectiveness of reservoir operation, whether by pressure depletion or by pressure maintenance. Among these are the maintenance of injection and production wells in good mechanical condition, the protection of wells against excessive corrosion, the general maintenance of well injectivity and well productivity (which are often interrelated), and the formation of hydrates that can interfere with the general injection and/or production operation.

Well Productivity and Testing

It is essential to maintain the producing capacities of gas-condensate wells above minimum levels for good economic performance. Much has been written about the productivities of gas and gas-condensate wells, their general producing characteristics, and the optimum methods for testing and reporting their productivities. Loss of productivity of gas-condensate wells can occur from reservoir

pressure decline (including possible effects from condensation of liquids in the reservoir and consequent reduction of effective gas permeability), from the invasion of water into producing wells, from solid precipitates in the pore space, from formation damage during well killing or workover operations, and from mechanical failure of downhole equipment. The engineer must have indices at his disposal that show the productivity histories of wells and whether productivity decline is excessive for prevailing producing conditions.

Productivity Testing. In making productivity tests on wells, orderly well-conditioning and overall test procedures should be used, as suggested in Chap. 33 or in standards recommended by Texas,²⁶ New Mexico,²⁷ Kansas,²⁸ and the Interstate Oil Compact Commission.²⁹

It is common to use wellhead pressures in determining well productivity (or injectivity) characteristics with arbitrary correction procedures for estimating BHP's from the observed surface pressures. No fully satisfactory methods have been devised for making accurate estimates of gas-condensate well BHP's, either static or flowing. Calculated static pressures can have serious uncertainties because of unknown amounts of liquid hydrocarbons or water in the wellbore and tubing and unknown temperature distribution. Calculated flowing pressures can have uncertainties because of inaccuracies in the detailed temperature distribution and the particular friction factor assumed for each specific case. Lessem *et al.*⁷⁴ provide helpful charts for approximating the temperature distribution in flowing gas wells. Errors and uncertainties of the above nature become worse as well depths increase. Consequently, for best results, downhole pressure measurements with accurate gauges should be used. Where this is not feasible, BHP's may be estimated from surface pressure readings for gas-condensate wells with better accuracy than is usually true for oil wells. Chaps. 33 and 34 discuss methods for making such estimates. For these methods, measured fluid properties (e.g., density) should be used whenever available in preference to calculated or correlation values.

For gas and gas-condensate wells, a plot of static and producing BHP's vs. producing rates (in millions of standard cubic feet per day) is not a straight line. Smooth curves with closer approximations to straight lines can be obtained by plotting squares of the static and producing well BHP's (absolute) vs. producing rate. A rough analogy to oilwell behavior is then obtained by plotting the differences in squares of the static and producing pressures vs. the corresponding producing rates (usually on log-log paper). If several pressures are obtained on a well at different rates, these procedures do not always yield straight-line relationships (see Chap. 33 and Ref. 75); however, they provide reasonable indices for limited extrapolation to future well behavior and for comparison of current with past well behavior. Estimation of future well productivity can be made by modifying initial well productivity to account for the changes in reservoir pressure and gas permeability as pressure declines and liquid is deposited in the pores. For no loss of gas permeability, a new productivity line can be drawn on the plot of pressure squared vs. rate, parallel to the original productivity line and through the square of the new static pressure selected; this yields an estimate of flowing rate for any

flowing pressure selected. If the original curve for rate vs. difference in squares of static and flowing pressures is used, rates can be estimated for any future flowing pressure by using the proper (future) static pressure; low-permeability wells would require special adjustment of earlier isochronal test data obtained (see Chap. 33 and Ref. 75). These methods yield approximations of future productivity as affected by pressure decline in the absence of fluid-phase and viscosity changes in the reservoir. If gas permeability, k_g , is likely to be seriously affected by condensation of liquids in the pores (and gas viscosity by pressure decline), then the change in gas mobility k_g/μ_g must be approximated and radial-flow calculations made (see Chap. 35) to estimate the new productivity curve corresponding to the static pressure selected for prediction.

Normally, the two aforementioned types of productivity estimates ignore the drawdown effects of production on liquid-phase distribution in the reservoir and any consequent additional reduction of gas permeability near the producing wells; minimum calculated reduction of productivity should, therefore, result from these two estimating methods. Large deviations from such estimates, based on a well's early characteristics, would indicate that the well should be analyzed for productivity troubles.

Excessive Productivity Loss. If the capacity of a producing well declines abnormally compared with that predicted from its original productivity (in the absence of excessive water production), and if appreciable liquid condensation around the wellbore within the formation is suspected, efforts to improve well productivity should be made. These could include the short-term injection of dry gas into the well (several days to several weeks) to evaporate part of the liquid, followed by immediate production to remove some of the vaporized liquid block.

Loss of well productivity caused by excessive water production has been discussed briefly. In some cases, well workover operations would be justified to reduce or to shut off water entry.

Other factors that can influence well productivity are deposits on the sandface or in the pores near the wellbore, perhaps caused by salts precipitated from reservoir water; any mechanical damage resulting from killing the well for pulling equipment or workover; mechanical failure of downhole equipment; and possible hydrates (see Chap. 33). In case of well productivity injury for mechanical reasons, conventional methods of well repair should be undertaken on the basis of the particular difficulty involved.

Various means are available for stimulating low-productivity wells; see Chaps. 54 and 55 and discussions by Clinkenbeard *et al.*⁷⁶

Well Injectivity

Maintenance of well injectivity is essential for the economic operation of cycling programs. Injectivity decline can be caused by sandface plugging or by buildup of reservoir pressure.

Injectivity Testing. The characterization of gas-injection wells is similar to that for gas-producing wells. In either case, analysis is made on the basis of plots of rates vs. the squares of BHP's or rates vs. differences of squares

of pressures. Consequently, after suitable well conditioning, as previously described, injectivity testing should consist of a series of injection rates at different pressures to establish the early injectivity performance of the well when well conditions are known to be good and the sandface is clean. If facilities are not available for obtaining a range of injection rates and pressures, it is sometimes acceptable to obtain production rates and pressures for the injection well through a reasonable range and use the pressure-squared relationship for extrapolating across the zero-rate axis into higher injection-pressure ranges to approximate well characteristics. Plots of production rate vs. difference in squares of pressure can also be adapted to estimate later well-injectivity behavior.

As in the case of producing wells, if injectivity declines with time, analysis of well conditions is required to decide whether corrective procedures should be used. If a gas-condensate reservoir is being operated essentially at constant pressure, then the obvious index of injectivity decline is whether the rate for each injection well remains constant at the injection-well pressure. Injection-rate decline at constant well pressure or injection-pressure rise at constant injection rate shows that injectivity is declining.

Injection-Well Plugging. Plugging of the sandface can occur in injection wells. This may result from liquid carry-over from the compressors (probably lubricating oil components) or from corrosion products from surface lines or well equipment.

Carry-over of lubricating oils from compressors can be serious. Usually, the remedy is to install high-efficiency aftercoolers, scrubbers, and/or mist extractors on the discharge side of the compressors. A particularly effective combination for this is the use of "drips" or collectors, followed by plate or screen impaction-type mist eliminators, followed by combination fibrous and wire-mesh filter elements.

When liquid-blocking of the sand around an injection wellbore cannot be relieved by backflowing (as mentioned later), consideration can be given to "slugging" the well with suitable volatile solvents. The solvent used should preferably be miscible with both the normal injection gas and the liquid that is suspected to be blocking the pores. While propane is a good solvent for many hydrocarbon liquids, some lubricating oils have constituents not soluble or miscible with propane. In these cases, other solvents (possibly nonhydrocarbons) should be used. Sometimes solvent injection is followed immediately by resumption of dry-gas injection. If successful, this dissolves part or all of the liquid block and spreads out the materials in the reservoir sufficiently to relieve the problem. In other cases, the solvent is injected into the formation for short periods and then produced back out to provide a type of washing intended to remove the liquid accumulation from the formation.

Corrosion products from steel lines between compressor discharge and the sandface can also provide serious well plugging. All well piping and casing and all surface lines should be cleaned thoroughly before they are installed to avert as much as possible the transportation of fine corrosion products to the sandface when injection starts. For continued protection during the life of injection equipment, liquid carry-over and mist-elimination measures should be combined with adequate control of corrosive

agents in the field gas. Sometimes the use of internally coated or lined pipe is justified. These and other corrosion-control procedures are best carried out with the help of a competent corrosion engineer.

Corrosion products that plug the sandface are sometimes removed by backflowing the injection well to blow the material off the sand and out of the well. Where this is feasible, such complete removal of the plugging agents from the borehole is believed to be the best for the well. Other remedies may include treating the well with inhibited hydrochloric acid to dissolve the corrosion products. Sometimes the acid is pushed back into the formation and injection is started immediately without backwashing or backflowing of the well. If repeated periodically, this procedure is questionable because it is possible to develop plugging farther away from the well face that could ultimately hinder injection and be difficult to correct.

Number of Wells Required

The number of wells used in exploiting gas-condensate reservoirs has varied from the equivalent of less than 160 acres/well to more than 640 acres/well. Bennett⁷⁷ discussed the general problem and pointed out that the first wells are "drilled to determine the upper and lower limits of condensate production; to determine the extent of the pool, the net pay, thickness, porosity, etc.; and to provide suitable production or injection wells to fit a final pattern," which will not necessarily have a regular geometrical design.

The number of wells to be drilled for gas-condensate operations must be analyzed for each specific case. Important factors to be considered are (1) contract commitments to deliver gas and products, (2) capacity of plant to be served, (3) productivities and injectivities of the wells, (4) maximum practical pattern (*h₀S*-weighted) efficiencies, controlled by number and location of wells (reservoir geometry is an important consideration), (5) amount of recoverable hydrocarbons and their value, and (6) project costs, including well-development costs. Items 3 through 5 must be balanced against Items 1, 2, and 6 to ensure that the economic objectives and contract commitments of the project are met. If wells are low in capacity, extra wells may be needed to meet production requirements during periods of well repair or workover.

Economics of Gas-Condensate Reservoir Operation

Arthur⁷⁸ and Boatright and Dixon⁷⁹ published discussions on the economics of cycling gas-condensate reservoirs. Arthur concluded that the most profitable method of operation depends on many factors, and the answer cannot be generalized. The following factors adapted from Arthur's list are considered important.

1. Reservoir formation and fluid characteristics, including occurrence or absence of black oil, size of reserves of products, properties and composition of reservoir hydrocarbons, productivities and injectivities of wells, permeability variation (controls the degree of bypassing of injected gas), and degree of natural water drive existing.
2. Reservoir development and operating costs.
3. Plant installation and operating costs.
4. Market demand for gas and liquid petroleum products.

5. Future relative value of the products.
6. Existence or absence of competitive producing conditions between operators in the same reservoir.
7. Severance, ad valorem, and income taxes.
8. Special hazards or risks (limited concession or lease life, political climate, and others).
9. Overall economic analysis.

In choosing between pressure depletion and pressure maintenance as operating methods for a gas-condensate reservoir, detailed analyses must be made for predicting optimum economics. Cycling and gas processing procedures require sizable plant expenditures. Possible processing methods, whether reservoir fluids are cycled or not, include stabilization, compression, absorption, and fractionation. The last two recover appreciably more condensables from wet gas than do the first two. If the removal of ethane from a gas stream is desirable for economic or other reasons, fractionation should be used.

When reservoir characteristics appear favorable for recovery of condensable hydrocarbons, it must be considered whether cycling would be economical. The primary comparison is between value of the estimated additional recovery of liquid products by cycling and the actual cycling costs, taking into account deferment of gas income and other factors. Economic analyses of cycling and noncycling are required and must be carried out in detail for maximum dependability with information factors and assumptions pertinent to each particular case. General information on valuation of oil and gas properties is given in Chap. 41.

Economic comparisons are of no value unless reasonably accurate predictions of physical reservoir behavior can be made. Consequently, in the gas-condensate reservoir case, the information given previously would have to be expanded to include schedules of annual production and injection volumes derived from the physical characteristics of the reservoir and from the external factors that would affect production rates. Schedules of investment, anticipated prices of products, operating costs, and taxes would also be required to complete the detailed information needed to make comparative economic analyses.

Nomenclature

- B_g = gas expansion factor (gas FVF)
 E_A = areal sweep efficiency
 E_D = displacement efficiency
 E_I = invasion efficiency
 E_p = pattern ($h\phi S$ -weighted) efficiency
 E_R = reservoir cycling efficiency
 E_V = volumetric sweep efficiency
 h = net pay thickness, ft
 k = permeability, md
 k_{rg} = relative permeability to gas, fraction
 k_{ro} = relative permeability to oil, fraction
 K = equilibrium ratio
 p = pressure, psi
 S = hydrocarbon fluid saturation of the pore space, %
 x = layer number
 z = deviation factor (compressibility factor)
 μ_g = gas viscosity, cp
 μ_o = oil viscosity, cp

ρ_g = gas density, g/cm³

ϕ = porosity, %

Φ_g = flow potential, psi

Chapter 40

Estimation of Oil and Gas Reserves

Gerry L. Smith,** H.J. Gruy & Assocs. Inc.

Estimating Reserves

General Discussion

Management's decisions are dictated by the anticipated results from an investment. In the case of oil and gas, the petroleum engineer compares the estimated costs in terms of dollars for some investment opportunity vs. the cash flow resulting from production of barrels of oil or cubic feet of gas. This analysis may be used in formulating policies for (1) exploring and developing oil and gas properties; (2) designing and constructing plants, gathering systems, and other surface facilities; (3) determining the division of ownership in unitized projects; (4) determining the fair market value of a property to be bought or sold; (5) determining the collateral value of producing properties for loans; (6) establishing sales contracts, rates, and prices; and (7) obtaining Security and Exchange Commission (SEC) or other regulatory body approvals.

Reserve estimates are just what they are called—estimates. As with any estimate, they can be no better than the available data on which they are based and are subject to the experience of the estimator. Unfortunately, reliable reserve figures are most needed during the early stages of a project, when only a minimum amount of information is available. Because the information base is cumulative during the life of a property, the reservoir engineer has an increasing amount of data to work with as a project matures, and this increase in data not only changes the procedures for estimating reserves but, correspondingly, improves the confidence in the estimates. Reserves are frequently estimated (1) before drilling or any subsurface development, (2) during the development drilling of the field, (3) after some performance data are available, and (4) after performance trends are well established. Fig. 40.1 demonstrates (1) the various periods in the life of an imaginary oil property, (2) the sequence

of appropriate recovery estimating methods, (3) the impact on the range of recovery estimates that usually results as a property ages and more data become available, (4) a hypothetical production profile, and (5) the relative risk in using the recovery estimates. Time is shown on the horizontal axis. No particular units are used in this chart, and it is not drawn to any specific scale. Note that while the ultimate recovery estimates may become accurate at some point in the late life of a reservoir, the reserve estimate at that time may still have significant risk. During the last week of production, if one projects a reserve of 1 bbl and 2 bbl are produced, the reserve estimate was 100% in error.

Reserve estimating methods are usually categorized into three families: analogy, volumetric, and performance techniques. The performance-technique methods usually are subdivided into simulation studies, material-balance calculations, and decline-trend analyses. The relative periods of application for these techniques are shown in Fig. 40.1.^{1,2} During Period AB, before any wells are drilled on the property, any recovery estimates will be of a very general nature based on experience from similar pools or wells in the same area. Thus, reserve estimates during this period are established by analogy to other production and usually are expressed in barrels per acre.

The second period, Period BC, follows after one or more wells are drilled and found productive. The well logs provide subsurface information, which allows an acreage and thickness assignment or a geologic interpretation of the reservoir. The acre-foot volume considered to hold hydrocarbons, the calculated oil or gas in place per acre-foot, and a recovery factor allow closer limits for the recovery estimates than were possible by analogy alone. Data included in a volumetric analysis may include well logs, core analysis data, bottomhole sample information, and subsurface mapping. Interpretation of these

*Original chapter in 1962 edition was written by Jan J. Arps.

**Deceased

Fig. 40.1—Range in estimates of ultimate recovery during life of reservoir.

data, along with observed pressure behavior during early production periods, may also indicate the type of producing mechanism to be expected for the reservoir.

The third period, Period CD, represents the period after delineation of the reservoir. At this time, performance data usually are adequate to allow derivation of reserve estimates by use of numerical simulation model studies. Model studies can yield very useful reserve estimates for a spectrum of operating options if sufficient information is available to describe the geometry of the reservoir, any spatial distribution of the rock and fluid characteristics, and the reservoir producing mechanism. Because numerical simulators depend on matching history for calibration to ensure that the model is representative of the actual reservoir, numerical simulation models performed in the early life of a reservoir may not be considered to have high confidence.

During Period DE, as performance data mature, the material-balance method may be implemented to check the previous estimates of hydrocarbons initially in place. The pressure behavior studied through the material-balance calculations may also offer valuable clues regarding the type of production mechanism existent in the reservoir. Confidence in the material-balance calculations

depends on the precision of the reservoir pressures recorded for the reservoir and the engineer's ability to determine the true average pressure at the dates of study. Frequent pressure surveys taken with precision instruments have enabled good calculations after no more than 5 or 6% of the hydrocarbons in place have been produced.

Reserve estimates based on extrapolation of established performance trends, such as during Period DEF, are considered the estimates of highest confidence.

In reviewing the histories of reserve estimates over an extended period of time in many different fields, it seems to be a common experience that the very prolific fields (such as East Texas, Oklahoma City, Yates, or Redwater) have been generally underestimated during the early "barrels-per-acre-foot" period compared with their later performance, while the poorer ones (such as West Edmond and Spraberry) usually are overestimated during their early stages.

It should be emphasized that, as in all estimates, the accuracy of the results cannot be expected to exceed the limitations imposed by inaccuracies in the available basic data. The better and more complete the available data, the more reliable will be the end result. In cases where property values are involved, additional investment in acquiring good basic data during the early stages pays off later. With good basic data available, the engineer making the estimate naturally feels more sure of his results and will be less inclined to the cautious conservatism that often creeps in when many of the basic parameters are based on guesswork only. Generally, all possible approaches should be explored in making reserve estimates and all applicable methods used. In doing this, the experience and judgment of the evaluator are an intangible quality, which is of great importance.

The probable error in the total reserves estimated by experienced engineers for a number of properties diminishes rapidly as the number of individual properties increases. Whereas substantial differences between independent estimates made by different estimators for a single property are not uncommon, chances are that the total of such estimates for a large group of properties or an entire company will be surprisingly close.

Petroleum Reserves—Definitions and Nomenclature³

Definitions for three generally recognized reserve categories, "proved," "probable," and "possible," which are used to reflect degrees of uncertainty in the reserve estimates, are listed as follows. The proved reserve definition was developed by a joint committee of the SPE, American Assn. of Petroleum Geologists (AAPG), and American Petroleum Inst. (API) members and is consistent with current DOE and SEC definitions. The joint committee's proved reserve definitions, supporting discussion, and glossary of terms, are quoted as follows. The probable and possible reserve definitions enjoy no such official sanction at the present time but are believed to reflect current industry usage correctly.

Proved Reserves Definitions³

The following is reprinted from the *Journal of Petroleum Technology* (Nov. 1981, Pages 2113-14) proved reserve definitions, discussion, and glossary of terms.

Proved Reserves. Proved reserves of crude oil, natural gas, or natural gas liquids are estimated quantities that geological and engineering data demonstrate with reasonable certainty to be recoverable in the future from known reservoirs under existing economic conditions.*

Discussion. Reservoirs are considered proved if economic producibility is supported by actual production or formation tests or if core analysis and/or log interpretation demonstrates economic producibility with reasonable certainty. The area of a reservoir considered proved includes (1) that portion delineated by drilling and defined by fluid contacts, if any, and (2) the adjoining portions not yet drilled that can be reasonably judged as economically productive on the basis of available geological and engineering data. In the absence of data on fluid contacts, the lowest known structural occurrence of hydrocarbons controls the lower proved limit of the reservoir. Proved reserves are estimates of hydrocarbons to be recovered from a given date forward. They are expected to be revised as hydrocarbons are produced and additional data become available.

Proved natural gas reserves comprise nonassociated gas and associated/dissolved gas. An appropriate reduction in gas reserves is required for the expected removal of natural gas liquids and the exclusion of nonhydrocarbon gases if they occur in significant quantities.

Reserves that can be produced economically through the application of established improved recovery techniques are included in the proved classification when these qualifications are met: (1) successful testing by a pilot project or the operation of an installed program in that reservoir or one with similar rock and fluid properties provides support for the engineering analysis on which the project or program was based, and (2) it is reasonably certain the project will proceed.

Reserves to be recovered by improved recovery techniques that have yet to be established through repeated economically successful applications will be included in the proved category only after successful testing by a pilot project or after the operation of an installed program in the reservoir provides support for the engineering analysis on which the project or program was based.

Estimates of proved reserves do not include crude oil, natural gas, or natural gas liquids being held in underground storage.

Proved Developed Reserves. Proved developed reserves are a subcategory of proved reserves. They are those reserves that can be expected to be recovered through existing wells (including reserves behind pipe) with proved equipment and operating methods. Improved recovery reserves can be considered developed only after an improved recovery project has been installed.

Proved Undeveloped Reserves. Proved undeveloped reserves are a subcategory of proved reserves. They are those additional proved reserves that are expected to be recovered from (1) future drilling of wells, (2) deepening of existing wells to a different reservoir, or (3) the installation of an improved recovery project.

*Most reservoir engineers add the expression "considering current technology."

Glossary of Terms

Crude Oil

Crude oil is defined technically as a mixture of hydrocarbons that existed in the liquid phase in natural underground reservoirs and remains liquid at atmospheric pressure after passing through surface separating facilities. For statistical purposes, volumes reported as crude oil include: (1) liquids technically defined as crude oil; (2) small amounts of hydrocarbons that existed in the gaseous phase in natural underground reservoirs but are liquid at atmospheric pressure after being recovered from oilwell (casinghead) gas in lease separators*; and (3) small amounts of nonhydrocarbons produced with the oil.

Natural Gas

Natural gas is a mixture of hydrocarbons and varying quantities of nonhydrocarbons that exists either in the gaseous phase or in solution with crude oil in natural underground reservoirs. Natural gas may be subclassified as follows.

Associated Gas. Natural gas, commonly known as gas-cap gas, that overlies and is in contact with crude oil in the reservoir.**

Dissolved Gas. Natural gas that is in solution with crude oil in the reservoir.

Nonassociated Gas. Natural gas in reservoirs that do not contain significant quantities of crude oil.

Dissolved gas and associated gas may be produced concurrently from the same wellbore. In such situations, it is not feasible to measure the production of dissolved gas and associated gas separately; therefore, production is reported under the heading of associated/dissolved or casinghead gas. Reserves and productive capacity estimates for associated and dissolved gas also are reported as totals for associated/dissolved gas combined.

Natural Gas Liquids

Natural gas liquids (NGL's) are those portions of reservoir gas that are liquefied at the surface in lease separators, field facilities, or gas processing plants. NGL's include but are not limited to ethane, propane, butanes, pentanes, natural gasoline, and condensate.

Reservoir

A reservoir is a porous and permeable underground formation containing an individual and separate natural accumulation of producible hydrocarbons (oil and/or gas) that is confined by impermeable rock and/or water barriers and is characterized by a single natural pressure system.

*From a technical standpoint, these liquids are termed "condensate"; however, they are commingled with the crude stream and it is impractical to measure and report their volumes separately. All other condensate is reported as either "lease condensate" or "plant condensate" and included in natural gas liquids.

**Where reservoir conditions are such that the production of associated gas does not substantially affect the recovery of crude oil in the reservoir, such gas may be reclassified as nonassociated gas by a regulatory agency. In this event, reserves and production are reported in accordance with the classification used by the regulatory agency.

Fig. 40.2—Geological map on top (—) and base (---) of reservoir.

In most situations, reservoirs are classified as oil reservoirs or as gas reservoirs by a regulatory agency. In the absence of a regulatory authority, the classification is based on the natural occurrence of the hydrocarbon in the reservoir as determined by the operator.

Improved Recovery

Improved recovery includes all methods for supplementing natural reservoir forces and energy, or otherwise increasing ultimate recovery from a reservoir. Such recovery techniques include (1) pressure maintenance, (2) cycling, and (3) secondary recovery in its original sense (i.e., fluid injection applied relatively late in the productive history of a reservoir for the purpose of stimulating production after recovery by primary methods of flow or artificial lift has approached an economic limit). Improved recovery also includes the enhanced recovery methods of thermal, chemical flooding, and the use of miscible and immiscible displacement fluids.

Probable Reserves

Probable reserves of crude oil, natural gas, or natural gas liquids are estimated quantities that geological and engineering data indicate are reasonably probable to be recovered in the future from known reservoirs under existing economic conditions. Probable reserves have a higher degree of uncertainty with regard to extent, recoverability, or economic viability than do proved reserves.

Possible Reserves

Possible reserves of crude oil, natural gas, or natural gas liquids are estimated quantities that geological and engineering data indicate are reasonably possible to be recovered in the future from known reservoirs under existing economic conditions. Possible reserves have a higher degree of uncertainty than do proved or probable reserves.

Computation of Reservoir Volume⁴

When sufficient subsurface control is available, the oil- or gas-bearing net pay volume of a reservoir may be computed in several different ways.

1. From the subsurface data a geological map (Fig. 40.2) is prepared, contoured on the subsea depth of the top of the sand (solid lines), and on the subsea depth of the base of the sand (dashed lines). The total area enclosed by each contour is then planimeted and plotted as abscissa on an acre-feet diagram (Fig. 40.3) vs. the corresponding subsea depth as the ordinate. Gas/oil contacts (GOC's) and water/oil contacts (WOC's) as determined from core, log, or test data are shown as horizontal lines.* After the observed points are connected, the combined gross volume of oil- and gas-bearing sand may be determined by the following methods.

*If working in SI units, the depths will be expressed in meters and the planimeted areas enclosed by each contour will be expressed in hectares. The resultant hectare-meter plot can be treated exactly like the following acre-foot example to yield reservoir volumes in cubic meters. (1 ha · m = 10,000 m³.)

Fig. 40.3—Acre-feet diagram.

Fig. 40.4—Isopachous map—gas sand.

Fig. 40.5—Isopachous map—oil sand.

- a. Planimetered from the acre-feet diagram.
- b. If the number of contour intervals is even, computed by *Simpson's rule*:

$$^{50}_3[(0+136)+4(24+103)+2(46)]=12,267 \text{ acre-ft.}$$

(The separate calculations of the volume of gross gas-bearing sand and gross oil-bearing sand by means of Simpson's rule are shown in the diagram of Fig. 40.3.)

- c. With somewhat less accuracy, computed by the *trapezoidal rule*:

$$50[\frac{1}{2}(0+136)+(24+46+103)]=12,050 \text{ acre-ft.}$$

- d. Computed by means of the somewhat more complicated *pyramidal rule*:

$$^{50}_3[(0+136)+2(24+46+103)+\sqrt{24 \times 88}+\sqrt{88 \times 209} \\ +\sqrt{209 \times 378}-\sqrt{42 \times 106}-\sqrt{106 \times 242}] \\ =11,963 \text{ acre-ft.}$$

- e. If the sand is of uniform thickness, it will oftentimes suffice to multiply the average gross pay thickness \bar{h}_t by the area enclosed by the contour $\frac{1}{2}Z$ ft above the WOC.

- f. If the area within the top contour is circular (area A , height Z), then the top volume is $\frac{1}{6}\pi Z + \frac{1}{2}AZ$ if treated as a segment of a sphere, and $\frac{1}{3}AZ$ if treated as a cone.

From a study of the individual well logs or core data, it is then determined what fraction of the gross sand section is expected to carry and to produce hydrocarbons.

Multiplication of this net-pay fraction by the gross sand volume yields the net-pay volume. If, for example, in the case illustrated with Figs. 40.2 and 40.3, it is found that 15% of the gross section consisted of evenly distributed shale or dense impervious streaks, the net gas- and oil-bearing pay volumes may be computed as, respectively,

$$0.85 \times 2,367 = 2,012 \text{ net acre-ft of gas pay}$$

and

$$0.85 \times 9,900 = 8,415 \text{ net acre-ft of oil pay.}$$

2. From individual well-log data, separate isopachous maps may be prepared for the net gas pay (Fig. 40.4) or for the net pay (Fig. 40.5) and the total net acre-feet of oil- or gas-bearing pay computed as under Item 1a, b, or c.

3. If the nature of the porosity varies substantially from well to well, and if good log and core-analysis data are

available on many wells, it is sometimes justified to prepare an isopachous map of the number of porosity feet (porosity fraction times net pay in feet) and compute the total available void space in the net-pay section from such an isopachous map by the methods discussed under Item 1a, b, or c.

Computation of Oil or Gas in Place

Volumetric Method

If the size of the reservoir, its lithologic characteristics, and the properties of the reservoir fluids are known, the amount of oil or gas initially in place may be calculated with the following formulas:

Free Gas in Gas Reservoir or Gas Cap (no residual oil present). For standard cubic feet of free gas,

$$G_{Fi} = \frac{43,560 V_g \phi (1 - S_{iw})}{B_g}, \quad (1)$$

where

V_g = net pay volume of the free-gas-bearing portion of a reservoir, acre-ft,

ϕ = effective porosity, fraction,

S_{iw} = interstitial water saturation, fraction,

B_g = gas FVF, dimensionless, and

43,560 = number of cubic feet per acre-foot.

Values for the gas FVF or the reciprocal gas FVF, $1/B_g$, may be estimated for various combinations of pressure, temperature, and gas gravity (see section on gas FVF).*

Oil in Reservoir (no free gas present in oil-saturated portion). For stock-tank barrels of oil,

$$N = \frac{7,758 V_o \phi (1 - S_{iw})}{B_o}, \quad (2)$$

where

N = reservoir oil initially in place, STB,

V_o = net pay volume of the oil-bearing portion of a reservoir, acre-ft,

B_o = oil FVF, dimensionless, and

7,758 = number of barrels per acre-foot.

*Refer to Chaps. 20 through 25 for detailed coverage of oil, gas, condensate and water properties, and correlations.

Table 40.1 shows the number of barrels of stock-tank oil per acre-foot for different values of porosity, ϕ , interstitial water saturation, S_{iw} , and the oil FVF, B_o .

Solution Gas in Oil Reservoir (no free gas present).

For standard cubic feet of solution gas,

$$G_s = \frac{7,758 V_o \phi (1 - S_{iw}) R_s}{B_o}, \quad (3)$$

where G_s is the solution gas in place, in standard cubic feet, and R_s is the solution GOR, in standard cubic feet per stock-tank barrel.

Material-Balance Method⁵⁻⁸

In the absence of reliable volumetric data or as an independent check on volumetric estimates, the amount of oil or gas in place in a reservoir may sometimes be computed by the material-balance method.⁵ This method is based on the premise that the PV of a reservoir remains constant or changes in a predictable manner with the reservoir pressure when oil, gas, and/or water are produced. This makes it possible to equate the expansion of the reservoir fluids upon pressure drop to the reservoir voidage caused by the withdrawal of oil, gas, and water minus the water influx. Successful application of this method requires an accurate history of the average pressure of the reservoir, as well as reliable oil-, gas-, and water-production data and PVT data on the reservoir fluids. Generally, from 5 to 10% of the oil or gas originally in place must be withdrawn before significant results can be expected. Without very accurate performance and PVT data the results from such a computation may be quite erratic,⁶ especially when there are unknowns other than the amount of oil in place, such as the size of a free-gas cap, or when a water drive is present.

When the number of available equations exceeds the number of such unknowns, the solution should preferably be by means of the "method of least squares."⁷ Because of the sensitivity of the material-balance equation

to small changes in the two-phase FVF, B_t , an adjustment procedure, called the Y method, may be used for the pressure range immediately below the bubblepoint. The method consists of plotting values of

$$Y = \frac{(p_b - p_R) B_{oi}}{p_R (B_t - B_{oi})}, \quad (4)$$

where

p_b = bubblepoint pressure, psia,

p_R = reservoir pressure, psia,

B_t = two-phase FVF for oil, dimensionless, and

B_{oi} = initial oil FVF, dimensionless,

vs. reservoir pressure, p_R , and bringing a straight line through the plotted points, with particular weight given to the more accurate values away from the bubblepoint. This straight-line relationship is then used to correct the previous values for Y , from which the adjusted values for B_t are computed. Values of B_t computed with this method for pressures substantially below the bubblepoint should not be used if differential liberation is assumed to represent reservoir producing conditions.

When an active water drive is present, the cumulative water influx, W_e , should be expressed in terms of the known pressure/time history and a water drive constant,⁸ thus reducing this term to one unknown. A completely worked-out example of the use of material balance that uses this conversion and in which the amount of oil in place is determined for a partial water drive reservoir where 36 pressure points and equations were available at a time when about 9% of the oil in place had been produced is given in Ref. 7.

The material-balance equation in its most general form reads

$$N = \frac{N_p [B_t + 0.1781 B_g (R_p - R_{si})] - (W_e - W_p)}{B_{oi} \left\{ m \frac{B_g}{B_{gi}} + \frac{B_t}{B_{oi}} - (m+1) \left[1 - \frac{\Delta p_R (c_f + S_{iw} c_w)}{1 - S_{iw}} \right] \right\}}, \quad (5)$$

TABLE 40.2—CLASSIFICATION OF MATERIAL-BALANCE EQUATIONS

Reservoir Type	Material-balance Equation*	Unknowns	Equation
Oil reservoir with gas cap and active water drive	$N = \frac{Np[B_t + 0.1781B_g(R_p - R_{si})] - (W_e - W_p)}{mB_{oi}\left(\frac{B_g}{B_{gi}} - 1\right) + (B_t - B_{oi})}$	N, W_e, m	6
Oil reservoir with gas cap; no active water drive ($W_e = 0$)	$N = \frac{Np[B_t + 0.1781B_g(R_p - R_{si})] + W_p}{mB_{oi}\left(\frac{B_g}{B_{gi}} - 1\right) + (B_t - B_{oi})}$	N, m	7
Initially undersaturated oil reservoir with active water drive ($m = 0$): 1. Above bubblepoint	$N = \frac{\left[N_p(1 + \Delta p_R c_o) - \frac{W_e - W_p}{B_{oi}}\right](1 - S_{iw})}{\Delta p[(c_o + c_f - S_{iw}(c_o - c_w))]}$	N, W_e	8
2. Below bubblepoint	$N = \frac{N_p[B_t + 0.1781B_g(R_p - R_{si})] - (W_e - W_p)}{B_t - B_{oi}}$	N, W_e	9
Initially undersaturated oil reservoir; no active water drive ($m = 0$), ($W_e = 0$): 1. Above bubblepoint	$N = \frac{\left[N_p(1 + \Delta p_R c_o) - \frac{W_p}{B_{oi}}\right](1 - S_{iw})}{\Delta p_R[c_o + c_f - S_{iw}(c_o - c_w)]}$	N	10

*The constant 0.1781 is 7,758 bbl/acre-ft = 43,560 sq ft/acre. This constant and 5.615, which converts barrels to cubic feet, may be omitted if all volumes are expressed in cubic meters.

where

- N_p = cumulative oil produced, STB,
- R_p = cumulative GOR, scf/STB,
- R_{si} = initial solution GOR, scf/STB,
- W_e = cumulative water influx, bbl,
- W_p = cumulative water produced, bbl,
- Δp_R = change in reservoir pressure, psi,
- B_{gi} = initial gas FVF, res cu ft/scf,
- m = ratio of initial reservoir free-gas volume and initial reservoir-oil volume,
- c_f = compressibility of reservoir rock, change in PV per unit PV per psi, and
- c_w = compressibility of interstitial water, psi⁻¹.

When a free-gas cap is present, this equation may be simplified to Eq. 6 of Table 40.2 by neglecting the reservoir formation compressibility c_f and the interstitial water compressibility c_w .

When such a reservoir has no active water drive ($W_e = 0$), Eq. 7 results.

For initially undersaturated reservoirs ($m = 0$) below the bubblepoint, Eqs. 6 and 7 reduce to Eqs. 9 and 11, depending on whether an active water drive is present.

For initially undersaturated reservoirs ($m = 0$) above the bubblepoint, no free gas is present ($R_p - R_{si} = 0$), while $B_t = B_{oi} + \Delta p_R c_o$ (where c_o is the compressibility of reservoir oil, volume per psi), so that general Eq. 5 reduces to Eqs. 8 and 10, depending on whether an active water drive is present.

For gas reservoirs the material-balance equation takes the form of Eq. 12 or 13, depending on whether an active water drive is present. The numerator on the right side in each case represents the net reservoir voidage by production minus water influx, while the denominator is the gas-expansion factor ($B_g - B_{gi}$) for the reservoir.

TABLE 40.3—CONDITIONS FOR UNIT-RECOVERY EQUATION, DEPLETION-TYPE RESERVOIR

	Initial Conditions*	Ultimate Conditions*
Reservoir pressure	p_i	p_a
Interstitial water, ϕS_{iw} , bbl/acre-ft	7,758	7,758
Free gas, ϕS_{gr} , bbl/acre-ft	0	7,758
Reservoir oil, bbl/acre-ft	$7,758 \phi (1 - S_{iw})$	$7,758 \phi (1 - S_{iw} - S_{gr})$
Stock-tank oil, bbl/acre-ft	$7,758 \phi \frac{1 - S_{iw}}{B_{oi}}$	$7,758 \phi \frac{1 - S_{iw} - S_{gr}}{B_{oa}}$

*Substitute 10 000 for the 7,758 constant if cubic meters per hectare-meter is used.

Saturated Depletion-Type Oil Reservoirs—Volumetric Methods

General Discussion

Pools without an active water drive that produce solely as the result of expansion of natural gas liberated from solution in the oil are said to produce under a depletion mechanism, also called an internal- or solution-gas drive. When a free-gas cap is present, this mechanism may be supplemented by an external or gas-cap drive (Page 40-13). When the reservoir permeability is sufficiently high and the oil viscosity low, and when the pay zone has sufficient dip or a high vertical permeability, the depletion mechanism may be followed or accompanied by gravity segregation (Page 40-14).

When a depletion-type reservoir is first opened to production, its pores contain interstitial water and oil with gas in solution under pressure. No free gas is assumed to be present in the oil zone. The interstitial water is usually not produced, and its shrinkage upon pressure reduction is negligible compared with some of the other factors governing the depletion-type recovery.

When this reservoir reaches the end of its primary producing life, and disregarding the possibility of gas-cap drive or gravity segregation, it will contain the same interstitial water as before, together with residual oil under low pressure. The void space vacated by the oil produced and by the shrinkage of the remaining oil is now filled with gas liberated from the oil. During the depletion process this gas space has increased gradually to a maximum value at abandonment time. The amount of gas space thus created is the key to the estimated ultimate recovery under a depletion mechanism. It is reached when the produced free GOR in the reservoir, which changes according to the relative permeability ratio relationship and the viscosities of oil and gas involved, causes exhaustion of the available supply of gas in solution.

Unit-Recovery Equation

The unit-recovery factor is the theoretically possible ultimate recovery in stock-tank barrels from a homogeneous unit volume of 1 acre-ft of pay produced by a given mechanism under ideal conditions.

The unit-recovery equation for a saturated depletion-type reservoir is equal to the stock-tank oil initially in place in barrels per acre-foot at initial pressure p_i minus the residual stock-tank oil under abandonment pressure p_a , as shown in Table 40.3.

By difference, the unit recovery by depletion or solution-gas drive is, in stock-tank barrels per acre-foot,

$$N_{ug} = 7,758 \phi \left(\frac{1 - S_{iw}}{B_{oi}} - \frac{1 - S_{iw} - S_{gr}}{B_{oa}} \right), \dots \dots (14)$$

where S_{gr} is the residual free-gas saturation under reservoir conditions at abandonment time, fraction, and B_{oa} is the oil FVF at abandonment, dimensionless. The key to the computation of unit recovery by means of this equation is an estimate of the residual free-gas saturation S_{gr} at the ultimate time. If a sufficiently large number of accurate determinations of the oil and water saturation on freshly recovered core samples is available, an approximation of S_{gr} may be obtained by deducting the average total saturation of oil plus water from unity. This method is based on the assumption that the depletion process taking place within the core on reduction of pressure by bringing it to the surface is somewhat similar to the actual depletion process in the reservoir. Possible loss of liquids from the core before analysis may cause such a value for S_{gr} to be too high. On the other hand, the smaller amount of gas in solution in the residual oil left after flushing by mud filtrate has a tendency to reduce the residual free-gas saturation. Those using this method hope that these two effects somewhat compensate for each other.

A typical S_{gr} value for average consolidated sand, a medium solution GOR of 400 to 500 cu ft/bbl, and a crude-oil gravity of 30 to 40°API is 0.25.

Either a high degree of cementation, a high shale content of the sand, or a 50% reduction in solution GOR may cut this typical S_{gr} value by about 0.05, while a complete lack of cementation or shaliness such as in clean, loose unconsolidated sands or a doubling of the solution GOR may increase the S_{gr} value by as much as 0.10.

At the same time, the crude-oil gravity generally increases or decreases the S_{gr} value by about 0.01 for every 3°API gravity.

Example Problem 1. A cemented sandstone reservoir has a porosity $\phi=0.13$, an interstitial water content $S_{iw}=0.35$, a solution GOR at bubblepoint conditions, $R_{sb}=300$ cu ft/bbl, an initial oil FVF $B_{oi}=1.20$, an oil FVF at abandonment $B_{oa}=1.07$, and a stock-tank oil gravity of 40°API. Based on the above considerations, the higher-than-average oil gravity would just about offset the effect of the somewhat lower-than-average GOR, and the residual free-gas saturation S_{gr} after a 0.05 reduction for the cementation can therefore be estimated at 0.20.

Solution. The unit recovery by depletion according to Eq. 14 would be

$$N_{ug} = (7.758)(0.13) \left(\frac{1-0.35}{1.20} - \frac{1-0.35-0.20}{1.07} \right) \\ = 122 \text{ STB/acre-ft } [157 \text{ m}^3/\text{ha} \cdot \text{m}],$$

where N_{ug} is the unit recovery by depletion or solution-gas drive, STB.

Muskat's Method.⁹ If the actual relationships between pressure and oil-FVF B_o , gas-FVF B_g , gas-solubility in oil (solution GOR) R_s , oil viscosity μ_o , and gas viscosity μ_g are available from a PVT analysis of the reservoir fluids, and if the relationship between relative permeability ratio k_{rg}/k_{ro} and the total liquid saturation, S_t , is known for the reservoir rock under consideration, the unit recovery by depletion can be arrived at by a stepwise computation of the desaturation history directly from the following depletion equation in differential form:

$$\frac{\Delta S_o}{\Delta p_R} = \frac{S_o \frac{B_g}{B_o} \frac{dR_s}{dp_R} + (1-S_o-S_{iw}) B_g \frac{d(1/B_g)}{dp_R} + S_o \frac{\mu_o}{\mu_g} \frac{k_{rg}}{k_{ro}} \frac{dB_o}{dp_R}}{1 + \frac{\mu_o}{\mu_g} \frac{k_{rg}}{k_{ro}}} \quad (15)$$

where

S_o = oil or condensate saturation under reservoir conditions, fraction,

μ_o = reservoir oil viscosity, cp,

μ_g = reservoir gas viscosity, cp,

k_{rg} = relative permeability to gas as a fraction of absolute permeability, and

k_{ro} = relative permeability to oil as a fraction of absolute permeability.

The individual computations are greatly facilitated by computing and preparing in advance in graphical form the following groups of terms, which are a function of pressure only,

$$\left(\frac{B_g}{B_o} \frac{dR_s}{dp_R} \right), \left[B_g \frac{d(1/B_g)}{dp_R} \right], \frac{\mu_o}{\mu_g}, \left(\frac{1}{B_o} \frac{dB_o}{dp_R} \right),$$

and the relative permeability ratio k_{rg}/k_{ro} , which is a function of total liquid saturation S_t only.

The accuracy of this type of calculation on a desk calculator falls off rapidly if the pressure decrements chosen are too large, particularly during the final stages when the GOR is increasingly rapidly.

With modern electronic computers, however, it is possible to use pressure decrements of 10 psi or smaller, which makes a satisfactory accuracy possible.

This stepwise solution of the depletion equation yields the reservoir oil saturation S_o as a function of reservoir pressure p_R . The results may be converted into cumulative recovery per acre-foot. In stock-tank barrels per acre-foot,

$$N_p = 7,758 \phi \left(\frac{1-S_{iw}}{B_{oi}} - \frac{S_o}{B_o} \right) \quad (16)$$

The results may be converted into cumulative recovery as a fraction of the original oil in place (OOIP) by

$$\frac{N_p}{N} = 1 - \left(\frac{S_o}{1-S_{iw}} \right) \left(\frac{B_{oi}}{B_o} \right) \quad (17)$$

while the GOR history, in standard cubic feet gas/stock-tank barrel, may be computed by

$$R = R_s + 5.615 \frac{B_o}{B_g} \frac{\mu_o}{\mu_g} \frac{k_{rg}}{k_{ro}} \quad (18)$$

where R is the instantaneous producing GOR, in standard cubic feet per stock-tank barrel, and the relative production rate in barrels per day by

$$q_o = \frac{k_o}{k_{oi}} \frac{\mu_{oi}}{\mu_o} \frac{p_R}{p_i} q_{oi} \quad (19)$$

where

q_o = oil-production rate, B/D,

k_o = effective permeability to oil, md,

k_{oi} = initial effective permeability to oil, md,

μ_{oi} = initial reservoir oil viscosity, cp, and

q_{oi} = initial oil-production rate, B/D.

It should be stressed that this method is based on the assumption of uniform oil saturation in the whole reservoir and that the solution will therefore break down when there is appreciable gas segregation in the formation. It is therefore applicable only when permeabilities are relatively low.

Another limitation of this method as well as of the Tarnier method, discussed hereafter, is that no condensation of liquids from the produced gas is assumed to take place in the tubing or in the surface extraction equipment. It should therefore not be applied to the high-temperature, high-GOR, and high-FVF "volatile" oil reservoirs to be discussed later.

Tarnier's Method. Babson¹⁰ and Tarnier¹¹ have advanced trial-and-error-type computation methods for the desaturation process that require a much smaller number of pressure increments and can therefore be more readily handled by a desk calculator. Both methods are based on a simultaneous solution of the material-balance equation (Eq. 11) and the instantaneous GOR (Eq. 18).

Tarnier's method is the more straightforward of the two. The procedure for the stepwise calculation of the cumulative oil produced $(N_p)_2$ and the cumulative gas produced $(G_p)_2$ for a given pressure drop from p_1 to p_2 is as follows.

TABLE 40.4—COMPUTED DEPLETION RECOVERY IN STB/ACRE-FT/PERCENT POROSITY FOR TYPICAL FORMATIONS

Solution GOR (cu ft/bbl) (R_{sb})	Oil Gravity, (°API) γ_o	Sand or Sandstone ($S_{iw} = 0.25$)			Limestone, Dolomite or Chert ($S_{iw} = 0.15$)	
		Unconsolidated	Consolidated	Highly Cemented	Vugular	Fractured
60	15	7.2	4.9	1.4	2.6	0.4
	30	12.0	8.5	4.9	6.3	1.8
	50	19.2	13.9	9.5	11.8	5.1
200	15	7.0	4.6	1.8	2.6	0.5
	30	11.6	7.9	4.4	5.8	1.5
	50	19.4	13.7	9.2	11.4	4.4
600	15	7.6	4.8	2.5	3.3	0.9
	30	10.5	6.5	3.6	4.7	(1.2)
	50	15.0	9.7	5.8	7.2	(2.1)
1,000	30	12.3	7.6	4.5	5.4	(1.6)
	50	12.0	7.2	4.1	4.8	(1.2)
2,000	50	10.6	6.4	4.0	(4.3)	(1.5)

1. Assume that during the pressure drop from p_1 to p_2 the cumulative oil production increases from $(N_p)_1$ to $(N_p)_2$. N_p should be set equal to zero at bubblepoint.

2. Compute the cumulative gas produced $(G_p)_2$ at pressure p_2 by means of the material-balance equation (Eq. 11), which for this purpose—and assuming $W_p = 0$ —is rewritten in the following form:

$$(G_p)_2 = (N_p)_2(R_p)_2 = N \left[(R_{si} - R_s) - 5.615 \times \frac{B_{oi} - B_o}{B_g} \right] - (N_p)_2 \left(5.615 \frac{B_o}{B_g} - R_s \right) \quad \dots (20)$$

3. Compute the fractional total liquid saturation $(S_l)_2$ at pressure p_2 by means of

$$(S_l)_2 = S_{iw} + (1 - S_{iw}) \frac{B_o}{B_{oi}} \left[1 - \frac{(N_p)_2}{N} \right] \quad \dots (21)$$

4. Determine the k_{rg}/k_{ro} ratio corresponding to the total liquid saturation $(S_l)_2$ and compute the instantaneous GOR at p_2 by means of

$$R_2 = R_s + 5.615 \frac{B_o}{B_g} \frac{\mu_o}{\mu_g} \frac{k_{rg}}{k_{ro}} \quad \dots (22)$$

5. Compute the cumulative gas produced at pressure p_2 by means of

$$(G_p)_2 = (G_p)_1 + \frac{R_1 + R_2}{2} [(N_p)_2 - (N_p)_1] \quad \dots (23)$$

in which R_1 represents the instantaneous GOR computed previously at pressure p_1 .

Usually three judicious guesses are made for the value $(N_p)_2$ and the corresponding values of $(G_p)_2$ computed by both Steps 2 and 5. When the values thus obtained for $(G_p)_2$ are plotted vs. the assumed values for $(N_p)_2$, the intersection of the curve representing the results of Step 2 and the one representing Step 5 then indicates the cumulative gas and oil production that will satisfy both equations. In actual application, the method is usually simplified further by equating the incremental gas production $(G_p)_2 - (G_p)_1$, rather than $(G_p)_2$ itself. This

equality signifies that at each pressure step the cumulative gas, as determined by the volumetric balance, is the same as the quantity of gas produced from the reservoir, as controlled by the relative permeability ratio of the rock, which in turn depends on the total liquid saturation. Although the Tarner method was originally designed for graphical interpolation, it also lends itself well to automatic digital computers. The machine then calculates the quantity of gas produced for increasing oil withdrawals by both equations and subtracts the results of one from the other. When the difference becomes negative, the machine stops and the answer lies between the last and next to last oil withdrawals.

Tarner's method has been used occasionally to compute recoveries of reservoirs with a free-gas cap or to evaluate the possible results from injection of all or part of the produced gas. When a free-gas cap is present, or when produced gas is being reinjected, breakthrough of free gas into the oil-producing section of the reservoir is likely to occur sooner or later, thus invalidating the assumption of uniform oil saturation throughout the producing portion of the reservoir, on which the method is based. Since such a breakthrough of free gas causes the instantaneous GOR (Eq. 18) as well as the entire computation method to break down, the use of Tarner's method in its original form for this type of work is not recommended. It should also be used with caution when appreciable gas segregation in an otherwise uniform reservoir is expected.

Computed Depletion-Recovery Factors. Several investigators^{9, 12-14} have used the Muskat and Tarner methods to determine the effects of different variables on the ultimate recovery under a depletion mechanism. In one such attempt¹² the k_{rg}/k_{ro} relationships for five different types of reservoir rock representing a range of conditions for sands and sandstones and for limestones, dolomites, and cherts were developed. These five types of reservoir rock were assumed to be saturated under reservoir conditions with 25% interstitial water for sands and sandstones and 15% for the limestone group and with 12 synthetic crude-oil/gas mixtures representing a range of crude-oil gravities from 15 to 50°API and gas solubilities from 60 to 2,000 cu ft/STB. Their production performance and recovery factors to an abandonment pressure equal to 10% of the bubblepoint pressure were then computed by means of depletion (Eq. 15).

**Notes:**

Interstitial water is assumed to be 30% of pore space and dead-oil viscosity at reservoir temperature to be 2 cp.

Equilibrium gas saturation is assumed to be 5% of pore space.

As here used "ultimate oil recovery" is realized when the reservoir pressure has declined from the bubblepoint pressure to atmospheric pressure.

FVF units are reservoir barrels per barrel of residual oil.

Solution GOR units are standard cubic feet per barrel of residual oil.

Example 1:

Required: Ultimate recovery from a system having a bubblepoint pressure = 2,250 psia, FVF = 1.6, and a solution GOR.

Procedure: Starting at the left side of the chart, proceed horizontally along the 2,250-psi line to FVF = 1.6. Now rise vertically to the 1,300-scf/bbl line. Then go horizontally and read an ultimate recovery of 23.8%.

Example 2:

Required: Convert the recovery figure determined in Example 1 to tank oil recovered.

Data requirements: Differential liberation data given in Example 1. Flash liberation data: bubblepoint pressure = 2,250 psia, FVF = 1.485, FVF at atmospheric pressure = 1.080 for both flash and differential liberation.

Procedure: Calculate the oil saturation at atmospheric pressure by substituting differential liberation data in the equation as follows:

$$\left[\left(\frac{S_o}{B_o} \right)_b - \left(\frac{S_o}{B_o} \right)_a \right] (100) \div \left[\left(\frac{S_o}{B_o} \right)_b \right] = N_{ul}$$

$$\left(\frac{0.700}{1.600} - \frac{S_o}{1.080} \right) (100) \div \left(\frac{0.700}{1.600} \right) = 23.8$$

Oil saturation at atmospheric pressure = 0.360.

Next, substitute the calculated value of oil saturation and the flash liberation data into the previous equation and calculate the ultimate oil recovery as a percentage of tank oil originally in place.

$$\left(\frac{0.700}{1.485} - \frac{0.360}{1.080} \right) (100) \div \left(\frac{0.700}{1.485} \right) = N_{ul}$$

N_{ul} (ultimate oil recovery) = 29.3% of tank oil originally in place.

Fig. 40.6—Chart for estimating ultimate recovery from solution gas-drive reservoirs.

These theoretical depletion-recovery factors, expressed as barrels of stock-tank oil per percent porosity, will be found in Table 40.4 for the different types of reservoir rocks, oil gravities, and solution GOR's assumed.

In cases where no detailed data are available concerning the physical characteristics of the reservoir rock and its fluid content, Table 40.4 has been found helpful in estimating the possible range of depletion-recovery factors. It may be noted that the k_{rg}/k_{ro} relationship of the reservoir rock is apparently the most important single factor governing the recovery factor. Unconsolidated intergranular material seems to be the most favorable, while increased cementation or consolidation tends to affect recoveries unfavorably. Next in importance is crude-oil gravity with viscosity as its corollary. Higher oil gravi-

ties and lower viscosities appear to improve the recovery. The effect of GOR on recovery is less pronounced and shows no consistent pattern. Apparently the beneficial effects of lower viscosity and more effective gas sweep with higher GOR is in most cases offset by the higher oil FVF's.

In general, these data seem to indicate a recovery range from the poorest combinations of 1 to 2 bbl/acre-ft for each percent porosity to the best combinations of 19 to 20 bbl/acre-ft/percent porosity. An overall average seems to be around 10 bbl/acre-ft/percent porosity.

It is also of interest to note that when the reservoir is about two-thirds depleted, the pressure has usually dropped to about one-half the value at bubblepoint.

In another attempt¹⁵ nine nomographs were developed, each for a given combination of the k_{rg}/k_{ro} curve, "dead-oil" viscosity, and interstitial water content. The nomograph for an average k_{rg}/k_{ro} relationship, an interstitial water content of 0.30, and a dead-oil viscosity of 2 cp is reproduced as Fig. 40.6. Instructions for its use are shown opposite the figure.

The authors¹³ also introduced an interesting empirical relationship between the relative permeability ratio k_{rg}/k_{ro} , the equilibrium gas saturation S_{gc} , the interstitial water saturation S_{iw} , and the oil saturation S_o :

$$\frac{k_{rg}}{k_{ro}} = \xi(0.0435 + 0.4556\xi), \dots\dots\dots (24)$$

where $\xi = (1 - S_{gc} - S_{iw} - S_o)/(S_o - 0.25)$. A similar correlation¹⁵ for sandstones that show a linear relationship between $1/p_c^2$ (where p_c = critical pressure) and saturation is

$$\frac{k_{rg}}{k_{ro}} = \frac{(1 - S^*)^2 [1 - (S^*)^2]}{(S^*)^4}, \dots\dots\dots (25)$$

where effective saturation $S^* = S_o/(1 - S_{iw})$. This equation represents a useful expression for calculating relative permeability ratios in sandstone reservoirs for which an average water saturation has been obtained by either electrical log or core analysis.

API Estimation of Oil and Gas Reserves

In a statistical study of the actual performance of 80 solution gas-drive reservoirs, the API Subcommittee on Recovery Efficiency¹⁶ developed the following equation for unit recovery (N_{ug}) below the bubblepoint for solution gas-drive reservoirs, in stock-tank barrels per acre-foot*:

$$N_{ug} = 3,244 \left[\frac{\phi(1 - S_{iw})}{B_{ob}} \right]^{1.1611} \times \left(\frac{k}{\mu_{ob}} \right)^{0.0979} \times (S_{iw})^{0.3722} \times \left(\frac{p_b}{p_a} \right)^{0.1741}, \dots\dots\dots (26)$$

where

- k = absolute permeability, darcies,
- B_{ob} = oil FVF at bubblepoint, RB/STB,
- μ_{ob} = oil viscosity at bubblepoint, cp,
- p_a = abandonment pressure, psig, and
- p_b = bubblepoint pressure, psig.

The permeability distribution in most reservoirs is usually sufficiently nonuniform in vertical and horizontal directions to cause the foregoing depletion calculations on average material to be fairly representative.

However, when distinct layers of high and low permeability, separated by impervious strata, are known to be present, the depletion process may advance more rapidly in high-permeability strata than in low-permeability zones. In such cases separate performance calculations should

be made for each permeability bank that is known to be continuous and the results converted into rate/time curves for each by combining Eqs. 16 and 19. The estimated ultimate recovery will then be based on a superposition of such rate/time curves for the different zones.

If there is a wide divergence in permeabilities, one may find that at a time when the combined rate for all zones has reached the economic limit the more permeable banks will be depleted and have yielded their full unit recovery while the pressure depletion and the recovery from the tighter zones are still incomplete.

Undersaturated Oil Reservoirs Without Water Drive Above the Bubblepoint—Volumetric Method¹⁷⁻¹⁹

With progressively deeper drilling, a number of oil reservoirs have been encountered that, while lacking an active water drive, are in undersaturated condition. Because of the expansion of the reservoir fluids and the compaction of the reservoir rock upon pressure reduction, substantial recoveries may sometimes be obtained before the bubblepoint pressure p_b is reached and normal depletion sets in. Such recoveries may be computed as follows.

The oil initially in place in stock-tank barrels per acre-foot at pressure p_i is according to Eq. 2,

$$N = \frac{7,758 \times \phi_i (1 - S_{iw})}{B_{oi}},$$

where ϕ_i is initial porosity. By combining this expression with the material-balance equation (Eq. 10), the recovery factor above the bubblepoint in stock-tank barrels per acre-foot may be expressed as

$$N_p = \frac{7,758 \phi_i (p_i - p_b) [c_o + c_f - S_{iw}(c_o - c_w)]}{B_{oi} [1 + c_o(p_i - p_b)]}, \quad (27)$$

where c_w is the compressibility of interstitial water in volume per volume per psi.

Example Problem 2. Zone D-7 in the Ventura Avenue field, described by E.V. Watts,¹⁹ is an example of an undersaturated oil reservoir without water drive. Its reservoir characteristics are

- p_i = 8,300 psig at 9,200 ft,
- p_b = 3,500 psig,
- ϕ_i = 0.17,
- S_{iw} = 0.40,
- B_{ob} = 1.45,
- B_{oa} = 1.15,
- γ_o = 32 to 33° API,
- c_o = 13×10^{-6} ,
- c_w = 2.7×10^{-6} ,
- c_f = 1.4×10^{-6} ,
- S_{gr} = 0.22, and
- R_{sb} = 900 cu ft/bbl.

Solution. On the basis of these data, Watts computes the recovery by expansion above the bubblepoint at 47 bbl/acre-ft and by a depletion mechanism below the bubblepoint at 110 bbl/acre-ft (see Ref. 19 for details).

* Because Eq. 26 is empirically derived, conversion to metric units ($m^3/ha \cdot m$) requires multiplication of N_{ug} by 1.2889.

Volatile Oil Reservoirs— Volumetric Methods²⁰⁻²⁵

Deeper drilling, with accompanying increases in reservoir temperatures and pressures, has also revealed a class of reservoir fluids with a phase behavior between that of ordinary "black" oil and that of gas or gas condensate. These intermediate fluids are referred to as "high-shrinkage" or "volatile" crude oils because of their relatively large percentage of ethane through decane components and resultant high volatility. Volatile-oil reservoirs are characterized by high formation temperatures (above 200°F) and abnormally high solution GOR and FVF (above 2). The stock-tank gravity of these volatile crudes generally exceeds 45°API.

The inherent differences in phase behavior of volatile oils are sufficiently significant to invalidate certain premises implicit in the conventional material-balance methods. In such conventional material-balance work it is assumed that all produced gas, whether solution gas or free gas, will remain in the vapor phase during the depletion process, with no liquid condensation on passage through the surface separation facilities. Furthermore, the produced oil and gas are treated as separate independent fluids, even though they are at all times in compositional equilibrium. Although these basic assumptions simplify the conventional material-balance calculations, highly inaccurate predictions of reservoir performance may result if they are applied to volatile-oil reservoirs.

In highly volatile reservoirs, the stock-tank liquids recovered by condensation from the gaseous phase may actually equal or even exceed those from the associated liquid phase. This rather surprising occurrence is exemplified in a paper by Woods,²⁴ in which the case history of an almost depleted volatile-oil reservoir is presented.

Example Problem 3. Woods' reservoir data for this volatile-oil reservoir were

$$\begin{aligned} p_i &= 5,000 \text{ psig,} \\ p_b &= 3,940 \text{ psig,} \\ T_R &= 250^\circ\text{F,} \\ \phi &= 0.198, \\ k &= 75 \text{ md,} \\ S_{iw} &= 0.25, \\ R_{sb} &= 3,200 \text{ scf/bbl,} \\ \gamma_{oi} &= 44^\circ\text{API,} \\ \gamma_{oa} &= 62^\circ\text{API, and} \\ B_{ob} &= 3.23. \end{aligned}$$

Solution. At 80% depletion when $p_R = 1,450$ psig and $R = 23,000$ scf/bbl, the percentage recovery was 21% of which 5% was from expansion above the bubblepoint, 9% from the depletion mechanism, and 7% from liquids condensed out of the gas phase by conventional field separation equipment (see Ref. 24 for details).

In view of the increasing number and importance of volatile-oil reservoirs in recent years, appropriate techniques have been developed to provide realistic predictions of the anticipated production performance of these reservoirs.²⁰⁻²⁵ The depletion processes are simulated by an incremental computation method, using multicomponent flash calculations and relative-permeability data, as indicated in the following stepwise sequence for a chosen pressure decrement:

1. The change in composition of the in-place oil and gas is determined by a flash calculation.
2. The total volume of fluids produced at bottomhole conditions is determined by a volumetric material balance.
3. The relative volumes of oil and gas produced at bottomhole conditions are determined by a trial-and-error procedure that involves simultaneously satisfying the volumetric material balance and the relative-permeability relationship.
4. This total well-stream fluid is then flashed to actual surface conditions to obtain the producing GOR and the volume of stock-tank liquid corresponding to the selected pressure decrement.

When this calculation procedure is repeated for successive pressure decrements, the resultant tabulations represent the entire reservoir depletion and recovery processes. Since these stepwise calculations are rather tedious and time-consuming, the use of digital computers is recommended.

This method of reservoir analysis provides compositional data on all fluid phases, including the total well-stream. This information is then readily available for separator, crude-stabilization, gasoline-plant, or related studies at any desired stage of depletion.

In the case of small reservoirs with relatively limited reserves, such lengthy laboratory work and phase-behavior calculations may not be justified. An empirical correlation was developed²⁴ for prediction of the ultimate recovery in such cases, based only on the initial producing GOR, R , the reservoir temperature, T_R , and the initial stock-tank oil gravity, γ_{oi} .

$$N_{ul} = -0.070719 + \frac{143.50}{R} + 0.000120807T_R + 0.0011807\gamma_{oi}, \dots \dots \dots (28)$$

where N_{ul} = ultimate oil production from saturation pressure p_b to 500 psi, in stock-tank volume per reservoir volume of hydrocarbon pore space.

It is claimed that this correlation will give values within 10% of those calculated by the more rigorous procedure previously outlined.

Oil Reservoirs With Gas-Cap Drive— Volumetric Unit Recovery Computed by Frontal-Drive Method²⁶⁻²⁸

The Buckley-Leverett frontal-drive method may be used in calculating oil recovery when the pressure is kept constant by injection of gas in a gas cap but is also applicable to a gas-cap drive mechanism without gas injection when the pressure variation is relatively small so that changes in gas density, solubility, or the reservoir volume factor may be neglected. A reservoir with a very large gas-cap volume as compared with the oil volume can sometimes be considered to meet these qualifications even though no gas is being injected.

The two basic equations, Eqs. 29a and b, refer to a linear reservoir under constant pressure with a constant cross-sectional area exposed to fluid flow and with the free gas moving in at one end of the reservoir and fluids being produced at a constant rate at the other end. Interstitial water is considered as an immobile phase.

Fig. 40.7—Frontal-drive method in gas-cap drive.

If the capillary-pressure forces are neglected, the fractional-flow equation of gas is

$$f_g = \frac{1 - Ek_{ro}(\mu_g/\mu_o)}{1 + (k_{ro}/k_{rg})(\mu_g/\mu_o)} \quad (29a)$$

and

$$E = \frac{k \sin \Theta A (\rho_o - \rho_g)}{365 \mu_g q_t} \quad (29b)$$

where

- f_g = fractional flow of gas,
- E = parameter,
- Θ = dip angle, degrees,
- A = area of cross-section normal to bedding plane, sq ft,
- ρ_o = density of reservoir oil, g/cm³,
- ρ_g = density of reservoir gas, g/cm³, and
- q_t = total flow rate, reservoir cu ft/D.

Since the ratio of k_{ro}/k_{rg} is a function of gas saturation, and all other factors are constant, f_g can be determined by Eq. 29a as a function of gas saturation (see Fig. 40.7, Curve A).

The rate-of-frontal-advance equation may be rearranged to give the time in days for a given displacing-phase saturation to reach the outlet face of the linear sand body as a function of the slope of the fractional flow vs. saturation curve (Fig. 40.7, Curve B) as follows:

$$t = \frac{5.615NB_o}{q_t(df_g/dS_g)} \quad (30)$$

Note: S'_g as used in this section is gas saturation as a fraction of the hydrocarbon-filled pore space. When N is in cubic meters, q_t is in cubic meters per day.

The calculation procedure is first to calculate the fractional-flow curve (Fig. 40.7, Curve A). The average gas saturation in the swept area at breakthrough, which is equivalent to the fraction of oil in place recovered, may then be obtained from the fractional-flow curve by constructing a straight line tangent to the curve through the origin and reading \bar{S}'_g at $f_g = 1.0$. The time of breakthrough at the outlet face may be computed from the slope of the curve at the point of tangency. The subsequent performance history after breakthrough may then be calculated by constructing tangents at successively higher values of S'_g and obtaining \bar{S}'_g in a similar manner.

Example Problem 4. Welge²⁸ presents a typical calculation of gas-cap drive performance for the Mile Six Pool in Peru.

Given:

Reservoir volume = $1,902 \times 10^6$ cu ft,
distance from original GOC to average
withdrawal point = 1,540 ft,

$$\text{average cross-sectional area} = \frac{1,902 \times 10^6}{1,540}$$

$$= 1.235 \times 10^6 \text{ sq ft,}$$

$$k_o = 300 \text{ md,}$$

$$\Theta = 17.50,$$

$$\mu_g = 0.0134 \text{ cp,}$$

$$\mu_o = 1.32 \text{ cp,}$$

$$q_t = 64,000 \text{ res cu ft/D [18 125 res m}^3\text{/d],}$$

$$B_o = 1.25,$$

$$B_g = 0.0141$$

$$N = 44 \times 10^6 \text{ STB [6.996} \times 10^6 \text{ m}^3\text{],}$$

$$R_s = 400 \text{ cu ft/bbl [71.245 m}^3\text{/m}^3\text{],}$$

$$\rho_o = 0.78 \text{ g/cm}^3, \text{ and}$$

$$\rho_g = 0.08 \text{ g/cm}^3.$$

Solution. The performance history calculations are given in Table 40.5 in a slightly simplified form.

Oil Reservoirs Under Gravity Drainage²⁹⁻³⁷

Occurrence of Gravity Drainage

Gravity drainage is the self-propulsion of oil downward in the reservoir rock. Under favorable conditions it has been found to effect recoveries of 60% of the oil in place, which is comparable with or exceeding the recoveries normally obtained by water drive. Gravity is an ever-present force in oil fields that will drain oil from reservoir rock from higher to lower levels wherever it is not overcome by encroaching edge water or expanding gas.

Gravity drainage will be most effective if a reservoir is produced under conditions that allow flow of oil only or counterflow of oil and gas. This may be attained under pressure maintenance by crestal-gas injection, which keeps the gas in solution, or it may be attained by a gradual reduction in pressure, so that the oil and gas can segregate continuously by counterflow. It also may be obtained by

first producing the reservoir under a depletion-type mechanism until the gas has been practically exhausted, then by gravity drainage. A thorough discussion of the many aspects of gravity drainage will be found in the classic paper by Lewis.³²

Several investigators³³⁻³⁶ have attempted to formulate gravity drainage analytically, but the relationships are quite complicated and not readily adaptable to practical field problems. Most studies agree, however, that the occurrence of gravity drainage of oil will be promoted by low viscosities, μ_o , high relative permeability to oil, k_{ro} , high formation dips or lack of stratification, and high density gradients ($\rho_o - \rho_g$). Thick sections of unconsolidated sand with minimal surface area, large pore sizes, low interstitial water saturation, and consequently high k_{ro} appear to be especially favorable.

These factors usually are combined in a rate-of-flow equation, which states that such flow must be proportional to $(k_{ro}/\mu_o)(\rho_o - \rho_g) \sin \Theta$, in which Θ represents the angle of dip of the stratum. Smith³⁷ compared the values of this term for a dozen reservoirs, some of which had strong gravity-drainage characteristics and some of which lacked such characteristics.

When expressing k_{ro} in millidarcies, μ_o in centipoises, and ρ_o and ρ_g in g/cm³, it was found that for reservoirs exhibiting strong gravity-drainage characteristics the value of the term $(k_{ro}/\mu_o)(\rho_o - \rho_g) \sin \Theta$ ranged from 10 to 203 and that in reservoirs where gravity-drainage effects were not apparent, this function showed values between 0.15 and 3.4.

Case Histories of Gravity Drainage After Pressure Depletion

The most spectacular cases of gravity drainage have been of this kind. Following are the two best known.

1. *Lakeview Pool in Kern County, CA.*^{31,32} The discovery well in the Lakewood gusher area blew out in March 1910, flowed wild for 544 days, and ultimately produced 8¼ million bbl of oil, depleting the reservoir pressure. Gravity drainage thereafter controlled this reservoir. There was no appreciable water influx. The sand is relatively clean and poorly cemented. The average depth is 2,875 ft. The formation dip is 15 to 45°. There are 126 producing wells on 588 acres. The net sand thickness averages 71 ft, the height of the oil column is 1,285 ft, and there are 41,798 net acre-ft of pay.

Reservoir data for this reservoir are $p_i = p_b = 1,285$ psig, p_R on Jan. 1, 1957 = 35 psig, $T_R = 115^\circ\text{F}$, $\phi = 0.33$, k ranges up to 4,800 md and averages 3,600 md (70% of samples above 100 md, 37% above 1,000 md), $S_{iw} = 0.235$, $R_{sh} = 200$ cu ft/bbl, $B_{oi} = 1.106$,

$\gamma_o = 22.5^\circ\text{API}$, N_p for Jan. 1, 1957 = 44.6 million bbl of oil; estimated ultimate 47 million bbl or 1,124 bbl/acre-ft, corresponding to 63% of the initial oil in place.

During the first 20 years the oil level in the field receded almost exactly in proportion to the amount of oil produced, just as in a tank.

2. *Oklahoma City Wilcox Reservoir, OK.*^{29,32} The discovery well, Mary Sudik No. 1, blew out in March 1930, and flowed wild for 11 days.

The segregation of gas and development of gravity drainage began to be important in 1934, when the average pressure became less than 750 psig, and was virtually complete by 1936, when the average pressure had dropped to 50 psig.

Water influx played an effective role until 1936, when it came to a halt after invading the bottom 40% of the reservoir. Gravity has been the dominant mechanism since. The Wilcox sand consists of typical round frosted sand grains, clean and poorly cemented.

The average depth is 6,500 ft; the formation dip is 5 to 15°; 884 wells have been drilled on a total area of 7,080 acres. The net pay thickness is 220 ft. The 890,000 net acre-ft of Wilcox pay contained originally 1,083 million bbl of stock-tank oil, as confirmed by material balance.

Reservoir data for this reservoir are $p_i = p_b = 2,670$ psi at minus 5,260 ft, $T_R = 132^\circ\text{F}$, $\phi = 0.22$, k ranges from 200 to 3,000 md, $S_{iw} = 0.03$ (oil wet), $R_{sh} = 735$ cu ft/bbl, $B_{oi} = 1.361$, $\gamma_{oi} = 40^\circ\text{API}$, $\gamma_{oa} = 38$ to 39°API .

According to Katz,²⁹ oil saturations found in the gas zone were between 1 and 26%, while saturations between 53 and 93% were found in the oil-saturated zone below the GOC. The oil saturation below the WOC has been estimated at 43%, showing gravity to be more effective than water displacement in this reservoir.

Cumulative production, N_p , for Jan. 1, 1958, is estimated at 525 million bbl and the ultimate recovery at 550 million bbl. After an estimated 189 million bbl displaced by the water influx is deducted, the upper 60% of the Wilcox reservoir will yield under gravity drainage ultimately 361 million bbl or 696 bbl/acre-ft, corresponding to 57% of the oil in place.

Oil Reservoirs With Water Drive—Volumetric Methods³⁸

General Discussion

Natural-water influx into oil reservoirs is usually from the edge inward parallel to the bedding planes (edgewater drive) or upward from below (bottomwater drive). Bottomwater drive occurs only when the reservoir thickness exceeds the thickness of the oil column, so that the oil/water interface underlies the entire oil reservoir. It is

TABLE 40.6—CONDITIONS FOR UNIT-RECOVERY EQUATION, WATER-DRIVE RESERVOIR

	Initial Conditions	Ultimate Conditions
Reservoir pressure	P_i	P_a
Interstitial water, bbl/acre-ft	$7,758\phi S_{iw}$	$7,758\phi S_{iw}$
Reservoir oil, bbl/acre-ft	$7,758\phi(1 - S_{iw})$	$7,758\phi S_{or}$
Stock-tank oil, bbl/acre-ft	$7,758\phi(1 - S_{iw})/B_{oi}$	$7,758\phi S_{or}/B_{oa}$

further possible only when vertical permeabilities are high and there is little or no horizontal stratification with impervious shale laminations.

In either case, water as the displacing medium moves into the oil-bearing section and replaces part of the oil originally present. The key to a volumetric estimate of recovery by water drive is in the amount of oil that is not removed by the displacing medium. This residual oil saturation (ROS) after water drive, S_{or} , plays a role similar to the final (residual) gas saturation, S_{gr} , in the depletion-type reservoirs.

To determine the unit-recovery factor, which is the theoretically possible ultimate recovery in stock-tank barrels from a homogeneous unit volume of 1 acre-ft of pay produced by complete waterflooding, the amount of interstitial water and oil with dissolved gas initially present will be compared with the condition at abandonment time, when the same interstitial water is still present but only the residual or nonfloodable oil is left. The remainder of the original oil has at that time been removed by water displacement.

Unit-Recovery Equation

The unit recovery for a water-drive reservoir is equal to the stock-tank oil originally in place in barrels per acre-foot minus the residual stock-tank oil at abandonment time (Table 40.6).

By difference, the unit recovery by water drive, in stock-tank barrels per acre-foot, is

$$N_{uw} = 7,758\phi \left(\frac{1 - S_w}{B_{oi}} - \frac{S_{or}}{B_{oa}} \right), \dots \dots \dots (31)$$

where N_{uw} is the unit recovery by water drive, in stock-tank barrels, and S_{or} is the residual oil saturation, fraction. The ROS at abandonment time may be found by actually submitting cores in the laboratory under simulated reservoir conditions to flooding by water (flood-pot tests). Another method commonly used is to consider the oil satu-

ration as found by ordinary core analysis after multiplying with the oil FVF at abandonment, B_{oa} , as the residual oil saturation in the reservoir to be expected from flooding with water. This is based on the assumption that water from the drilling mud invades the pay section just ahead of the core bit in a manner similar to the water displacement process in the reservoir itself.

Recovery-Efficiency Factor

The unit recovery should be multiplied by a permeability-distribution factor and a lateral-sweep factor before it may be applied to the computation of the ultimate recovery for an entire water-drive reservoir.

These two factors usually are combined in a recovery-efficiency factor. Baucum and Steinle³⁸ have determined this recovery-efficiency factor for five water-drive reservoirs in Illinois. Table 40.7 lists the recovery efficiencies for these reservoirs, together with some other pertinent data.

Average Recovery Factor From Correlation of Statistical Data

In 1945, Craze and Buckley,^{39,40} in connection with a special API study on well spacing, collected a large amount of statistical data on the performance of 103 oil reservoirs in the U.S. Some 70 of these reservoirs produced wholly or partially under water-drive conditions. Fig. 40.8 shows the correlation between the calculated ROS under reservoir conditions and the reservoir oil viscosities for these water-drive reservoirs. The deviation of the ROS from the average trend in Fig. 40.8, vs. permeability, is given by the average trend in Fig. 40.9. The deviation of the ROS from the average trend in Fig. 40.8, vs. reservoir pressure decline, is given by the average trend in Fig. 40.10.

Example Problem 5. In a case where the porosity, $\phi=0.20$, the average permeability, $k=400$ md, the interstitial water content, $S_{iw}=0.25$, the initial oil FVF, $B_{oi}=1.30$, the oil FVF under abandonment conditions, $B_{oa}=1.25$, the initial reservoir oil viscosity, $\mu_o=1.0$ cp, and the abandonment pressure, $p_a=90\%$ of the initial pressure, p_i , determine the average ROS.

Solution. S_{or} may be estimated as $0.35+0.03-0.04=0.34$ and the average water-drive recovery factor from Eq. 31 is

$$N_{uw} = (7,758)(0.20) \left(\frac{1-0.25}{1.30} - \frac{0.34}{1.25} \right) \\ = 473 \text{ STB/acre-ft.}$$

TABLE 40.7—RECOVERY-EFFICIENCY FOR WATER-DRIVE RESERVOIR

Reservoir Number	ϕ	S_{iw}	B_o	S_{or}^*	Unit-Recovery Factor (bbl/acre-ft)	Actual Recovery* (bbl/acre-ft)	Recovery Efficiency (%)
1	0.179	0.400	1.036	0.20	526	429	82
2	0.170	0.340	1.017	0.20	592	430	73
3	0.153	0.265	1.176	0.20	504	428	85
4	0.192	0.370	1.176	0.20	500	400	80
5	0.196	0.360	1.017	0.20	653	482	74
							Average = 79

*From flood-pot tests.

Fig. 40.8—Effect of oil viscosity on ROS water-drive sand fields.

In another statistical study of the Craze and Buckley data and other actual water-drive recovery data on a total of 70 sand and sandstone reservoirs, the API Subcommittee on Recovery Efficiency¹⁶ developed Eq. 32 for unit recovery for water-drive reservoirs, N_{uw} . In stock-tank barrels per acre-foot,*

$$N_{uw} = 4,259 \left[\frac{\phi(1-S_{iw})}{B_{oi}} \right]^{1.0422} \times \left(\frac{k\mu_{wi}}{\mu_{oi}} \right)^{0.0770} \times (S_{iw})^{-0.1903} \times \left(\frac{p_i}{p_a} \right)^{-0.2159}, \quad (32)$$

where symbols and units are as previously defined except permeability, k , is in darcies, and pressure, p , is in psig.

Example Problem 6. For the same water-drive reservoir used previously and assuming $\mu_{wi} = 0.5$ cp, the API statistical equation yields the following unit recovery factor:

$$\begin{aligned} N_{uw} &= 4,259 \left[\frac{(0.20)(1-0.25)}{1.30} \right]^{1.0422} \\ &\times \left[\frac{(0.4)(0.5)}{1.0} \right]^{0.0770} \times (0.25)^{-0.1903} \\ &\times \left(\frac{1.0}{0.9} \right)^{-0.2159} \\ &= 504 \text{ STB/acre-ft.} \end{aligned}$$

Because data were arrived at by comparing indicated recoveries from various reservoirs with the known parameters from each reservoir, the estimated residual oil and the average recovery factor based on these correlations allows for a recovery-efficiency factor (permeability-distribution factor times lateral-sweep factor) that is not present in the unit-recovery factor based on actual residual oil as found by flood-pot tests or in the cores.

*Because Eq. 32 is empirically derived, conversion to metric units ($\text{m}^3/\text{ha} \cdot \text{m}$) requires multiplication of N_{ug} by 1.2889.

Fig. 40.9—Relation between deviation of ROS from average trend in Fig. 40.8 and permeability water-drive sand fields.

Water-Drive Unit Recovery Computed by Frontal-Drive Method²⁶⁻²⁸

The advance of a linear flood front can be calculated by two equations derived by Buckley and Leverett²⁶ and simplified by Welge²⁸ and by Pirson.²⁷ These are known as the fractional-flow equation and the rate-of-frontal-advance equation. This method assumes that (1) a flood bank exists, (2) no water moves ahead of this front, (3) oil and water move behind the front, and (4) the relative movement of oil and water behind the front is a function of the relative permeability of the two phases.

If the throughput is constant and the capillary-pressure gradient and gravity effects are neglected, the fractional-flow equation can be written as follows:

$$f_w = \frac{1}{1 + (k_{ro}/k_{rw})(\mu_w/\mu_o)}, \quad (33)$$

Fig. 40.10—Relation between deviation of ROS from average trend in Fig. 40.8 and pressure-decline water-drive sand fields.

Fig. 40.11—Fraction of water flowing in total stream f_w and slope of f_w curve df_w/dS_w vs. water saturation S_w (example: frontal-water-drive problem).

where f_w is the fraction of water flowing in the reservoir at a given point, k_{rw} is the water relative permeability, fraction, and μ_w is the reservoir water viscosity, cp. Since k_{ro}/k_{rw} is a function of water saturation, f_w can be determined by Eq. 33 as a function of water saturation for a given water/oil viscosity ratio (see Fig. 40.11, Curve A).

The Buckley-Leverett rate-of-frontal-advance equation may be rearranged to give the time in days for a given displacing phase saturation to reach the outlet face of the linear sand body as a function of the slope of the fractional flow vs. saturation curve (Fig. 40.11, Curve B) as follows:

$$t = \frac{5.615 NB_o}{q_t(df_w/dS_w)} \quad (34)$$

where df_w/dS_w is the slope of the f_w vs. S_w curve; the time, t , is in days; and the total liquid flow rate, q_t , is in reservoir cubic feet per day.

The average water saturation behind the flood front at breakthrough, and therefore the oil recovery, may be obtained from the fractional-flow curve by constructing a straight line tangent to the curve through S_{iw} at $f_w=0$, and reading \bar{S}_{iw} at $f_w=1.0$. The time of breakthrough at the producing well may be computed from the slope of the curve at the point of tangency. The subsequent performance history after breakthrough may be calculated by constructing tangents at successively higher values of S_{iw} and obtaining \bar{S}_{iw} in a similar manner.

Table 40.8 illustrates the calculation procedure for a water drive at constant pressure in a homogeneous reservoir and with a water-influx rate equal to the production rate.

Fig. 40.12—Example of frontal-drive problem, unit-recovery factor, and WOR vs. time.

Fig. 40.12 is a plot of the results of the performance-history calculation from Table 40.8. If the economic limit is taken to be a WOR of 50, then it can be noted from Fig. 40.12 that the unit-recovery factor will be 575 bbl/acre-ft to be recovered in 20.7 years.

Effect of Permeability Distribution^{1,41-44}

In some reservoirs there may be distinct layers of higher and lower permeabilities separated by impervious strata, which appear to be more or less continuous across the reservoir. In such a case, water and oil will advance much more rapidly through the higher-permeability streaks than through the tighter zones, and therefore the recovery at the economic limit will be less than that indicated by the unit-recovery factor.

Methods for computing waterflood recoveries that take into account the permeability distribution were proposed by Dykstra and Parsons,⁴¹ Muskat,⁴² and Stiles.⁴³

In the Dykstra-Parsons paper⁴¹ it is assumed that individual zones of permeability are continuous from well to well, and a computation procedure as well as charts are presented for the coverage or fraction of the total volume of a linear system flooded with water for given values of (1) the mobility ratio $k_{rw}\mu_o/k_{ro}\mu_w$, (2) the produced WOR, and (3) the permeability variance.

This permeability variance is a statistical parameter that characterizes the type of permeability distribution. It is obtained by plotting the percentage of samples "larger than" the sample being plotted vs. the logarithm of permeability for that sample on log-probability graph paper and then dividing the difference between the median or 50% permeability and the 84.1% permeability by the median permeability. Although the Dykstra-Parsons method

* $N = 597,000$ STB. $B_{oi} = 1.30$. $\phi = 0.20$. $S_{iw} = 0.25$, and $q_f = 200$ B/D $\times 5$ 615 cu ft/bbl = 1,222 reservoir cu ft/D.

does not allow for variations in porosity, interstitial water, and floodable oil in the different permeability groups, it has apparently been used extensively and successfully on close-spaced waterfloods, mainly in California.

Johnson⁴⁴ in 1956 published a simplification of this method and presented a series of charts showing the fractional recovery of oil in place at a given produced WOR for a given permeability variance, mobility ratio, and water saturation. Reznik *et al.*⁴⁵ published an extension to the Dykstra-Parsons method that provides a discrete analytical solution to the permeability stratification problem on a real-time basis.

In the Stiles method⁴³ it again is assumed that individual zones of permeability are continuous from well to well and that the distance of penetration of the flood front in a linear system is proportional to the average permeability of each layer. Instead of representing the entire permeability distribution by one statistical parameter, Stiles tabulates the available samples in descending order of permeability and plots the results in terms of dimensionless permeability and cumulative capacity fraction as a function of cumulative thickness. From these data, Stiles computes the produced water cut of the entire system as the watering out progresses through the various layers, starting with those of the highest permeability. Stiles then assumes that at a given time each layer that has not had breakthrough will have been flooded out in proportion to the ratio of its average permeability to the permeability of the last zone that had just had breakthrough, and then constructs a recovery vs. thickness relationship. This then is combined with previous results to yield a recovery vs. water-cut graph. The Stiles method is used extensively and successfully, mainly in the midcontinent and Texas, for close-spaced waterfloods. It does not make allowance for the difference in mobility existing in the formation ahead of and behind the flood front, which the Dykstra-Parsons method allows for. It also does not provide for differences in porosity, interstitial water, and floodable oil in the various permeable layers.

Arps¹ introduced in 1956 a variation of the Stiles method, called the "permeability-block method." This method handles the computations by means of a straightforward tabulation and does make allowance for the differences in porosity, interstitial water, and floodable oil existing in the various permeable layers. Since it is designed primarily for the computation of recoveries from water-drive fields above their bubblepoint, no free-gas saturation

is assumed. The method further assumes that (1) no oil moves behind the front, (2) no water moves ahead of the front, (3) watering out progresses in order from zones of higher to zones of lower permeability, and (4) the advance of the flood front in a particular permeability streak is proportional to the average permeability.

This method, applied to a hypothetical pay section 100 ft thick, is illustrated in Table 40.9, which is based on data from a Tensleep sand reservoir in Wyoming where good statistical averages of more than 3,000 core analyses were available. Part of these cores were taken with water-base mud that yielded the residual-oil figures on Line 6. Another portion was taken with oil-base mud and yielded the interstitial-water figures of Line 7. An oil/water viscosity ratio of 12.5 was used in calculating the WOR of Line 13.

In Group 1 the recovery of 61.7 bbl/acre-ft for WOR=15.5 is the product of the fraction of samples in the group and the unit-recovery factor. In all other groups for WOR=15.5 the full recovery is reduced in the proportion of its average permeability to 100 md. The total recovery at WOR=15.5 is shown as 175.6 bbl/acre-ft. The cumulative recoveries for WOR's of 35.9, 76.5, 307.7, and infinity are calculated in a similar manner. Fig. 40.13 is a plot of WOR vs. recovery factor. From Fig. 40.13 it can be seen that, if the economic limit is taken to be a WOR of 50, the recovery factor would be 297 bbl/acre-ft.

It should be stressed that the permeability-block method is applicable only when the zones of different permeability are continuous across the reservoir, or between the source of the water and the producing wells. When the waterfront has to travel over large distances, nonuniformity of permeability distribution in lateral directions begins to dominate, and recoveries will approach those obtainable if the formation were entirely uniform (permeability distribution factor=1). In such a case, an estimate based on the permeability-block method may be considered as conservative, except for the fact that one of the basic assumptions of this method is that the WOC, or front, moves in pistonlike fashion through each permeability streak, sweeping clean all recoverable oil. In reality, part of this oil will be recovered over an extended period after the initial breakthrough, which may tend to make the estimate optimistic. Those using the permeability-block method hope that these two effects are more or less compensating.

TABLE 40.9—WATER DRIVE PERMEABILITY-BLOCK CALCULATIONS

Group	1	2	3	4	5	Total
(1) Permeability range, md	> 100	50 to 100	25 to 50	10 to 25	0 to 10	
(2) Percent of samples in group	8.5	10.9	14.5	21.2	44.9	100.0
(3) Average permeability, md	181.3	69.0	34.4	16.1	2.4

Effect of Buoyancy and Imbibition

In limestone pools producing under a bottomwater drive, such as certain of the vugular D-3 reef reservoirs in Alberta, one finds an extreme range in the permeabilities, often running from microdarcies on up into the darcy range. Under those conditions the modified Stiles method heretofore described yields results that are decidedly too

low. The reason is that, in pools like the Redwater D-3, there is a substantial density difference between the rising salt water and the oil. While the water rises and advances through the highly permeable vugular material, it may at first bypass the low-permeability matrix material, leaving oil trapped therein. However, as soon as such bypassing occurs, a buoyancy gradient is set up across this tight material, which tends to drive the trapped oil out vertically into the vugular material and fractures. In the case of Redwater D-3, where the density difference between salt water and oil is 0.26, while the vertical permeabilities for matrix material are only a fraction of the horizontal permeabilities, a simple calculation based on Darcy's law applied to a vertical tube shows that during the anticipated lifetime of the field very substantial additional oil recovery may be obtained because of this so-called buoyancy effect.

To calculate the recovery under a buoyancy mechanism it is necessary first to determine by statistical analysis of a large number of cores the average interval between high-permeability zones or fractures. A separate computation is then made for each of the permeability ranges to determine what percentage of the matrix oil contained in a theoretical tube of such average length may be driven out during the producing life of the reservoir under the effect of the buoyancy phenomenon.

Surprisingly improved recoveries are sometimes indicated by this method over what one would expect from a Stiles type of calculation, and the results from recent studies of the rise in water table of the Redwater D-3 seem to confirm the validity of this concept.

In addition to this buoyancy phenomenon the effect of capillarity and preferential wetting of the reservoir rock by water also should be considered. Imbibition of water from fractures and vugular material into the low-permeability matrix as the water advances may materially aid the buoyancy mechanism but is much more difficult to evaluate quantitatively.

Fig. 40.13—Example of modified Stiles permeability-block method WOR vs. recovery factor.

TABLE 40.10—PSEUDOCRITICAL CALCULATIONS FROM GAS ANALYSIS

Component (1)	Volume % or Mol% (2)	Critical Temperature (°R) (3)	Critical Pressure (psia) (4)	2 × 3	2 × 4
				100 (5)	100 (6)

Volumetric Recovery Estimates for Nonassociated Gas Reservoirs⁴⁶⁻⁵³

Compressibility Factor

The compressibility factor z is a dimensionless factor which, when multiplied by the reservoir volume of gas, as computed by the ideal-gas laws, yields the true reservoir volume. The reservoir volume occupied by 1 lbm-mole of gas (gas weight in pounds equal to molecular weight), in cubic feet, is

$$G = \frac{(10.73)z(460 + T_R)}{p_R}, \quad \dots \dots \dots (35)$$

where G is the total initial gas in place in reservoir, in standard cubic feet, and T_R is the reservoir temperature, °F. For example, 1 lbm-mole of methane (molecular

weight 16.04) under standard conditions ($p_R = 14.7$ psia, $T_R = 60^\circ\text{F}$) occupies 379.4 cu ft.

The compressibility factor may be determined in the following ways.

1. Experimentally by PVT analysis of a gas sample.
2. By computation from an analysis of the gas expressed in mol% or volume %. With this method a weighted-average or pseudocritical pressure and temperature are obtained for the gas by multiplying the individual critical pressure and temperature for each component, with the corresponding mol% of such component as shown in Table 40.10.

The gas whose composition is given in Table 40.10 has a pseudocritical temperature of 382.8°R and a pseudocritical pressure of 663.2 psia. The pseudoreduced temperature then is found at a temperature of 150°F as $(460 + 150)/382.8 = 1.59$ and its pseudoreduced pressure

Fig. 40.14A—Compressibility factors for natural gases.

at 750 psia as $750/663.2 = 1.13$. These ratios are entered into the chart of Fig. 40.14A to read $z = 0.91$. This correlation chart⁴⁶ and an extended correlation chart⁴⁷ for higher-pressure gas reservoirs up to 20,000 psia, Fig. 40.14B, are designed for gaseous mixtures containing methane and other natural gases but substantially free of nitrogen. For hydrocarbon gases containing substantial amounts of hydrogen sulfide or CO_2 , these correlations do not apply, and additional corrections are necessary as described in Ref. 48. (See Chap. 20 for complete coverage of gas properties and gas property correlations, some of which are specific to computer applications.)

TABLE 40.11—PSEUDOCRITICAL CALCULATIONS FROM SPECIFIC GRAVITY

Specific gravity of Gas (Air = 1.0)	Pseudocritical Temperature (°R) (460 + °F)	Pseudocritical Pressure (psia) (14.7 + psig)

1.50	629	612
1.60	658	600
1.65	673	593

Fig. 40.16—Gas FVF $B_g = \frac{14.17}{p_R + 14.7} \frac{460 + T_R}{460 + 60} z$

and reciprocal gas FVF

$$\frac{1}{B_g} = \frac{p_R + 14.7}{14.7} \frac{460 + 60}{460 + T_R} \frac{1}{z}$$

vs. pressure, psig, and temperature, °F.
Gas gravity 0.7 (air 1.0).

3. By computation from the specific gravity of the gas. If only the specific gravity of the gas (air = 1.0) is known, another approximate correlation can be used, based on California natural gases,⁴⁹ which is expressed by Table 40.11.

For example, if the specific gravity of a gas is 0.66, the pseudocritical temperature can be estimated by interpolation as 381°R and pseudocritical pressure as 670 psia. The pseudoreduced values then are found as before and the z factor read from Fig. 40.14A.

Gas FVF

The gas FVF, B_g , is a dimensionless factor representing the volume of free gas at a reservoir temperature of $T^\circ\text{F}$ and a pressure of p psia per unit volume of free gas under standard conditions of 60°F and 14.7 psia. If the compressibility factor, z , is known, B_g may be computed by

$$B_g = \frac{14.7}{p_R} \frac{460 + T_R}{460 + 60} z = 0.02827 (460 + T_R) \frac{z}{p_R} \quad (36)$$

Typical values of the gas FVF, B_g , and the reciprocal gas FVF, $1/B_g$, for different temperatures and pressures and for gases of specific gravities between 0.6 and 1.0 will be found in Figs. 40.15 through 40.19.

In estimating gas reserves, the estimator should be careful to indicate clearly the pressure base at which the reserves are stated. Reserves at a base pressure of 14.4 psia will be approximately 16% greater than the same reserves stated at a base pressure of 16.7 psia.

Fig. 40.17—Gas FVF $B_g = \frac{14.17}{p_R + 14.7} \frac{460 + T_R}{460 + 60} z$

and reciprocal gas FVF

$$\frac{1}{B_g} = \frac{p_R + 14.7}{14.7} \frac{460 + 60}{460 + T_R} \frac{1}{z}$$

vs. pressure, psig, and temperature, °F.
Gas gravity 0.8 (air 1.0).

Fig. 40.18—Gas FVF $B_g = \frac{14.17}{p_R + 14.7} \frac{460 + T_R}{460 + 60} z$

and reciprocal gas FVF

$$\frac{1}{B_g} = \frac{p_R + 14.7}{14.7} \frac{460 + 60}{460 + T_R} \frac{1}{z}$$

vs. pressure, psig, and temperature, °F.
Gas gravity 0.9 (air 1.0).

The standard pressure base for the states of Texas, Oklahoma, and Kansas is 14.65 psia (14.4 lbm plus 4 oz/sq in.); for Colorado, Louisiana, Nebraska, Mississippi, Montana, New Mexico, and Wyoming it is 15.025 psia (14.4 lbm plus 10 oz/sq in.); and for California it is 14.73 psia).

Gas In Place

According to Eq. 1, the gas in place in a reservoir containing nonassociated gas and interstitial water, but no residual oil, in standard cubic feet of free gas, is

$$G_{Fi} = \frac{43,560 V_g \phi (1 - S_{iw})}{B_g}$$

Oftentimes the recoverable gas from a reservoir is estimated by multiplying the gas in place by an overall recovery factor.

For example, with a pressure gradient of 46.5 psi/100 ft of depth, a surface temperature of 74°F, a temperature gradient of 1.5°F/100 ft of depth, a specific gravity of the gas of 0.7, and a recovery factor for blanket high-permeability formations of around 80%, typical values of the recoverable gas in thousands of cubic feet per acre-foot is found in Table 40.12 for various combinations of porosity, ϕ , and interstitial-water content, S_{iw} .

The numbers in Table 40.12 are not directly applicable to wide-spaced low-permeability formations, such as those which require fracturing or other stimulation tech-

Fig. 40.19—Gas FVF $B_g = \frac{14.17}{p_R + 14.7} \frac{460 + T_R}{460 + 60} z$

and reciprocal gas FVF

niques to produce at commercial rates. In such cases allowance should be made for the fact that the economic limit of production may be reached before the entire spacing unit is depleted. Known or suspected lenticularity of the gas-bearing formation also should be taken into account in estimating the potential drainage area.

Unit Recovery for a Gas Reservoir Without Water Drive

Dry Gas. The unit-recovery factor (the theoretically possible ultimate recovery from a homogeneous unit volume of pay under ideal conditions) for a dry-gas reservoir without water influx is equal to the gas initially in place at pressure p_i , minus the gas remaining under abandonment pressure at ultimate recovery, p_a , both expressed in standard cubic feet per acre-foot of sand (Table 40.12). By difference, the unit recovery for a dry-gas reservoir, in standard cubic feet of gas per acre-foot, is

$$G_{ul} = 43,560\phi(1 - S_{iw}) \left(\frac{1}{B_{gi}} - \frac{1}{B_{ga}} \right), \quad (37)$$

where G_{ul} is the ultimate gas recovery from reservoir, in standard cubic feet, and B_{ga} is the gas FVF at abandonment, in reservoir cubic feet per standard cubic foot. The abandonment pressure (p_a) to be used depends on the operating pressure of the pipeline outlet, the availability of compressors to boost low-pressure gas to pipeline pressures, the depth of the reservoir, the size of the production tubing, and the permeability and pay thickness of the reservoir.

Gas Condensate. In gas-condensate reservoirs, condensation of hydrocarbon liquids may occur upon pressure drop in the reservoir and in the surface separation equipment. Condensation of liquids in the reservoir may cause the unit-recovery factor as computed for a dry-gas reservoir to be optimistic, because the volume of condensate in the reservoir at abandonment pressure is usually smaller than the reservoir volume of the gases at that pressure which condensed into liquid. Recovery of condensate in the surface separation equipment also reduces the amount of free gas available for sale. In rich gas-condensate reservoirs without water drive produced under pressure-depletion conditions, the recovery computations should therefore be based on an actual laboratory depletion study

of a recombined sample. If such an analysis is not available, an approximation may be made on the basis of the fact that the amount of free gas corresponding to 1 cu ft of condensate is usually about 150 to 200 scf. Based on an average figure of 175 cu ft (1 m³ of condensate on the average corresponds to 175 std m³ of gas), the unit recovery in terms of residue or sales gas, when the residual condensate saturation in the reservoir at abandonment time is S_{or} , and the average produced gas/condensate ratio is R_p scf/bbl, may be estimated, in standard cubic feet residue gas per acre-foot, as

$$G_{ul} = 43,560\phi \frac{R_p}{R_p + 175} \left(\frac{1 - S_{iw}}{B_{gi}} - \frac{1 - S_{iw} - S_{or}}{B_{ga}} - 175 S_{or} \right), \quad (38)$$

S_{or} may be estimated from a material-balance calculation on the condensate present in the reservoir gas under initial conditions, and the condensate to be recovered during the depletion of the reservoir in the surface separation equipment.

Effect of Permeability Distribution

Unless a gas reservoir is known to be permeable and homogeneous, the unit-recovery factor should be corrected for the fact that depletion may progress more rapidly in the high-permeability strata than in the low-permeability zones, particularly if these zones are separated by impervious strata. An uneconomic rate of production may be reached before the tighter zones are drained down to abandonment pressure. In many cases, nonuniformity of permeability in lateral directions provides a compensating influence. In very hard and tight formations, extensive fracturing may have the same result. A computation based on the assumption that the strata of different permeabilities are uniform and continuous across the reservoir is therefore in most cases too pessimistic. Such a computation does provide a means, however, to indicate the minimum recoverable reserves while the assumption of a completely homogeneous reservoir and the direct use of the unit-recovery factor indicate a maximum figure for the recoverable reserves.

A permeability-block method to compute such minimum reserves for a nonassociated dry gas reservoir is as follows.

According to Eqs. 13 and 14 of Sec. 11.15 in Ref. 50, the boundary pressure in a closed cylindrical gas reservoir, drained by a well in the center with zero pressure against the sandface, may be approximated as

$$p_R = \left(\frac{1}{p_i} + C_1 \frac{k_{rg}}{\phi_h} t \right)^{-1}, \dots \dots \dots (39)$$

while the gas production rate is

$$q_g = C_2 k_g h_e p^2, \dots \dots \dots (40)$$

in which C_1 and C_2 are constants and ϕ_h and h_e are effective hydrocarbon porosity and effective thickness, respectively.

It will be assumed that a large number of core analyses are available on a gas reservoir, which are divided in permeability groups as shown on Table 40.13. The average permeability, k , for each group is then corrected to the relative gas permeability, k_{rg} , at the given S_{iw} saturation. The average porosity, ϕ , for each group is corrected also to the effective hydrocarbon-bearing porosity, $\phi_h = \phi(1 - S_{iw})$.

It will further be assumed that each permeability group represents a separate and distinct homogeneous layer having a relative gas permeability k_{rg} and a hydrocarbon-filled porosity ϕ_h equal to the average for each group. Each layer is sealed off from the others and feeding into a common wellbore that is exposed to zero pressure.

To keep the computations as simple as possible it will further be assumed that the ideal-gas laws are applicable. The same method may be applied by taking the deviation from the ideal-gas laws into consideration, by assuming other than zero wellbore pressure, and by taking into account liquid condensation in gas-condensate reservoirs, but such computations soon become rather unwieldy.

By the time Group 1, comprising the highest permeability, is bled down to a pressure p_1 , a time t has expired, which according to Eq. 39 is equal to

$$t = \frac{(\phi_h)_1}{C_1(k_{rg})_1 p_i} \left(\frac{p_i}{p_1} - 1 \right), \dots \dots \dots (41)$$

The fractional pressure p_n/p_i in any layer n at this same time t is found by substituting the t value of Eq. 41 into Eq. 39.

$$\frac{p_n}{p_i} = \left[1 + \frac{(k_g)_n (\phi_h)_1}{(k_g)_1 (\phi_h)_n} \left(\frac{p_i}{p_1} - 1 \right) \right]^{-1}, \dots \dots \dots (42)$$

The combined production rate from all layers, q_n , at this time is, according to Eq. 40,

$$q_n = C_3 \sum_1^n (k_g)_n (h_e)_n \left(\frac{p_n}{p_i} \right)^2, \dots \dots \dots (43)$$

TABLE 40.13—CONDITIONS FOR UNIT RECOVERY EQUATION IN A DRY-GAS RESERVOIR

	Initial Conditions	Ultimate Conditions
Reservoir pressure	p_i	p_a
Interstitial water, cu ft/acre-ft	$43,560 \phi S_{iw}$	$43,560 \phi S_{iw}$
Free gas, scf/acre-ft	$\frac{43,560 \phi (1 - S_{iw})}{B_{gi}}$	$\frac{43,560 \phi (1 - S_{iw})}{B_{ga}}$

while the cumulative production from all layers, G_{pn} , at this time is

$$G_{pn} = C_4 \sum_1^n (\phi_h)_n (h_e)_n \left(1 - \frac{p_n}{p_i} \right), \dots \dots \dots (44)$$

in which C_3 and C_4 are constants.

The fractional production rate from all layers, f_{gn} , with respect to the initial production rate from all layers is, therefore,

$$f_{gn} = \frac{\sum_1^n (k_g)_n (h_e)_n (p_n/p_i)^2}{\sum_1^n (k_g)_n (h_e)_n}, \dots \dots \dots (45)$$

while the cumulative production from all layers as a fraction of the total gas in place in all layers is

$$\frac{G_{pn}}{G_n} = \frac{\sum_1^n (\phi_h)_n (h_e)_n [1 - (p_n/p_i)]}{\sum_1^n (\phi_h)_n (h_e)_n}, \dots \dots \dots (46)$$

Thus a rate-cumulative relationship may be established based on Eqs. 45 and 46, whereby the rate is expressed as a fraction or percentage of the initial rate, and the cumulative as a fraction or percentage of the gas in place. By selecting an appropriate economic limit rate the recovery factor can then be found. The computation procedure is illustrated with the example in Table 40.14.

Usually only three or four assumptions for the ratio p_i/p_1 are necessary to delineate the curve, which may then be plotted on semilog paper as shown in Fig. 40.20.

In this particular case, it could be estimated that the minimum recovery factor for this reservoir at a time when the production rate has declined to 1% of its initial value would be on the order of 74% of the gas in place.

Fig. 40.20—Permeability-block method for gas reservoirs without water drive.

Recovery From Gas Reservoirs With Water Drive

In the case of gas reservoirs with effective water drive, the pressure will be wholly or partially maintained by the movement of water into the reservoir as gas is withdrawn, the magnitude of the pressure decline being dependent on the rate of gas withdrawal with respect to the rate of water influx. Because the portion of the reservoir that will be ultimately invaded by water is not always predictable, and because the amount of gas that as a nonwetting phase may be bypassed by the water is difficult to estimate, the recovery from gas reservoirs with water drive is usually estimated by applying a recovery factor to the volume of gas originally in place as calculated by Eq. 1. The selection of this recovery factor depends on the thickness and homogeneity of the sand, the relative permeability of the sand to gas and water at varying gas saturations, and the geometry and dip of the gas-bearing strata.

Because gas is trapped and bypassed by the advancing water and because of the associated water production problems, recovery factors are significantly lower for gas reservoirs with water drive than for those producing by volumetric expansion. Typical factors range from 50 to 70% for water-drive gas reservoirs as compared with 70 to 90% for expansion-drive gas reservoirs.

Production-Decline Curves^{35,54-58}

General Principles

All estimates of ultimate recovery by extrapolation of a performance trend fundamentally follow the same pattern. The two quantities one usually wishes to determine are either remaining oil reserves or remaining productive life. Cumulative production and time, therefore, normally are selected as independent variables and are plotted as abscissas. A varying characteristic of the well performance that can be measured easily and recorded then is selected

as a variable to produce a trend curve. For extrapolation purposes this variable has to meet two qualifications: (1) its value must be a more or less continuous function of the independent variable and change in a uniform manner; and (2) it must have a known endpoint.

By plotting the values of this continuously changing dependent variable as ordinates vs. the values of the independent variable (cumulative production or time) as abscissas, and graphically extrapolating the apparent trend until the known endpoint is reached, an estimate of the remaining reserves or remaining life can be obtained. The basic assumption in this procedure is that whatever causes controlled the trend of a curve in the past will continue to govern its trend in the future in a uniform manner.

This extrapolation procedure is therefore strictly of an empirical nature, and a mathematical expression of the trend curve based on physical considerations of the reservoir can be set up only for a few simple cases.⁵⁴

Among the many dependent variables that can be used in estimates based on performance trends, the rate of production is by far the most popular when production is not restricted. In that case one commonly refers to production-decline curves. The two main types are rate/time and rate/cumulative curves for each of the two independent variables. Rate of oil production as the dependent variable has the advantage of always being readily available and accurately recorded. The endpoint requirement is also easily met, since known or estimated operating costs usually make it possible to determine accurately the economic-limit rate and thus the endpoint of the curve.

Gradual changes in the production rate of a well may be caused by the following.

1. Decreasing efficiency or effectiveness of the lifting equipment.
2. Reduction of productive index, or completion factor,⁵⁷ or increase in the skin effect⁵⁸ as a result of physical changes in and around the wellbore such as deposition of wax, salt, or asphaltenes from the produced fluids or the accumulation of loose sand, silt, mud, or cavings.
3. Changes in bottomhole pressure, GOR, water percentage, or other reservoir conditions.

To be used for reserve estimation, production decline caused by reservoir conditions must be distinguished from that caused by wellbore conditions or by failure of the lifting equipment.

The efficiency of the lifting equipment may be checked by conventional inspection for tubing or valve leaks, and the volumetric pump efficiency by dynamometer, sonic fluid-level tests, etc. Such tests may indicate the need for a pulling job to replace the downhole pumping equipment or gas-lift valves.

A study of the completion factor, skin effect, or productive index over a period of time by means of bottomhole pressure-buildup analysis^{57,58} may indicate an adverse wellbore condition that can sometimes be corrected by appropriate stimulation methods.

Unless defective conditions of the wellbore are detected or cured, the reserve estimates obtained by decline-curve analysis will be limited to those recoverable under existing and sometimes only partially effective wellbore conditions.

When the lifting equipment is operating properly and wellbore conditions are found to be satisfactory, a declining production trend must reflect changing reservoir con-

TABLE 40.15—SAMPLE CALCULATION OF ECONOMIC LIMIT FOR A WELL*

Crude price per bbl	28.00
Gas revenue per bbl	2.00
Total	\$30.00
Less production taxes	1.43
Less royalty (12.5% after production taxes)	3.57
Leaves net income per gross bbl	\$25.00
Estimated direct operating cost at economic limit	\$2,500 per month
Estimated economic-limit rate	100 gross bbl/month

*The price and taxation of oil and gas has changed significantly in the history of the industry. The estimated price anticipated to be in effect at abandonment time are appropriate for this calculation.

ditions, and the extrapolation of such a trend can then be a reliable guide for prediction of the remaining recoverable reserves.

Economic Limit

The economic-limit rate is the production rate that will just meet the direct operating expenses of a well. In determining this economic limit it is often advisable to analyze closely the expenditures charged against a well, and determine how much actually would be saved if the well were abandoned. This saving yields the best yardstick of the economic limit of production, because certain expenses may have to be continued if other wells on the lease are kept in operation. Table 40.15 is a sample calculation of the economic limit for a well.

Nominal and Effective Decline

There are two types of decline.⁵⁵ The *nominal decline* rate, a , is defined as the negative slope of the curve representing the natural logarithm of the production rate of q vs. time t , or

$$a = - \frac{d \ln q}{dt} = - \frac{dq/dt}{q} \quad (47)$$

Nominal decline, being a continuous function, is used mainly to facilitate the derivation of the various mathematical relationships.

The *effective decline* rate d , being a stepwise function and therefore in better agreement with actual production recording practices, is the rate more commonly used in practice. It is the drop in production rate from q_i to q_1 over a period of time equal to unity (1 month or 1 year) divided by the production rate at the beginning of the period, or

$$d = \frac{q_i - q_1}{q_i} \quad (48)$$

The time period may be 1 month or 1 year for effective monthly or annual decline, respectively.

TABLE 40.16—CONSTANT-PERCENTAGE DECLINE (EFFECTIVE DECLINE ¼ to 4% PER MONTH)

Different Types of Production-Decline Curves

Three types of production-decline curves are commonly recognized.⁵⁴ With *constant-percentage decline* the nominal decline rate, a , is constant, or

$$a = -\frac{dq/dt}{q}, \quad (49)$$

which after integration leads to the rate/time relationship

$$q = q_i e^{-at}, \quad (50)$$

After integrating a second time, the cumulative production at time t is obtained as expressed by the rate/cumulative relationship:

$$N_p = \frac{q_i - q}{a}, \quad (51)$$

From Eq. 50, the remaining life to abandonment time may be obtained as

$$t_a = \frac{\ln F_q}{a}, \quad (52)$$

in which $F_q = q_i/q_a$, or, by elimination of decline a with Eq. 51,

$$t_a = \frac{N_{pa}}{q_i} \left(\frac{F_q \ln F_q}{F_q - 1} \right) \quad (53)$$

In other words, the future life under constant-percentage decline will be $(F_q \ln F_q)/(F_q - 1)$ times as long as the life required to produce the same ultimate N_{pa} at constant rate q_i .

With *hyperbolic decline* the nominal decline rate a is proportional to a fractional power n of the production rate, this power being between 0 and 1, or

$$a = -\frac{dq/dt}{q} = bq^n, \quad (54)$$

in which the constant b is determined under initial conditions by

$$b = \frac{a_i}{q_i^n}. \quad (55)$$

After integration the following rate/time relationship is obtained:

$$q = q_i (1 + na_i t)^{-1/n}. \quad (56)$$

After a second integration the cumulative production at time t is obtained as expressed by the rate/cumulative equation

$$N_p = \frac{q_i^n}{(1-n)a_i} (q_i^{1-n} - q^{1-n}). \quad (57)$$

Under certain conditions, production obtained by gravity drainage will follow this type of decline for the exponent $n = 1/2$ (Ref. 35). The rate/time relationship then reads

$$q = \frac{q_i}{[1 + (a_i/2)t]^2} \quad (58)$$

and the rate/cumulative relationship

$$N_p = \frac{2\sqrt{q_i}}{a_i} (\sqrt{q_i} - \sqrt{q}). \quad (59)$$

From Eq. 58 the remaining life to abandonment time for this special case of hyperbolic decline ($n = 1/2$) may be obtained as

$$t_a = \frac{2(\sqrt{F_q} - 1)}{a_i}, \quad (60)$$

96	0.2989248	55.3849412	0.2343571	50.2772181	0.1836224	45.8337740	0.1437816	41.9547020
108	0.2570438	58.6935382	0.1954848	52.8298360	0.1485650	47.8019996	0.1128278	43.4714366
120	0.2210306	61.5385833	0.1630601	54.9590562	0.1202007	49.3944488	0.0885379	44.6616435

or, after elimination of initial decline a_i by Eq. 59,

$$t_a = \frac{N_{pa}}{q_i} \sqrt{F_q} \quad (61)$$

In other words, the future life under hyperbolic decline ($n = 1/2$) will be $\sqrt{F_q}$ times as long as the life required to produce the same ultimate N_{pa} at constant rate q_i .

With harmonic decline, the nominal decline rate a is proportional to the production rate, or

$$a = -\frac{dq/dt}{q} = bq, \quad (62)$$

in which the constant b is determined under initial conditions by

$$b = \frac{a_i}{q_i} \quad (63)$$

After integration, the following rate/time relationship for harmonic decline is obtained:

$$q = \frac{q_i}{1 + a_i t} \quad (64)$$

After a second integration the cumulative production at time t is obtained as expressed by the rate/cumulative relationship

$$N_p = \frac{q_i}{a_i} \ln \frac{q_i}{q} = \frac{q_i}{a_i} \ln F_q \quad (65)$$

From Eq. 64, the remaining life to abandonment time may be obtained as

$$t_a = \frac{F_q - 1}{a_i} \quad (66)$$

or, after elimination of initial decline a_i with Eq. 65,

$$t_a = \frac{N_{pa}}{q_i} \left(\frac{F_q - 1}{\ln F_q} \right) \quad (67)$$

In other words, the future life under harmonic decline will be $(F_q - 1)/\ln F_q$ times as long as the life required to produce the same ultimate N_{pa} at constant rate q_i .

Relationship Between Effective and Nominal Decline. The effective decline rate d (or d_i for initial conditions) for the three types of production-decline curves is related to the nominal decline rate a (or a_i for initial conditions) as follows.

$$d = 1 - e^{-a} \quad (68)$$

and

$$a = -\ln (1 - d) \quad (69)$$

For hyperbolic decline,

$$d_i = 1 - (1 + na_i)^{-1/n} \quad (70)$$

and

$$a_i = \frac{1}{n} [(1 - d_i)^{-n} - 1] \quad (71)$$

For harmonic decline,

$$d_i = \frac{a_i}{1 + a_i} \quad (72)$$

and

$$a_i = \frac{d_i}{1 - d_i} \quad (73)$$

An analysis of a large number of actual production-decline curves assembled by Cutler⁵⁶ indicates that most decline curves normally encountered are of the hyperbolic type, with values for the exponent n between 0 and 0.7, while the majority fall between 0 and 0.4. Gravity-drainage production under certain conditions will have an exponent $n = 0.5$ (Ref. 59). The occurrence of harmonic decline ($n = 1$) is apparently rare.

Decline Tables for Constant-Percentage Decline

Tables 40.16 and 40.17 will facilitate computations of future rates and cumulative production for constant effective decline percentages 100*d*, from ¼ to 10% per month. Hand-held calculator and computer programs are available for constant-percentage decline and other types of production-decline calculations.

With constant-percentage decline the production rate in successive months may be designated as a geometric series,

$$(1-d)(1-d)^2(1-d)^3 \dots (1-d)^t$$

in which the rate during the last month preceding the period studied equals unity. For each monthly decline percentage 100*d* the "Rate" column in the decline tables represents the production rate per month $(1-d)^t$ after the number of months *t* shown in the left and right time columns has expired. The cumulative production,

$$\frac{(1-d)[1-(1-d)^t]}{d},$$

after *t* months is shown in the columns labeled "Cumulative."

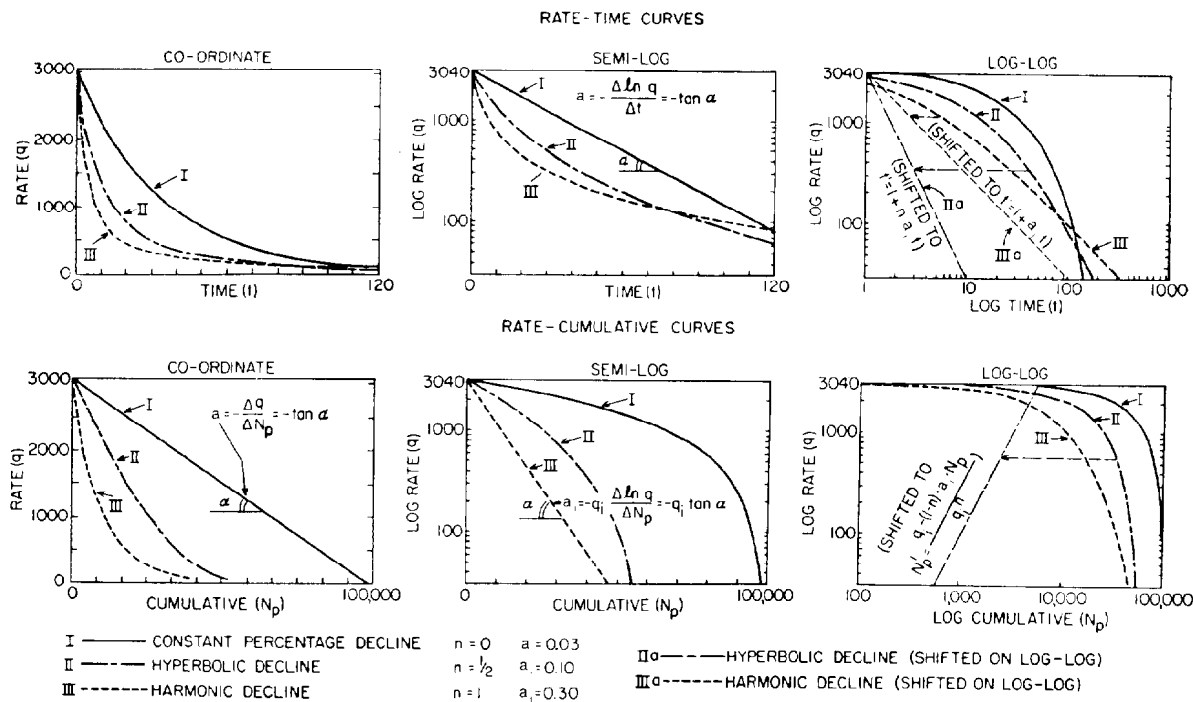

Fig. 40.21—Three types of production-decline curves on coordinate, semilog, and log-log graph paper.²

Example Problem 7. The production from a lease has declined from 4,286 to 3,000 bbl/month in 10 months. Assuming constant-percentage decline, what is the monthly decline and what will be the production rate 40 months later and the cumulative production over this 40-month period?

Solution. (See Table 40.16.)

$$3,000 \div 4,286 = 0.700.$$

Following the 10-month horizontal line, a rate of 0.700 is encountered in the table for 3½% decline per month. Rate 40 months later:

$$3,000 \times (\text{rate})_{36} \times (\text{rate})_4 = 3,000 \times 0.27732 \times 0.86718$$

$$= 721 \text{ bbl/month.}$$

Cumulative production over 40-month period:

$$3,000 \times [(\text{cum.})_{36} + (\text{rate})_{36} \times (\text{cum.})_4]$$

$$= 3,000 \times (19.92528 + 0.27732 \times 3.66204) = 62,822 \text{ bbl.}$$

Straightening Production-Dcline Curves

Fig. 40.21 shows the rate/time and rate/cumulative trends of the three types of production-decline curves on regular coordinate paper, semilog paper, and log-log paper.

Inspection of this chart shows that in the case of constant-percentage decline the rate/time curve becomes a straight line on semilog paper, while the rate/cumulative curve straightens out on regular coordinate paper. In either case the tangent of the angle of slope is equal to the nominal-decline fraction.

In the case of hyperbolic-type decline curves the rate/time relationship as well as the rate/cumulative relationship can be straightened out after shifting to become straight lines on log-log paper. The shifted rate/cumulative curve in this case assumes a reverse slope. Besides the extra work involved in shifting, this type of paper also has the disadvantage that the horizontal scale on which the unknown variable is plotted usually becomes rather crowded at the point where the answer is desired. For this reason, special graph paper for hyperbolic decline has been designed,⁵⁴ which makes it possible to plot either time or cumulative on a linear scale and still obtain the advantage of straight-line extrapolation.

In the case of harmonic decline it may be noted that the rate/time relationship can also be straightened out on log-log paper after shifting, and assumes a slope of 45°. It may be of interest that in this case a plot of the inverse of the production rate vs. time on a linear scale also yields a straight line. The rate/cumulative relationship for harmonic decline becomes a straight line on semilog paper. The nominal-decline fraction in this case is equal to the rate times the tangent of the slope angle.

As a matter of convenience the semilog paper most often is used for rate/time extrapolations, while regular coordinate paper is favored for rate/cumulative extrapolations. Because straight-line extrapolation on this paper requires constant-percentage decline, it will be obvious that such extrapolations may provide results that are too conservative. Experienced engineers usually allow for this by graphically flattening the decline slope in the later stages.

A geometric construction method for such extrapolation is described by Arps.⁵⁴

Loss-Ratio Method

The inverse of the nominal decline rate $q/(dq/dr)$ is called the "loss ratio" and may be used in tabular form for extrapolation purposes and for identification of the type of decline. In constant-percentage decline the loss ratio is constant, while in hyperbolic decline the first derivative of the loss ratio is constant and equal to the exponent n . In harmonic decline the first derivative of the loss ratio is constant and equal to one.

Extrapolation of various production-decline curves by difference tables with the loss-ratio method is described in Ref. 54.

Relationship Between Reserves and Decline

From the rate/cumulative equation for constant-percentage decline,⁵⁵ it may be noted that the remaining reserves, N_r , are equal to the difference between the present production rate and the production rate at the economic limit, divided by the nominal-decline fraction, provided the same time units are used for determining both the decline and the production rates.

This leads to the following short cut: when the nominal decline is 1% per month, the remaining reserves are 100 times the difference in monthly production rates; for a nominal decline of 2% per month this ratio equals 50; for 3% it is 33⅓; for 4% it is 25, etc.

When production rates are on a daily or annual basis the same formula holds, provided the decline is expressed on the same time basis.

Other Performance Curves

Oil Percentage in Total Fluid vs. Cumulative Oil

Another variable that is often substituted for the production rate in water-drive fields—particularly when the production of oil is restricted—is the oil percentage of the total fluid produced. Because projections of this oil percentage vs. time are not often required, one usually finds this oil-percentage variable plotted only vs. cumulative. An example of such a curve on semilog paper is shown for a Tar Springs sand reservoir in Illinois in Fig. 40.22. The endpoint in this case is the lowest oil percentage that, combined with the total fluid-producing capacity of the lease, will just cover operating expenses.

Cumulative Gas vs. Cumulative Oil

It is a characteristic of most depletion-type oil reservoirs that only a fraction of the oil in place is recoverable by primary production methods. Gas, on the other hand, moves much more freely through the reservoir, and it can generally be assumed that at abandonment time only the

solution gas in the remaining oil at the then-prevailing pressure plus the free gas at that same pressure are left in the reservoir. In other words, even though it is not known exactly how much oil may be recovered, a much firmer idea is generally available of the amount of gas that will be produced during the primary production period. This provides us with the possibility of an endpoint to a performance curve. The cumulative-gas/cumulative-oil method is illustrated in Fig. 40.23. Cumulative oil production is plotted on the horizontal scale, while the cumulative gas production is plotted on the vertical scale. As is normal in depletion-type fields, the trend of the curve appears to steepen with increasing GOR's.

For depletion-type reservoirs, the GOR sometimes is plotted on semilog paper vs. cumulative oil. Such a curve often shows a fairly good straight-line relationship, which may be used to predict the trend of the cumulative-gas/cumulative-oil curve.

From a volumetric calculation an estimate is made of the total gas to be released from the reservoir down to an assumed abandonment pressure. This figure, which in this case was 1.42 billion cu ft, is marked on Fig. 40.23 as a horizontal line and represents the ceiling of the cumulative-gas/cumulative-oil curve.

By extrapolating the current trend until it intersects the estimate for the total gas available, we can obtain an estimate for the total primary oil recovery.

Material-Balance Method for Nonassociated Gas Reservoirs

The best performance variable in the case of free-gas reservoirs is the static formation pressure. This pressure usually is measured periodically by bottomhole pressure

bomb, or if there are no liquids present in the tubing, it may be calculated from observed shut-in tubing pressures.

The general material-balance equation for a gas reservoir with active water drive may be rewritten as*

$$\frac{1}{B_g} = \frac{1}{B_{gi}} - \frac{G_p + (5.615W_p/B_g)}{GB_{gi}} + \frac{5.615W_e}{GB_g B_{gi}} \quad (74)$$

For a gas reservoir without active water drive ($W_e=0$), this equation converts to*

$$\frac{1}{B_g} = \frac{1}{B_{gi}} - \frac{G_p + (5.615W_p/B_g)}{GB_{gi}}, \quad \dots \dots \dots (75)$$

and the same equation for a gas reservoir without active water drive ($W_e=0$) and without significant water production ($W_p=0$) reads

$$\frac{1}{B_g} = \frac{1}{B_{gi}} - \frac{G_p}{GB_{gi}} \quad \dots \dots \dots (76)$$

By plotting the reciprocal of the gas FVF, $1/B_g$, on regular coordinate paper vs. cumulative gas produced, G_p , or in case of appreciable water production vs. the term $G_p + 5.615(W_p/B_g)$, a straight line should result if no active water-drive mechanism exists (Fig. 40.24, Curve a). This straight line intersects the vertical axis at the value $1/B_{gi}$ and its extrapolation to the horizontal axis indicates the amount of free gas in place, G . When an active water drive exists, the plotted data fall on a curve

*Delete 5.615 if all volumes are cubic meters.

Fig. 40.22—Oil percentage vs. cumulative relationship on semi-log paper. Tar Springs sand production, Calvin Field, IL.

Fig. 40.23—Cumulative gas vs. cumulative oil recovery. Lake sand production, Bankline-Owen Field, TX.

Fig. 40.24—Graphical evaluation of material-balance equation for gas reservoirs.

with a gradually diminishing slope (Curve *b*), which intersects the vertical axis at the value $1/B_{gi}$. Extrapolation of the initial tangent of this curve to its intersection with the horizontal axis also indicates the amount of free gas in place, G .

Instead of plotting the reciprocal gas FVF, $1/B_g$, it is often more convenient to plot p/z on the vertical axis, as shown on the right side of the scale in Fig. 40.24. The ultimate gas recovery at the abandonment pressure, p_a , is then found by the intersection of the curve with the value p_a/z_a at abandonment time.

Fig. 40.25—Abandonment line (subsea) vs. cumulative oil recovery. Woodbine sand, East Texas field.

WOC or Abandonment Contour vs. Cumulative Oil

Another method that is sometimes practiced in the larger water-drive fields such as east Texas is to choose the depth of the WOC, or abandonment contour, as the dependent variable to be plotted vs. the cumulative oil recovery as the independent variable. The endpoint of this type of performance curve is the average depth of the top of the sand for a given lease. The method of extrapolation in this case is based on the simple assumption that whenever the abandonment contour progresses to the top of the sand the lease is ready for abandonment. An example of this is shown in Fig. 40.25.

Plotting this type of chart for many leases in the East Texas field indicates that the rise in the water table appears to be more or less proportional to the cumulative oil production.

A plot of p/z vs. cumulative gas production, such as Fig. 40.24, is theoretically sound and should give reliable results for normally pressured, constant-volume gas reservoirs. Typically, however, a plot of cumulative gas production for an overpressured gas reservoir (where reservoir pressure exceeds the normal hydrostatic or relaxation pressure) will yield two slopes. An initial slope will be observed above relaxation pressure, and a steeper slope will occur after reservoir pressure drops below relaxation pressure. The second slope will extrapolate correctly to yield initial gas in place and ultimate gas recovery. Solution of Eq. 77,⁶⁰ will yield results equivalent to extrapolation of the correct (second) slope if proper values of formation compressibility (c_f) and water compressibility (c_w) are entered:

$$G_p = G \left\{ \frac{\frac{p_i}{z_i} - \frac{p}{z} \left[1 - \frac{\Delta p_R (c_w S_{iw} + c_f)}{(1 - S_{iw})} \right]}{\frac{p_i}{z_i}} \right\} \dots (77)$$

Improved Recovery Reserves

Estimates of improved recovery reserves for conventional fluid injection and various enhanced recovery processes are often made by applying an overall reservoir recovery efficiency in a volumetric calculation. The overall reservoir recovery efficiency, E_R , may be expressed as the product of three efficiencies: the displacement (or microscopic) efficiency, E_D , the pattern sweep efficiency, E_P , and the invasion efficiency, E_I . The resulting volumetric equation for improved recovery reserves, N_{IR} , is

$$N_{IR} = E_R \left(\frac{7,758 A h \phi S_o}{B_o} \right), \dots (78)$$

where E_R is the recovery efficiency $= E_D \times E_P \times E_I$, fraction, S_o is the oil saturation at start of improved recovery process, fraction, and other symbols and units as previously defined.

Methods for estimating the various efficiency terms are presented earlier in this chapter and in Chap. 44. Reliable estimates of improved recovery reserves often require the use of reservoir simulation models (see Chap. 48) to account properly for process variables and reservoir heterogeneities.

Nomenclature

- a = nominal decline rate; the negative slope of the curve representing the natural logarithm of the production rate q vs. time t ; also the instantaneous rate of change of the production rate vs. time, divided by the instantaneous production rate q ; expressed as a decimal fraction with time in months or years
- A = area, in Eq. 29b in square feet, elsewhere in acres
- b = constant (in decline-curve analysis, Eq. 63)
- B_g = gas FVF, a dimensionless factor representing the volume of free gas at a reservoir temperature of T_R , °F, and a pressure of p_R , psia per unit volume of free gas under standard conditions of 60°F and 14.7 psia
- B_o = oil FVF; a dimensionless factor representing the volume of oil saturated with solution gas at reservoir temperature T_R and pressure p_R , per unit volume of stock-tank oil; it may be determined by PVT analysis of a bottomhole or recombined sample or obtained from appropriate correlation charts; a typical oil FVF relationship vs. gas solubility R_s would be of the type
- $$B_o = 1.05 + 0.0005R_s$$
- B_t = two-phase FVF for oil; a dimensionless factor representing the volume of oil and its original complement of dissolved gas at reservoir temperature T_R and pressure p_R per unit volume of stock-tank oil; this two-phase formation factor for oil, B_t , is related to the oil FVF B_o , the gas FVF B_g , the gas-solubility factor R_s , and the gas-solubility factor at the bubblepoint R_{sb} by
- $$B_t = B_o + 0.1781B_g(R_{sb} - R_s)$$
- c_f = compressibility of reservoir rock (formation); expressed as change in PV per unit PV per psi; c_f appears to vary inversely with rock porosity from 10×10^{-6} (10 microsips) for 2% porosity, to 4.8×10^{-6} (4.8 microsips) for 10% porosity, and 3.4×10^{-6} (3.4 microsips) for 25% porosity
- c_o = compressibility of reservoir oil; in volume per psi for undersaturated oil above the bubblepoint; typical values for c_o range from 5×10^{-6} (5 microsips) for low-gravity oils to 25×10^{-6} (25 microsips) for higher-gravity oils, with 10×10^{-6} (10 microsips) being a good average
- c_w = compressibility of interstitial water; in volume per volume per psi; although the water compressibility c_w varies somewhat with pressure, temperature, and the amount of salt or gas in solution, 3×10^{-6} (3 microsips) represents a good average value
- d = effective decline rate; the drop in production rate per unit of time (month or year) divided by the production rate at the beginning of the period; expressed as a decimal fraction
- E = parameter in Eqs. 29a and b
- E_R = recovery efficiency, fraction
- f_g = fractional flow of gas
- f_w = water fraction of flow stream in reservoir that consists of oil and water
- F_q = ratio of initial to final production rate q_i/q_a (in decline-curve analysis, Page 40-28)
- G = total initial gas in place in reservoir, scf
- G_{Fi} = free reservoir gas in place, scf
- G_p = cumulative gas produced, scf
- G_s = solution gas in place, scf
- G_{ul} = ultimate gas recovery from reservoir, scf
- h_e = effective thickness, ft
- h_l = average gross pay thickness, ft
- k = absolute permeability, md
- k_o = effective permeability to oil, md
- k_{rg} = relative permeability to gas as a fraction of absolute permeability
- k_{ro} = relative permeability to oil as a fraction of absolute permeability
- k_{rw} = relative permeability to water as a fraction of absolute permeability
- \ln = natural logarithm to the base e
- \log = common logarithm to the base 10
- m = ratio of initial reservoir free gas volume and initial reservoir oil volume; related to the amount of free initial reservoir gas G_{Fi} , the initial gas FVF B_{gi} , the amount of initial reservoir oil in place N , and the initial oil FVF B_{oi} by
- $$m = G_{Fi}B_{gi}/5.615NB_{oi}$$
- n = exponent (in decline-curve analysis)
- N = reservoir oil initially in place, STB
- N_{IR} = improved reserves, STB
- N_p = cumulative oil produced, STB
- N_r = remaining oil reserves as of date of study, STB
- N_{ug} = unit recovery by depletion or solution-gas drive, STB
- N_{ul} = ultimate recovery from reservoir, STB
- N_{uw} = unit recovery by water drive, STB
- p_c = critical pressure, psia
- p_R = reservoir pressure, psia; generally measured by bottomhole pressure bomb at a depth representative of the entire reservoir, e.g., the midpoint of the oil or gas column; although the vertical pressure gradient in oil fields may range from as low as 20 or 30 psi/100 ft to as high as 90 or 100 psi/100 ft of depth, typical hydrostatic gradients usually range from 44 to 52 psi/100 ft

q_a = production rate at abandonment, B/D

q_g = rate of gas production, scf/D

q_o = rate of oil production, B/D

q_t = rate of total fluid production, B/D (on Page 40-14 q_t designates the total flow rate of oil and free gas, on Page 40-18 the total flow rate of oil and water; both expressed in cubic feet per day under reservoir conditions)

R = instantaneous producing GOR, scf/STB

R_p = cumulative GOR, scf/STB, related to cumulative gas produced, G_p , and cumulative oil produced, N_p , by

$$R_p = G_p / N_p$$

R_s = solution GOR (gas-solubility factor); the number of standard cubic feet of gas, liberated under specified separator conditions, which are in solution in 1 bbl of stock-tank oil at reservoir temperature T_R and pressure p_R ; it may be determined by PVT analysis of a bottomhole or recombined sample or obtained from appropriate correlation charts. A typical gas-solubility relationship vs. pressure for medium-gravity crude, expressed in cubic feet per barrel, would be of the type

$$R_s = 135 + 0.25p_R$$

S^* = effective saturation, fraction

S_g = free-gas saturation under reservoir conditions, fraction of pore space

S'_g = free-gas saturation under reservoir conditions, fraction of hydrocarbon-filled pore space (Page 40-14):

$$S'_g = S_o / (1 - S_{iw})$$

S_{gc} = equilibrium (or critical) free-gas saturation, which is the maximum free-gas saturation reached when lowering the pressure below the bubblepoint, before the relative permeability to gas becomes measurable; expressed as a fraction of pore space under reservoir conditions

S_{gr} = residual free-gas saturation under reservoir conditions at abandonment time, fraction of pore space

S_{iw} = interstitial water saturation, fraction of pore space; generally determined by (1) analysis of water content of cores taken with a nonaqueous drilling fluid, (2) measurement of capillary pressure on cores, or (3) quantitative analysis of electrical logs

S_o = oil or condensate saturation under reservoir conditions, fraction of pore space

S_{or} = residual-oil saturation under reservoir conditions, fraction of pore space, generally determined by multiplying the residual oil saturation from core analysis by B_o

S_t = total liquid saturation under reservoir conditions, fraction of pore space:

$$S_t = 1 - S_g = S_o + S_w$$

t = time, days (Eq. 30) or months

T_R = reservoir temperature, °F, measured at a depth representative of the entire reservoir; e.g., at the midpoint of the oil or gas column. Vertical temperature gradients in oil fields range from 0.5 to 3°F/100 ft of depth with 1.5°F/100 ft being a good average

T_{sc} = standard temperature, 60°F

V = gross pay volume, acre-ft

V_g = net pay volume of the free-gas-bearing portion of a reservoir, acre-ft

V_o = net pay volume of the oil-bearing portion of a reservoir, acre-ft

W_e = cumulative water influx, bbl

W_p = cumulative water produced, bbl

z = compressibility factor for the free gas in the reservoir; a dimensionless factor, which, when multiplied by the reservoir volume of gas as computed by the ideal-gas laws, yields the true reservoir volume

Z = height, ft

γ_o = gravity of stock-tank liquid (oil or condensate), °API

Θ = angle of formation dip, degrees

μ_g = reservoir gas viscosity, cp, ranging from 0.01 cp at low temperatures and pressures to 0.06 cp for high gas gravities at very high temperatures and pressures, with 0.02 cp being a good average

μ_o = reservoir oil viscosity, cp, ranging from less than 0.1 cp for volatile oils under very high temperatures and pressures to very high values for low-gravity oils that will barely flow at all; most reservoir oils, however, fall between 0.4 and 2 cp

μ_w = reservoir water viscosity, cp, ranging from 0.2 cp at high temperatures to 1.5 cp at lower temperatures, with 0.5 cp being a good average

ρ_g = density of reservoir gas, g/cu cm

ρ_o = density of reservoir oil, g/cu cm

ϕ = effective porosity, as a fraction of bulk pay volume; generally determined by laboratory analysis of cores, side-wall samples, or cuttings; quantitative analysis of electrical, radioactivity, or sonic logs; typical values for ϕ range from as low as 0.03 in tight limestones, and from 0.10 to 0.20 in cemented and consolidated sandstones, to as high as 0.35 in unconsolidated sands

ϕ_h = effective hydrocarbon-bearing porosity, as a fraction of bulk pay volume, $= \phi(1 - S_{iw})$

Subscripts

a = abandonment time conditions
 b = bubblepoint conditions
 i = initial conditions

Key Equations in SI Metric Units

$$G_{Fi} = \frac{V_g \phi (1 - S_{iw}) 10\,000}{B_g}, \quad (1)$$

where

G_{Fi} is in std m³ of free gas,
 V_g is net pay volume of free gas-bearing portion of reservoir, in ha·m, and
 10 000 is m³/ha·m.

$$N = \frac{V_o \phi (1 - S_{iw}) 10\,000}{B_o}, \quad (2)$$

where N is reservoir oil initially in place, in m³, and V_o is net pay volume of the oil-bearing portion of a reservoir, in ha·m.

$$G_s = \frac{V_o \phi (1 - S_{iw}) R_s 10\,000}{B_o}, \quad (3)$$

where G_s is solution gas in place, in std m³, and R_s is solution GOR, in std m³/stock-tank m³ of oil.

$$N = \frac{N_p [B_i + B_w (R_p - R_{si})] - (W_i - W_p)}{B_{oi} \left\{ m \frac{B_o}{B_{oi}} + \frac{B_i}{B_{oi}} - (m+1) \left[1 - \frac{\Delta p_R (c_f + S_{wi} c_w)}{1 - S_{wi}} \right] \right\}}, \quad (5)$$

where

N_p is cumulative oil produced, in m³,
 R_p is cumulative GOR, in std m³/stock-tank m³,
 R_{si} is initial solution GOR, in std m³/stock-tank m³,
 W_e is cumulative water influx, in m³,
 W_p is cumulative water produced, in m³,
 Δp_R is change in reservoir pressure, in atm,
 c_f is compressibility of reservoir rock change, in PV per unit PV per atm, and
 c_w is compressibility of interstitial water, atm⁻¹.

$$N_p = \phi \left(\frac{1 - S_{iw}}{B_{oi}} - \frac{S_o}{B_o} \right) 10\,000, \quad (16)$$

where N_p is in m³/ha·m.

$$R = R_s + \frac{B_o \mu_o k_{rg}}{B_g \mu_g k_{ro}}, \quad (18)$$

where R is instantaneous producing GOR, in std m³/stock-tank m³, and R_s is solution GOR, in std m³/stock-tank m³.

$$E = \frac{0.009k \sin \Theta A (\rho_o - \rho_g)}{\mu_g q_t}, \quad (29b)$$

where A is area of cross section normal to bedding plane, in m², and q_t is total flow area, in res m³/d.

$$t = \frac{NB_o}{q_t (df_g/dS_g)}, \quad (30)$$

where N is in m³ and q_t is in m³/d.

$$G = \frac{82.057 z T_R}{p_R}, \quad (35)$$

where

G is reservoir volume, in cm³/g mol,
 T_R is reservoir temperature, in K, and
 p_R is reservoir pressure, in atm.

$$B_g = \frac{1}{p_R} \frac{(273.16 + T_R)}{(273.16 + T_{sc})} z = 0.00346 (273.16 + T_R) \frac{z}{p_R}, \quad (36)$$

where

T_{sc} is standard temperature, 15.56°C
 1 is standard pressure, in atm
 T_R is in °C, and
 p_R is in atm.

$$G_{ul} = 10\,000 \phi \frac{R_p}{R_p + 175} \times \left(\frac{1 - S_{iw}}{B_{gi}} - \frac{1 - S_{iw} - S_{or}}{B_{ga}} - 175 S_{or} \right), \quad (38)$$

where R_p is in std m³ gas/m³ condensate and G_{ul} is in std m³ residue gas/ha·m.

$$N_{IR} = E_R \left(\frac{10\,000 A h \phi S_o}{B_o} \right), \quad (78)$$

where A is in ha and h is in m.

Chapter 41

Valuation of Oil and Gas Reserves

Forrest A. Garb, H.J. Gruy & Assocs.*
Timothy A. Larson, Ernst & Whitney

Types of Oil and Gas Property Ownership

The most common types of oil and gas property ownership in the U.S.¹ are mineral interests, working interests, royalties, overriding royalties, net-profits interests, and production payments.

A mineral interest in a property is a part of the "fee simple" interest. In most states, the mineral interest can be severed from the surface interest and transferred by a mineral deed (in Louisiana, the mineral and surface interest cannot be severed in perpetuity). The owner of the minerals, either through fee simple title or by a mineral deed, can execute a lease of the oil and gas rights. Consideration paid for a lease is called a lease bonus. During the primary term of the lease, it can be held by paying rentals, production, or drilling activities. The rentals, usually called delay rentals, are paid in lieu of drilling or production. From an income-tax standpoint, these rentals are ordinary income to the lessor and are deductible by the lessee. For tax purposes, a bonus must be capitalized as a part of the cost of the lease by the lessee. This bonus is income that is subject to depletion for the mineral-interest owner; although if the lease is not eventually productive, the depletion taken must be restored to income in the year the lease is proved worthless.

A "royalty" or "royalty interest" is the mineral owner's share of production free of the expense of production. It is distinguished from a mineral interest by the absence of operating rights. The basic royalty interest usually is expressed as a fraction of the total production, such as $\frac{1}{8}$ of $\frac{1}{8}$, $\frac{1}{8}$ of $\frac{1}{4}$. Royalty has historically been subject to production taxes, federal excise taxes [Windfall Profits Tax (WPT)], and in some states, *ad valorem* taxes.

An "overriding royalty interest" is an interest in oil and gas produced free of the expense of production and in addition to the usual landowner's royalty. It continues for the life of the lease and is subject to production taxes, WPT taxes, and in some states, *ad valorem* taxes. An

overriding royalty interest is commonly expressed as a fraction of the revenue accruing to the working interest; for example, $\frac{1}{8}$ of $\frac{1}{8}$ of the total oil and gas produced.

In some areas, such as the Rocky Mountains, overriding royalties are often expressed as a percentage of $\frac{1}{8}$ of the total oil and gas produced.

A "net-profits interest" is a share of the gross production measured by the lessee's net profits from the operation of a specific tract of land. It is normally carved out of the working interest.

A "carried interest" is a fractional interest in an oil and gas property that gives the owner no personal obligation for operating or development costs. The operating or development costs attributable to such fractional interest are borne and paid by the owners of the remaining fractional working interest, who recoup such expenditures or an agreed sum out of production from the property.

A "production payment" is a share of the oil, gas, and other minerals produced from a tract of land, free of the cost of production, that terminates when a specific sum from the sale of the oil, gas, and other minerals has been realized by the owner of the interest. There is no personal liability to pay the sum specified in the instrument creating the production payment; the owner looks only to production from the tract of land for the sum specified. A production payment is usually expressed in dollars and may carry an incremental payment computed in the manner of interest. A production payment is said to be "carved out" when it is transferred out of another oil and gas interest. It is "reserved" when the interest is retained by the seller upon the sale of another oil and gas interest. Production payments limited to oil or gas only are called "oil payment" or "gas payment," respectively.

A reversionary interest is usually a portion of the working interest that reverts to another party on the occurrence of some defined event. This event is often the payout of the investment or some multiple of the investment or may be the passing of some defined time period.

*Author of the original chapter was Jan J. Arps (deceased).

TABLE 41.1—REVENUE INTERESTS

A owns: $\frac{1}{8}$ of $\frac{8}{8}$ less $\frac{1}{4}$ of $\frac{1}{8}$ of $\frac{8}{8}$ less $\frac{1}{8}$ of $\frac{1}{8}$ of $\frac{8}{8}$ or $\frac{5}{64}$ (of $\frac{8}{8}$) or	RI=0.07812
B owns: $\frac{1}{4}$ of $\frac{1}{8}$ of $\frac{8}{8}$ or $\frac{1}{32}$ (of $\frac{8}{8}$) or	RI=0.03125
C owns: $\frac{1}{8}$ of $\frac{1}{8}$ of $\frac{8}{8}$ or $\frac{1}{64}$ (of $\frac{8}{8}$) or	RI=0.01562

All or any part of each of these oil and gas interests may be purchased, sold, or mortgaged at the owner's election.

Each economic interest in a property represents the right to a certain fraction of the gross income from the sales of oil and gas [revenue-interest fraction (RI)], and an obligation to pay a certain fraction of the cost of production [working-interest fraction (WI)]. In the case of royalty interests, overriding royalty interests, carried interests, and production payments, the WI is zero because these interests are free of the cost of production.

A "working interest" is the lessee's or operating interest under an oil and gas lease. The typical oil and gas lease provides for a royalty to be paid to the lessor or other royalty owners, free of the expenses of production; the balance of the production represents the working interest of the lessee, and this part of the production bears the entire expense of production. The working interest created by an oil and gas lease may be further divided by the creation of overriding royalties, production payments, net-profits interests, and carried working interests. When there is one lessee under an oil and gas lease, he must pay the entire cost of production and his WI is 100%. Where two or more lessees jointly own a lease, the WI of each lessee when totaled should add up to 100% of the working interest under such lease. The various co-owners of such a lease normally enter into an operating agreement and designate an operator of the property. For example, for a joint-interest owner who owns a quarter of the working interest, the WI equals 0.25. The WI is in effect equal to the fraction of the cost of production that a lessee has to pay.

An RI, also referred to as net interest or division-order interest, is a fractional interest in the total gross revenue from a tract of land that represents the actual quantity of total oil and gas produced from such land attributable to an oil and gas interest in such land. An RI is commonly expressed as a decimal fraction of % of the gross revenue from such production.

An example may clarify the system. Landowner A leases his land for oil and gas purposes to D, retaining the usual $\frac{1}{8}$ royalty interest. In order to hedge against non-

productive development, A sells $\frac{1}{4}$ of his $\frac{1}{8}$ royalty to B and $\frac{1}{8}$ of his $\frac{1}{8}$ to C. A, B, and C thus become the royalty owners under the land mentioned above. Their RI's are computed in Table 41.1.

D, the original lessee, then conveys the lease to E, retaining $\frac{1}{6}$ of $\frac{7}{8}$ overriding-royalty interest. The lease is now said to be burdened with a $\frac{1}{6}$ override. D now owns $\frac{1}{6}$ of $\frac{7}{8}$ or $\frac{7}{48}$, or RI=0.05469.

To support him with his development and operating costs, E now sells one-fourth of his interest in the lease to F. E now owns $\frac{3}{4}$ of ($\frac{7}{8}$ of $\frac{8}{8}$ less $\frac{1}{6}$ of $\frac{7}{8}$ of $\frac{8}{8}$) or $\frac{31}{512}$, or RI=0.61524, while paying $\frac{3}{4}$ of the costs or WI=0.75. F now owns $\frac{1}{4}$ of ($\frac{7}{8}$ of $\frac{8}{8}$ less $\frac{1}{6}$ of $\frac{7}{8}$ of $\frac{8}{8}$) or $\frac{10}{512}$, or RI=0.20508 while paying $\frac{1}{4}$ of the costs or WI=0.25.

The working- and revenue-interest fractions pertaining to the various economic interests in this example should now each add up to unity, as shown in Table 41.2.

Valuation²⁻¹³

Determination of Fair Market Value

Fair market value of an oil- or gas-productive property, as commonly understood, is the price at which the property would be sold after exposure to the market for a reasonable period of time by a willing seller to a willing buyer, neither being under compulsion to buy or to sell, and both being competent and having reasonable knowledge of the facts.

Fiske,³ presenting the viewpoint of the Internal Revenue Service in 1956, listed six methods used to determine the fair market value in order of preferential weight: (1) an actual sale of the property near the valuation date; (2) a bona fide offer to sell or purchase the property near the valuation date; (3) actual sales of similar properties in the same or nearby oil and gas fields near the valuation date; (4) valuations made for purposes other than federal taxation near the valuation date; (5) analytical appraisals; and (6) opinions of qualified oil or gas operators.

This section deals with the determination of the fair market value of oil and gas properties by the analytical- or engineering-appraisal method, enumerated by Fiske as

TABLE 41.2—WORKING AND REVENUE INTEREST FRACTIONS

	Fraction of Working Interest (decimal fraction of costs)	Revenue- Interest Fraction (decimal fraction of revenue)
Landowner (Lessor)	0	0.07812
Royalty Owner	0	0.03125
Royalty Owner	0	0.01562
Overriding-Royalty Owner	0	0.05469
Operator	0.75	0.61524
Nonoperator	0.25	0.20508
Total	1.00	1.00000

Item 5. With this method, the appraiser estimates the recoverable hydrocarbon reserves from the property and appraises the probable future net income or cash flow to be realized from the production and sale of these reserves. While fair market value for a hydrocarbon-producing property is not a precise number, it can be approximated within rather close limits by use of the engineering-appraisal method.⁴

Preparing a Cash-Flow Projection

For the purpose of determining future net income or cash flow, oil and gas production should be forecast on information about future demand for petroleum or on the basis of purchase contracts if these govern but should not exceed the physical ability of the well or wells to produce. Where proration or market curtailment is in force, trends in oil and gas allowables or market should be considered.

Usually, the gross income from oil and gas sales to be obtained from such production is based by the appraiser on current posted prices for crude oil and on predicted economic conditions.

The constant price projections are required for financing and Securities Exchange Commission filings, while the predicted prices that are based on economic studies are used for business decisions.

Gas prices should be based on gas-purchase contracts in force on the properties being appraised. The effect of escalation clauses in such gas-purchase contracts, which are subject to future approval by regulatory agencies, are usually set out separately.

In most states, oil and gas production is subject to state, county, and local taxes payable by the producer. The producer customarily charges the appropriate part of these taxes to the various interests in a given property. Tax rates on oil and gas production in the various states have historically varied and may be obtained from the state regulatory agency. The taxes are usually collected by the pipeline company by deduction from the runs.

Corporation or private income taxes are normally considered outside the scope of an oil and gas property valuation, but some valuation formulas make indirect allowance for them. Tax ramifications can totally change the economics of a proposed transaction and related evaluation. For certain purposes, such as bank evaluations, income taxes, as an inherent part of the future income, are sometimes specifically included in the forecast.

Operating or production costs comprise the expenses required to produce the oil and gas and to maintain the leases. These costs, usually called direct lifting costs, include the cost of labor, field supervision, power, fuel, repairs, stimulation and/or recompletion of wells, plant repairs, transportation, insurance, and other such items. As the age of the wells increases, additional expenditures may have to be made to keep the wells in operating condition and possibly for disposal of produced salt water.

Capital expenditures include the cost of construction of gasoline plants, repressuring systems, additional development wells, artificial lifting equipment, engines, tanks, and other durable items required to produce all the economically recoverable oil.

An owner of a working interest in oil or gas properties pays the full amount of his working-interest share of direct costs and capital expenditures, but he pays production and federal excise taxes only on the production to his net

revenue interest. Royalty or overriding royalty interests, however, ordinarily bear none of the normal lifting costs or capital expenditures but do bear production and federal excise taxes on their revenue-interest portion of the oil or gas produced.

The gross income to be realized from the production of the revenue-interest portion of the oil and gas reserves, when reduced by the amounts necessary for production and federal excise taxes, the working-interest share of operating expenses, repairs, recompletions, and additional capital expenditures, is the future net income or the net cash flow generated from the production of the estimated oil and gas reserves. Salvage value of equipment at the time of abandonment is ordinarily not included in the cash-flow projection because such income is usually offset by the cost of properly plugging and abandoning the property in compliance with state regulations. An exception is sometimes made where the life of the property is short and such salvageable equipment minus abandonment costs constitutes a major part of the value.

After the technical analysis of the properties has been made, which results in a determination of the volume and rate of production of oil and gas, and these data have been reduced to a projection of future operating net income or cash flow, it becomes necessary to establish the appraisal value.

Analytical Methods for Computation of Appraisal Value

Although there are many methods for computing appraisal value, only the most popular will be discussed. All these compute the appraisal value of a property by the discounted-cash-flow procedure and give proper weight to the time pattern of future income. Appraisal values that are based on a given fraction of the undiscounted future cash income or on payout in a given number of years do not meet this requirement and are not included.

The examples provided are from the original edition of this handbook and reflect the economic conditions current at that time. The methodology remains valid, however, and any values in the examples would be subject to change with time.

Appraisal value equal to a fraction of the present worth of the net cash flow before federal taxes computed at a safe rate of interest. Method 1 is relatively simple, easy to understand, and widely used. It is based on the premise that future income should only be discounted at an interest rate that reflects the current-time value of money and that such interest rate—which fluctuates with the prevailing cost of money—is not used as a vehicle for the risk factor. In its application, the combined present worth of the future operating net income or cash flow is calculated by discounting the future annual cash-flow increments at prevailing or projected compound interest rates. An example of such a present-worth computation at an interest rate of 10%/yr is shown in Table 41.3. While Table 41.3 is a hand calculation, most calculations are made with electronic data processing equipment, as shown in Table 41.4.

The total present worth of the future net operating income, which in this example is \$1,499,941, is not to be construed as the market value of the oil or gas property. The purchaser of such a property logically is entitled to

0.40 through 0.32	45 through 60	4	68 through 98	78

a profit above the bank interest rate. Also, when cash flow is computed by this method, the federal income taxes on the operating net income usually are not deducted, and allowance must be made for them. In addition, a risk-of-doing-business factor is usually included.

Depending on whether cost-depletion or percentage-depletion allowance is applicable and depending on the amounts of future intangible development expenditures and equipment depreciation, this federal income tax liability will vary on the basis of the tax rate applicable to the interest owner.

The profit margin required in the transaction may also vary widely because of risks inherent in the operation of the property and the respective trading ability of the parties to the transaction.

In addition, in the opinion of many operators, the long-term inflationary trend may put a premium on future income from sales of a basic raw material, such as crude oil or natural gas.

Prospective purchasers should, therefore, weigh all these factors with the federal taxes payable and the risks of the operations as negative factors and the inflationary effects and possible additional "romance" in the transaction as plus factors. Thus they can arrive at the proper fraction of the present worth at some safe interest rate that they are willing to pay.

In a speech presented at the Petroleum Engineers Club of Dallas, Oct. 17, 1952, H.J. Gruy considered as fair market value "two-thirds of future net cash income before amortization and federal taxes, discounted at 5%/yr." This methodology is still in use. However, the discount rate at the time of the evaluation is substituted for the 5%/yr rate.

A study by Garb *et al.*¹⁰ in 1981 indicated that, in spite of varying tax and economic conditions, one classic yardstick for estimating the value of oil in the ground had remained reasonably constant through the years. An analysis of 10 major transactions during the period 1979-81, a volatile oil-price period, indicated that oil reserves in the ground demonstrated a market value of approximately one-third of their posted wellhead price.

Dodson⁹ listed in 1959, among some seven different methods that may be used to determine the fair market value of oil and gas reserves, "percentages of the present worth, which may vary from 50 to 100% but which recently have been from 75 to 80%."

A study by Arps⁶ of 34 actual property transactions made during the postwar years in the mid-continent, gulf coast, and California showed that the percentage of the 5% discounted value of future net cash income (before amortization and federal taxes) paid for these properties varied with their future lives, as shown in Table 41.5.

These data show a tendency for the average percentages of the last column to increase when the estimated life of the properties becomes longer. In none of these transactions did the total consideration exceed two-thirds of the undiscounted future net cash income before federal taxes. Fagin¹¹ introduced an empirical "market-value yardstick" that is based on the trend in actual prices paid for producing properties during the postwar years in long-life fields such as East Texas (see Table 41.6). To find the market value by this yardstick for constant-rate production of a similar character, the percentage shown in Col. 3 of the market-value-yardstick table for the applicable number of years of constant-rate production of Col. 2 of this table is determined. This percentage is then multiplied with the average 5% deferment factor of Col. 1 and with the undiscounted future net cash flow to yield the estimated market value.

Example Problem 1. A property with an estimated future net cash flow of \$1,000,000 and a 10-year constant-rate life would have a market value of $0.73 \times 0.79 \times \$1,000,000 = \$577,000$.

Solution. When the given cash-flow projection does not show a constant rate, the appropriate percentage is found in Col. 3, which corresponds to the applicable average 5% deferment factor from Col. 1 of Table 41.6. This percentage is then multiplied by the average 5% deferment factor of Col. 1 and by the undiscounted future net cash flow to yield the estimated market value.

Example Problem 2. A property with an estimated future net cash flow of \$500,000, which has a 5% discounted value of \$375,000 (average deferment factor 0.75), would have a market value of $0.72 \times 0.75 \times \$500,000 = \$270,000$.

While the examples use a 5% discount factor that is no longer valid, the methodology remains valid. Users of this technique should use discount rates appropriate for the time of the evaluation.

Appraisal value equal to the present value of the net cash flow before federal taxes computed at a speculative rate of interest. Unlike Method 1, the profit margin over and above bank interest rates to take care of inherent risks and federal income tax liabilities is incorporated in Method 2 the higher discount rate. The possible range of such speculative rates of return is reflected by various quotations from the literature. This method is, again, fairly

simple in its application, because federal income taxes are not included in the computation.

Use of Method 2 leads to comparatively high market values for properties of very short life. Because experience shows that very few transactions are made where the total consideration exceeds two-thirds of the future net cash income, experienced engineers in such cases usually limit their appraisal value to this maximum. This formula also tends to discriminate against long-life transactions because high speculative rates of return compound rapidly and reduce the value of cash-flow increments 20 to 30 years, hence to very small amounts. For example, Table 41.7 shows that the midyear lump-sum deferment

TABLE 41.7—MIDYEAR LUMP-SUM DEFERMENT FACTORS $F_{LS} = (1+i)^{1/2-t}$ (continued)

factor for income received in Year 30 amounts to 0.2371 for 5% interest, 0.0601 for 10% interest, and 0.0046 for 20% interest. Because of these shortcomings, the use of Method 2 is not recommended, particularly when long-life properties are involved with a high profit-to-investment ratio.

In a speech presented at the Oil and Gas Inst. in Dallas, March 26, 1949, E.L. DeGolyer commented, "It is rather surprising that more often than not the latter method, i.e. one-half of a 4% discounted future net revenue, is very close to the future net revenue (before amortization and federal taxes) discounted at 10½% per year."

Dodson⁹ listed in 1959 among some seven different methods that may be used to determine the fair market

value of oil and gas reserves, "rate of return on investment of apparently 14% or more."

From a study of five actual and representative valuations that have served as a basis for settlement for gift or *ad valorem* taxes, Reynolds⁷ concluded in 1959 that: "The range of from 13% to 21% annual rate of return before tax adjustments provides limits on which the engineer can operate." He also observed that the data from these appraisals "indicate that the project with a short life will demand a higher rate of return than one with a long life and low risk. This is probably caused by the investors' long-range faith in the oil industry, the belief that higher prices per unit are in the offing, and the fact that less money management is necessary for reinvesting earnings."

TABLE 41.7—MIDYEAR LUMP-SUM DEFERMENT FACTORS $F_{LS} = (1+i)^{-1/2-t}$ (continued)

The aforementioned rates of return were applied to the entire transaction, including the reserved production payment. Because of "leverage" afforded by the then-permitted ABC method of purchasing properties, the actual rate of return on the equity capital was higher than the rate of return for the transaction as a whole.

The calculated pretax internal rate of return remains a useful yardstick for establishing a fair market value. The acceptable rate of return at any time will be a function of comparative investment opportunities and the subjective assessment of the risk. At the time of this writing, pretax rate of return must fall between 20 and 30% to be competitive with other investment options.

Appraisal value equal to the present value of the net cash flow after federal income taxes computed at an intermediate rate of interest. Method 3 is the most sophisticated approach to the fair-market-value problem. It requires an actual computation of the federal tax liability for each year and is rather laborious. The method also requires tax and accounting information that may not be readily available to the evaluating engineer. Those favoring this method generally use electronic-data-processing facilities that reduce the actual work by the valuation engineer to the preparation of the basic input data. The rate of return in this type of computation comes close to the actual rate of return that, aside from price fluctuations and errors in estimating, may be realized on the purchase. If this method is followed, the fair market value may be defined as the cash value that, if paid for the property, would yield a satisfactory rate of return on the purchase price. A satisfactory rate of return or yield is one that is sufficient to induce the buyer to risk his funds in the particular project rather than in safer investments offering a lower yield. This rate must be commensurate with the physical hazards of producing and the economic hazards of future production. In principle, it is the same incentive recognized in the regulation of public utilities, where the reasonable rate of return upon the fair value of the property (the rate base) is held to be that sufficient to induce the investment of capital in establishing, maintaining, and expanding the property.

Check List of Data Required for Evaluation of Oil- and Gas-Producing Properties

Because the previously discussed evaluation procedures

are reflections of the pattern of future revenues, most evaluation methods are based on the predicted projections of oil and gas production. These projections are prepared either by extrapolating established trends in producing capacity or by academically estimating anticipated production on the basis of geologic interpretations and/or analogy (see Chap. 40).

To make a sound valuation of a given producing property, the appraiser requires certain basic data. The following check list may serve as a reminder when collecting such data.

Maps and Cross Sections. These include ownership maps, geological-structure maps, isopach maps, geological cross sections, etc.

Lease-Location Data. List leases to be included and show for each lease the lease name, number of producing wells, number of temporarily abandoned wells, total number of acres, field name, county, state, and legal description of lease.

Well Logs. These logs include all electrical, acoustic, and radioactivity logs that have been run in each well. Also, if available, geological-sample logs and directional well-survey reports should be included.

Core-Analysis Data. All core-analysis reports for the zones that have been cored and analyzed should be included.

Fluid-Sample-Analysis Data. This includes all bottom-hole fluid-sample-analysis reports and, for gas wells, gas-analysis, specific-gravity, or recombined-sample-analysis reports.

Well History. Chronological history of all well operations including original drilling and completion, recompletions, and remedial work to date should be included. If not otherwise included in a complete chronological well history, provide the following data for each well: conservation commission completion, potential test, and GOR reports; completion (and/or recompletion) date; elevation; kelly bushing, derrick floor, and ground level; total depth* and plugged-back depth; casing size and setting depth; tubing size and setting depth; drillstem test data including intervals tested, time open, fluid recovered, and bottomhole pressure (BHP) data; coring data, including intervals cored, footage recovered, and core description;

*All depths should be referred to a single datum for which the elevation above sea level is also given. The kelly bushing datum is preferred.

geological tops of all major formations encountered; well-location plats or location description; producing formation name, interval perforated, initial production and potential test data; depths to top, bottom, oil/water contact, and gas/oil contact; and pay thickness (gross feet and net feet).

Past-Production History. This history includes tabulation of oil, water, and gas production by months, by leases, by wells, and by pay zones since original completion. Also, include other past history reports, such as production methods (type and size of equipment and dates installed); BHP and wellhead pressure reports; open-flow potential test reports (gas wells); conservation commission (or USGS) production, allowable, and MER reports; pipeline run statements; water-disposal and treating reports; fluid-injection records; and production history of offset operations.

Current Production Data. Tabulate for each well the most current actual test of oil, water, and gas produced and include test date, choke size [or stroke length and strokes per minute (spm)], producing tubing pressure, and producing casing pressure. For gas wells, indicate latest shut-in tubing and casing pressures, including date well was shut in and duration of shut-in time.

Current-Allowable Data. Summarize allowable formula and current daily allowable rates for each well, per producing day, and per calendar day.

Gross Crude Price. For each lease, give the name of the crude purchaser, the average gravity of the oil, and the gross price paid. If the crude is trucked, show the trucking cost per barrel (may be obtained from pipeline run statements).

Gross Gas Price. For each lease, give the name of the gas purchaser and summarize the provisions of the gas contract such as the gross gas price per 1,000 cu ft, the contract pressure base, the minimum delivery pressure, the effective date and term of the contract, and escalation clauses (may be obtained from gas contracts and FPC approval certificates).

Severance and Local Taxes. Indicate the total value of both severance and local (state, county, school, etc.) taxes in terms of a percentage of the total gross income or as an amount per barrel of oil or Mcf of gas produced.

Federal Excise Tax (WPT) Information. This should include, where applicable, tier, company or entity classification for tax, natural gas classification, and price controls, if any.

Operating Expenses. Tabulate actual gross operating expenses per well per month for each lease during the past year. State whether such expenses include, in addition to all direct costs, such items as well-stimulation expenses, workover or recompletion expenses, a portion of district or division overhead expenses, or severance and *ad valorem* taxes.

Completion and Recompletion Costs. In case of undeveloped or nonproducing reserves, provide an estimate of completed well costs or recompletion costs for reserves behind the casing.

Division of Interests. Tabulate the working interest (fraction of $\%$ of the costs) and the revenue interest (fraction of $\%$ of the income) for each interest owner so that for each lease 100% of the working interest and 100% of the revenue interest lease is accounted for. Indicate the lease operator (copy of division orders for oil and gas).

Existing Production Payments or Liens. Tabulate the balance due on all production payments or liens as of a recent date and indicate provisions for the rate of payment.

Lease and Assignment Provisions. Summarize special provisions of all leases and assignments that may adversely affect the value of the leases. In particular, show special provisions concerning shallower or deeper rights and commitments or obligations for the drilling of wells (may be obtained from lease and assignment agreements).

Lease Facilities. Provide complete information concerning lease-facility wells, such as water wells, disposal wells, and injection wells. Provide specifications (size, capacity, etc.) for major lease-facility equipment, such as gas compressors, oil-treating plants, and water-injection plants.

Operating Agreements. In case of joint interest or unitized properties, provide a list of the basic provisions of the operating agreement, such as preferential rights to purchase other interests, obligations for development, basis of overhead allocation, and "call" on the oil (may be obtained from operating agreements and/or letter agreements).

Unitization Agreements. In case of unitized properties, provide a list of the basic provisions of the unitization agreement concerning the basis for calculation of participation percentages and future revisions of same owing to possible future adjustments in operating methods, unitized area, etc. (may be obtained from unitization agreements).

Special Reports. Provide a copy of all special geological and engineering reports that contain data pertinent to a current evaluation of the property. In particular, special engineering reports concerning plans for future development and secondary recovery operations may be helpful in projecting future production rates and future net operating income.

Income Tax Information. Include if applicable.

Forecast of Future Rate of Production¹²

Declining Production

When a property has a well-established performance history and the production rate shows a persistent decline, the appraiser should first make sure that this decline is not caused by either decreasing effectiveness of the lifting equipment or adverse wellbore conditions.

If he finds that the lifting equipment is operating properly and that the wellbore is clean, the past decline may be used as a guide for the projection of future production. First the type and rate of decline must be established.

Constant-Percentage Decline

When the drop in production rate per unit of time is a constant percentage of the production rate, the production curve is of the constant-percentage-decline type. This can best be demonstrated by plotting the production rate vs. time on semilogarithmic paper, with the production rate on the log scale, which should then show a straight-line trend. The production rate may also be plotted vs. cumulative production on regular coordinate paper, which should again show a straight-line trend for this type of decline (Fig. 40.1, Curve I). In either case, the slope of the curve represents the nominal decline fraction or percentage. The decline may also be found by observing the

Fig. 41.1—Graphical extrapolation of hyperbolic and harmonic rate/time curves on semilog paper. Step 1: Smooth out the given production curve, and select three equidistant points on it (A, B, and C). Step 2: Draw a vertical line midway between A and C through Point B. Step 3: Project A and C horizontally on this middle line and find Points A' and C'. Step 4: Draw A'D parallel to BC. Step 5: Project D back horizontally on the curve and find Point F. Step 6: draw DX parallel to FE, and find the unknown extrapolated Point X at the intersection with the horizontal line through E.

ratio between the production at the end of a given period and at the beginning of that period and obtaining the effective decline by interpolation from Table 40.16 or 40.17. For example, if the production rate from a well or lease declined from 4,286 to 3,000 bbl/month in 10 months, the ratio between these two production rates is 0.70, and one may read from Table 40.16 that such a drop in rate in 10 months corresponds to an effective decline of $3\frac{1}{2}\%$ /month.

The forecast may then be made on that basis either by reading the future rates from an extrapolation of the straight-line trend on the semilog decline chart or by computing the future rates by means of Table 40.16 or 40.17. Such extrapolation is then continued until the economic-limit rate of production is reached.

Hyperbolic Decline

When the drop in production rate per unit of time expressed as a fraction of the production rate is proportional to a fractional power n of the production rate ($0 < n < 1$), the production curve is of the hyperbolic-decline type.

This is usually evident from a plot of the production rate vs. time on semilog paper, which for this case will not follow a straight line but will show a gradual flattening out.

A rate-cumulative graph on regular coordinate paper will show the same type of curvature (Fig. 40.21, Curve II).

Hyperbolic-decline curves may be straightened out for extrapolation by plotting on double logarithmic or log-log paper after the curves are shifted by adding or subtracting a constant amount to all time or cumulative values. This is a laborious and, with the development of computers, outdated procedure. Most appraisers prefer a graphical extrapolation of the rate/time curve on semilog paper. Such extrapolation may be supported by actually

computing a few points of the curve by means of Eq. 60 of Chap. 40 or by using the graphical extrapolation method on semilog paper shown in Fig. 41.1, which is based on the "three-point rule"¹²: "For any two points on a hyperbolic rate-time curve, for which the production rates are in a given ratio, the point midway in between will have a production rate which is a fixed number of times the rate of either the first or the last point, regardless of where the first two points are chosen."

For example, when the three equidistant points on the past-performance portion of the curve show production rates of 2,000, 1,300, and 1,000 bbl/month, then the future time interval between the ordinates of 1,000 and 650 bbl/month must be equal to the time interval between the ordinates of 650 and 500 bbl/month.

The future projection is then obtained by reading the production rates from the graphically extrapolated curve. Hyperbolic decline is the most common form of production-decline trend found with nonprorated or capacity production. The fractional power n is usually between 0 and 0.50, with the latter value applicable to gravity-drainage-type production under certain conditions.

Harmonic Decline

When the drop in production rate per unit of time expressed as a fraction of the production rate is proportional to the production rate itself, the production curve is of the harmonic-decline type.

Such a curve, plotted as a rate/time graph on semilog paper, does not follow a straight line but shows a rather persistent, pronounced curvature. The rate-cumulative graph on regular coordinate paper shows the same strong curvature (see Fig. 40.21, Curve III).

Harmonic decline may be identified graphically by plotting the inverse of the production rate vs. time on regular coordinate paper, which should then show a straight line. It may also be demonstrated by plotting the rate-cumulative relationship on semilog paper, which should also follow a straight line.

Harmonic decline for production-decline curves does not occur very often, and extrapolation on this basis usually provides a projection that is too optimistic. It is occasionally applicable to capacity production from depletion-type gas wells or to nonprorated production from reservoirs with a bottomwater drive where it is economically feasible to lift and to dispose of large volumes of water.

Extrapolation of the rate/time graph may best be carried out by plotting the inverse of the production rate vs. time on regular coordinate paper and extending the straight line obtained.

A rate/time graph on semilog paper may also be extended by the same construction on the basis of the three-point rule for hyperbolic decline illustrated in Fig. 41.1.

Part Constant Rate—Part Declining Production

In the above discussion, it was assumed that past performance showed the production to be declining, and in such cases the projection is merely based on a continuation of that decline trend.

When no past decline trend is available because the property is relatively new or under proration or market curtailment, however, the appraiser must base his projection on a volumetric estimate of the ultimate recovery and

try to match the future performance of the property against this estimate. This is usually done by assuming a rate of decline typical for this type of production and computing, by means of Eq. 55 of Chap. 40, the cumulative recovery to be obtained when the production is declining from the prorated rate to the economic limit. The number of months of constant-rate production preceding this decline period is then found by subtracting the cumulative production at the appraisal date as well as the estimated production to be obtained during the decline period from the estimated ultimate recovery and dividing the result by the assumed monthly production rate under proration.

Proration or Market Curtailment

Historically, production frequently has been limited by proration. Future operations may encounter proration to guard against loss of reserves through wasteful operations or may encounter curtailment of production because of low market demand. These considerations must be projected in a proper assessment of properties located in affected areas.

Produced Product Prices

The volatility of international energy markets has eliminated any confidence in estimating future product prices on the basis of plots of historical data. Most evaluations are currently performed over a range of assumptions. Constant oil and gas price evaluations are most frequently required for securities registration and for financing purposes. Projected economic conditions that assume maximum and minimum cost and price assumptions are usually applied in management decisions.

Development and Operating Costs¹³⁻¹⁵

Development Costs

Costs of development include the drilling and completion of wells and such improvements as roads, buildings, pipelines, tanks, natural-gasoline plants, and power installations. These costs are changing constantly owing to both economic conditions beyond the control of the operator and technical improvements in drilling and production methods.

The drilling and completion of wells usually constitutes the chief item of expense for development. Shallow wells that are drilled with a portable outfit may cost as little as \$20,000. In the hilly districts of Kentucky, it may require a greater outlay to move the drilling rig to the location than the cost of the well itself. Costs on the high side, apart from exceptional experiences with mishaps or long fishing jobs, may reach tens of millions of dollars for 18,000 to 25,000 ft.

The initial exploratory well generally costs much more than the development wells, and the continued development of a field almost always brings lowered costs with improved methods and increased competition among contractors.

Tangible and Intangible Costs. For income-tax purposes, development costs are divided into two categories: tangible and intangible. Tangible development costs represent the physical property that has salvage value, such as derrick, pipe, and smaller equipment. They are capitalized and retired through annual charges to depreciation.

Intangible drilling and development costs are labor, power, fuel, freight and hauling, water, repairs, and other items that provide no salvage return after completion of the well or that have no physical identity. This class of costs may either be capitalized and retired through annual charges or written off as an expense item in the income account during the year it was incurred. Generally, the latter course is followed. The intangible costs make up 60 to 70% of the entire well cost; the percentage is greater with the shallow wells or any other wells where the casing program requires less pipe than usual.

Well Spacing. An important consideration in appraising undeveloped properties is the prevailing well spacing. Properties that are already fully drilled present no problem, but those that are yet to be developed require consideration of this feature because the future profits will be controlled greatly by the number of wells required.

The number of development wells commonly required as a matter of practical necessity by reason of offset, competitive situations, and the specific lease requirements and obligations is generally much larger than the minimum number of wells required for proper drainage.

Operating Expenses

These expenses cover the field operations necessary to bring the oil and gas to the surface and to deliver a salable product to the stock tank or the gas pipeline.

Direct Lifting Expenses and Direct Expenses. The operating costs are generally divided into direct lifting expenses at the property, such as labor, power, fuel, repairs, renewals, and into-the-field organization; or district expenses, such as supervision, engineering, accounting, timekeeping, warehousing, and general transportation, which in turn are distributed over a number of property units on some ratable basis.

In the determination of a proper measure of production costs for use in estimates, the appraiser may first ascertain the definite record of the property under consideration, or else he may draw on his experience with similar properties elsewhere.

Cost per Well-Month. Operating expenses are preferably expressed on a per-well-month basis rather than per barrel of oil produced. The field cost of operating any given well is the same, within reasonable limits, whether the amount pumped is large or small. The pumping assembly that is installed for pumping an 80-B/D well continues in use when less than half that amount is being produced, but the cost of the operation continues practically unchanged.

Average Cost per Barrel. The use of an average cost per barrel may be acceptable when the production rates are so severely restricted that they are expected to continue at a uniform pace over a considerable period of time. When the production is declining, however, the assumption of an average cost per barrel that is based on a past-experience figure for the property under consideration may lead to erroneous results. The reason is that, with declining production and constant or nearly constant per-well costs, the operating cost per barrel must increase with time until it equals the gross income at the economic limit.

TABLE 41.8—FIELD OR DISTRICT OPERATING COST

Labor, including benefits and transportation furnished	20 to 30%
District expense, including insurance, professional services, damages, etc.	20 to 30%
Repairs and maintenance	30 to 50%
Power, water, waste disposal, and oil treating	5 to 15%

In the case of constant-percentage decline, allowance may be made for this increasing tendency by computing a weighted-average operating cost per barrel with the following relationship:

$$O_u = \frac{O_i \ln q_i/q_a}{q_i - q_a} \quad (1)$$

where

- O_u = weighted average operating cost, dollars,
- O_i = operating expenses per well-month, dollars,
- q_i = initial production rate, bbl/D, and
- q_a = production rate at abandonment, bbl/D.

Example Problem 3. If the operating cost per well-month, O_i , is estimated at \$300, and if the initial production rate, q_i , is 2,113 bbl/well/month, while the economic-limit production rate, q_a , is 113 bbl/well/month, the weighted-average operating cost/bbl over the life of the property is

$$\frac{300 \ln 2,113/113}{2,113 - 113} = \$0.44.$$

In the case of hyperbolic decline ($n = 1/2$), Eq. 1 takes the form

$$\bar{O}_u = \frac{O_i}{q_i} \sqrt{q_i/q_a} \quad (2)$$

In the case of harmonic decline, this relationship reads

$$\bar{O}_u = \frac{O_i}{q_i} \left(\frac{q_i/q_a - 1}{\ln q_i/q_a} \right) \quad (3)$$

In the case of constant-rate production, the average operating cost per gross barrel is simply the estimated operating cost per well-month divided by the rate of production.

The most desirable cost estimate and the one that is conclusive if it can be ascertained is the actually recorded experience at the property subject to such modifications as may appear to be warranted in the judgment of the appraiser.

Range of Costs. Operating costs per well for primary production range from almost insignificant amounts per well-month up to \$10,000 or more per well-month. The latter rate is found offshore or where heavy equipment handles large volumes of water with the oil and where power and maintenance charges are high. Many farms throughout the eastern U.S. contain wells that yield less than 1/2 B/D;

their profitable operation is possible only because repair expenses are negligible and the men who milk the cows also attend the wells.

For entire fields or districts, operating costs generally break down as shown in Table 41.8. Labor and district expense are of about equal magnitude and together comprise about half the total operating costs. The other half is for repairs, maintenance, power, water, waste disposal, and oil treating.

Stimulation Costs. Stimulation costs—such as reacidizing, reshooting, refracturing, and other stimulation treatments—should be considered as part of the operating costs. Fracturing costs have mounted in recent years to where such stimulation expenses may add from 10 to nearly 100% to the operating costs.

Recompletion Costs. Operating costs generally cover only those expenses necessary to keep a well on production for a given productive interval. The cost of recompleting a well into a different producing zone, therefore, is normally treated as a development expense.

Ad Valorem Taxes. To the direct operating expenses should be added the *ad valorem* or property taxes. These taxes show a wide variation in different states and counties and may range from almost nothing to as high as 15%.

Trucking Charges. In case the property is not connected to a pipeline and oil must be trucked out, such charges are usually charged directly against the gross income from oil and gas sales on a per-barrel basis.

The various forms of *production taxes* and WPT's directly levied against the oil and gas produced and commonly collected by the purchaser are not normally included under operating expenses but are charged directly against the gross income from oil and gas sales.

Administration and Supervision

Under this heading are charged direction, executives, central-office expense, accounting, insurance, supervision, personnel relations, and public relations. They are generally designated as overhead as distinguished from the field and district controllable expenses. In many company records, the charges vary widely because of both management ability and the differences in accounting methods.

Production Taxes

Taxes levied directly against oil and gas produced by the various states and usually collected by the pipeline company come under a variety of names—such as gross production taxes, severance tax, excise taxes, stream-pollution taxes, conservation taxes, maintenance taxes, license taxes, school taxes, state taxes, or gas-gathering taxes.

Federal Taxes¹⁶

General

When a projection of future cash net income is made in the appraisal method previously described, provision for estimated federal income taxes is made before discounting such future projection to present worth. In this

method, income taxes are considered an inherent part of the cost of doing business that must be provided for out of the producing operation.

The producing properties that often have difficulties are those whose owners failed to provide for future income taxes. An oil producer may be able to continue exploration and drilling activities at an increasing rate so that his exploration expenses and intangible drilling deductions will reduce income taxes for a number of years. But if such an operator eventually runs out of drilling locations or funds for further development, he may be forced to sell property to meet his taxes or loan obligations. According to this method, the correct approach is to include federal income taxes in the cash-flow projection and to consider any tax savings obtainable through exploration and drilling activities solely as a credit to those activities, reducing their net cost. Often, the appraiser allows indirectly for such income taxes by a higher than normal discount rate or by taking a fraction of the present worth before income taxes. Computation of the net operating income after federal taxes requires a thorough understanding of current tax provisions. Because of the volatility of taxation, the tax consequences on the property valuation at the time of the appraisal should be verified. The most important points of federal tax provisions are summarized below.

Depletion is generally considered to be the gradual exhaustion of a wasting asset through production. The objective of the depletion allowance is to permit the taxpayer owing an economic interest a reasonable deduction for the estimated cost of the reserves thus exhausted. The 1954 Code, Sec. 611, as amended provides that, in the case of oil and gas wells, the taxpayer will be allowed to deduct a reasonable allowance for depletion and depreciation of improvements.

Cost depletion under this provision is computed by multiplying the depletable basis in the property at the end of the tax period, unadjusted by current period depletion, by a fraction, the numerator being unit sales for the taxable period and the denominator unit reserves at the end of the period plus unit sales during the period. In contrast, percentage depletion for oil and gas wells is 15% of the taxpayer's gross income from the property but cannot exceed 50% of its taxable income. It is also limited to 65% of the total taxable income of the interest owner/taxpayer, with any amount disallowed by this limitation deductible in a future year when sufficient taxable income exists. The taxpayer is permitted to deduct, and is required to adjust basis for, either cost or percentage depletion, whichever is highest.

Although cost depletion is limited to the recovery of the taxpayer's basis in the property, percentage depletion is not so limited; if the taxpayer has no depletable basis in a property or if the entire basis has been recovered through prior depletion charges, he may still continue to claim depletion computed on a percentage basis.

Percentage depletion is permitted only as a deduction to independent producers and royalty owners on a maximum of 1,000 B/D of oil equivalent. The deduction is not allowed to integrated oil companies. Gas production for this purpose is converted to oil equivalent volumes at a rate of 6 Mcf to 1 bbl oil. It should also be noted that the transfer of a proven property to another interest owner will generally cause the loss of the percentage

depletion deduction to the transferee with respect to that property.

In determining taxable income from the property for percentage-depletion purposes, deduction must be made not only for ordinary operating expenses of the specific property, including equipment depreciation, but also for intangible drilling and development costs and for a proportionate amount of the overhead properly attributable to the producing function. In determining the overhead allocation, it is customary to allocate general overhead expenses between the producing operations and the other activities carried on by the taxpayer, frequently in proportion to the expenses directly attributable to each activity, and then further to allocate that portion of the overhead attributable to the producing function among specific properties usually in relation to the direct expense from such properties.

Capitalized Leasehold Costs. Ordinarily, a depletable basis in an oil or gas property is of no particular advantage to the taxpayer. The items that must be capitalized as leasehold costs are direct costs (such as lease bonuses or lease-purchase prices) and acquisition costs (such as title-examination fees, recording fees, documentary stamps if any), and geological and geophysical expenses incurred as a result of which the taxpayer either acquires or retains a property interest. Delay rentals paid on unproductive properties may be expensed or capitalized at the election of the taxpayer, and if the taxpayer has elected to capitalize intangible drilling and development costs, such items are added to the depletable basis in the property.

Intangibles. While expenditures for tangible items of well equipment and related items are capitalized and recovered by periodic depreciation allowances throughout their useful lives, in the case of expenditures for intangible drilling and development costs (intangibles), the taxpayer in the oil and gas industry may elect to deduct such items when they are paid or accrued or to capitalize them for recovery through depletion allowances. Because percentage depletion is allowed without reference to the basis of the property, it is apparent that only in infrequent cases would the taxpayer choose to capitalize intangibles.

This concept requires that all costs of drilling and developing an oil property be divided into the two categories—tangible and intangible, the former to be recovered through depreciation. In general, items with a salvage value are classed as tangibles while intangibles embrace all items without a salvage value. Examples of intangibles include labor, fuel, repairs, hauling, and supplies used in drilling, shooting, and cleaning of wells; any necessary site preparation, such as ground clearing, drainage road making, surveying, and geological work; and in the construction of derricks, tanks, pipelines, and other physical structures necessary for drilling and preparation for production.

The decision to expense intangibles must be made by the taxpayer for his first taxable year in which intangibles are paid or incurred. The choice is available only to the owner of an operating or working interest who undertakes the risk of drilling on the property.

Once the capitalized cost and applicable depletion methods have been determined, the allowable depletion, D_A , is the higher of cost depletion, D_C , or percentage

depletion, if applicable, with the latter equal to 15% of gross income, V_{DE} , but limited as stated above under cost depletion.

The allowable depletion selected will therefore be 15% of gross depletion, V_{DE} , when

$$D_A = V_{DE},$$

where

$$V_{TI} > V_{DE} > D_C$$

and

$$V_{DE} = (0.15 \times V) < (0.65 \times I_T), \quad \dots \dots \dots (4)$$

where

D_A = allowable depletion, highest of D_C or lesser of V_{DE} and V_{TI} ,

V_{DE} = "percent of gross" revenue, percentage depletion,

V_{TI} = "50% of net" percentage depletion, equal to 50% of taxable net income, dollars,

D_C = cost depletion; portion of leasehold cost proportional to reserves produced in a given year, dollars,

V = gross revenue (value); the total earned income from oil and gas sales, dollars, and

I_T = interest owner's taxable income, dollars.

The allowable depletion selected will be 50% of net percentage depletion, when

$$D_A = V_{TI},$$

where

$$V_{DE} > V_{TI} > D_C$$

and

$$V_{TI} = 0.50 O_G C_{PT} V O_a C_I D_P, \quad \dots \dots \dots (5)$$

where

O_G = general overhead expenses, dollars,

C_{PT} = local production tax, dollars,

O_a = operating expenses per well-month, dollars,

C_I = intangible drilling and development costs, dollars, and

D_P = depreciation, the decline in value of tangible assets with use of passage of time (obsolescence),

or cost depletion, D_C , when

$$D_A = D_C,$$

$$D_C > V_{DE} > V_{TI},$$

$$D_C > V_{TI} > V_{DE},$$

$$V_{DE} > D_C > V_{TI},$$

$$V_{TI} > D_C > V_{DE},$$

and

$$D_C = \frac{s}{N_r + s} \times C_{dl}, \quad \dots \dots \dots (6)$$

where

C_{dl} = depletable leasehold cost basis at beginning of tax period, dollars,

N_r = reserves at end of tax period, bbl or Mcf, and

s = unit sales during periods.

Example Problem 4. An operator owns half of the working interest ($WI=0.50$) in a two-well lease that produced 20,000 bbl of oil during the taxable year. His revenue interest is $\frac{1}{2}$ of $\frac{7}{8}$ ($RI=0.4375$). The remaining reserves (Q) on Jan. 1 are estimated to be 50,000 bbl. His depletion leasehold cost (LC) on Dec. 31 of the taxable year is \$20,000. The gross income per barrel of oil produced is \$30, plus \$2 from associated gas sales. Local production taxes are 5% of gross income, or \$1.60/net bbl, while operating expenses, including district expenses and *ad valorem* taxes, are \$2,000/well/month. General overhead (GO) is \$1/net bbl. Intangible development cost during the year was \$40,000, while equipment depreciation is \$2/net bbl of oil produced. What is the allowable depletion?

Solution.

$$V_{DE} = 0.15 \times 0.4375 \times 20,000 \times 32 = 42,000.$$

$$D_C = \frac{20,000}{50,000 + 20,000} \times 20,000 = \$5,714.$$

$$V_{TI} = 0.50 \times [0.4375 \times 20,000 \times (30 + 2 - 1.60 - 1 - 2)$$

$$- 0.50 \times 40,000 - 0.50 \times 2 \times 12 \times 2,000] = \$97,875.$$

In this case, apparently, $V_{TI} > V_{DE} > D_C$ and the allowable depletion is therefore $D_A = V_{DE} = \$7,700$.

Alternative Minimum Tax. The Internal Revenue Code of 1954 has been amended at various times to include provisions requiring that a taxpayer pay a specified rate of tax on certain defined tax preference items. These preference items currently include two oil- and gas-related expenses: percentage depletion deductions in excess of the depletable basis in a specific property and certain intangible drilling and development costs. The latter item is not applicable to corporate taxpayers.

While the percentage depletion preference item is fairly self-explanatory, the determination of the intangibles that must be included as a preference item requires computation:

$$C_{IP} = C_{IX} - I_a.$$

TABLE 41.9—TIER AND RATE STRUCTURE, WPT

	Independent Producer (%)	Other than Independent Producer (%)
Tier 1 (oil other than Tier 2 or 3)	50	70
Tier 2 (stripper oil and certain U.S. government interests)	30	50
Tier 3 (newly discovered, heavy and incremental tertiary oil)	30	30
Tier 3 (newly discovered oil subsequent to May 31, 1979)	15	15

where

C_{IP} = preference intangible drilling costs, dollars,
and

C_{IX} = intangible costs minus C_{IA} , dollars.

I_a is the net income from productive oil and gas properties, defined as the aggregate amount of gross income from all such properties, less deductions allocable to the properties reduced by C_{IX} as set forth above.

This preference item can be reduced if the taxpayer chooses to capitalize all or any portion of the intangibles paid or incurred during the year.

Windfall Profit Tax. In April 1980, Congress passed the Windfall Profit Tax Act that was designed to tax the oil and gas interest owner on the windfall profit that was to be received as a result of the deregulation of domestic crude-oil prices. The taxable profit is the excess of the selling price over what the price would have been were it sold before decontrol, adjusted by an inflation factor. An additional adjustment is allowed for severance taxes imposed on the difference between the controlled and decontrolled price. The tax base is also limited to 90% of the net income from the property.

Once the tax base is determined, the appropriate tax rate must then be applied. Three tiers have been specifically defined into which all taxable crude oil falls. The rates applicable to each tier depend on the classification of the interest owner and the nature of the oil produced. Exemptions for certain interest owners and oil types are also provided. The current tier and rate structure is given in Table 41.9.

Newly discovered oil, which falls within Tier 3, is subject to a tax rate schedule that declines from 22.5% in 1984 to 15% in 1986 and thereafter.

Tax Consequences Related to Conveyances. Oil and gas taxation of property conveyances has evolved into a complex set of rules that are necessary because of the many variations of transactions that involve oil and gas interests. Any appraiser who is valuing an interest that includes tax consequences should be aware of the types of various transactions.

There are four primary methods of disposing of oil and gas interests: sale, sublease, special sharing arrangements in a partnership, and production payments. The acquisition of interests may involve the reciprocal of these methods as well as the receipt of an interest for services.

The sale/purchase of an interest provides the easiest forum within which to determine the tax consequences. The

seller will recognize gain that will be characterized as capital or ordinary, depending on various factors that involve the classification of the seller and the tax history of the property. The buyer will merely have basis in the property that should be allocated between the mineral interest and lease and well equipment. Note that an interest owner will often look to the appraiser for guidance regarding the amount that should be allocated to lease and well equipment.

A sublease commonly arises where the transfer of a working interest is burdened with a nonoperating interest retained by the assignor. Consideration received by the assignor is ordinary income because it is characterized as a lease bonus. Any basis in the property is attributed to the nonoperating interest that is depletable; it is not allowed as an offset to the income. The assignee's purchase price will be allocated between leasehold cost and lease and well equipment, if applicable.

Special sharing arrangements are frequently used in a partnership context to allow special allocation of certain items of income and deduction. The partnership allocation rules explained in the Internal Revenue Code and the regulations published by the Dept. of the Treasury should be used as a guide to confirm the tax treatment of such allocations. A problem exists in the standard "third for a quarter" transaction outside the partnership context; the expenses paid by the assignee attributable to the seller's retained interest are considered leasehold cost. They are not deductible even if they are in the nature of intangibles.

A production payment is the right to a specific share of production from an oil and gas property. Where the production payment is used to finance a project, it is treated as a loan by the lender and the interest owner who carved it out of production. Where a working-interest owner retains a production payment and conveys his working interest, he is treated as having sold his interest and should report the proceeds as income realized from the sale of the property. In certain instances, the holder of the production payment may be treated as owning an economic interest. As indicated previously, this would allow the possible deduction of depletion, subject to the restrictions discussed.

The acquisition of an interest in an oil and gas property is frequently made through the performance of services. At one time, it was generally believed that, at the date of transfer, the party receiving the interest was not involved in a taxable event. He, along with the other vendors, dealers, and professionals involved in the property, was merely contributing capital to enable its development. This position, while originally accepted by the Internal Revenue Service, has recently come under

Fig. 41.2—Discounted-cash-flow method. Rate of return $j' = \Sigma P / \Sigma C_B = P / C_B = \text{constant}$. At abandonment time, $C_i = \Sigma m_k$ (no interest).

Fig. 41.4—Morkill method. Rate of return $j' = \Sigma P / \Sigma (C_i - S) = P / (C_i - S) = \text{constant}$. At abandonment time t_a , $C_i = S$ (including interest).

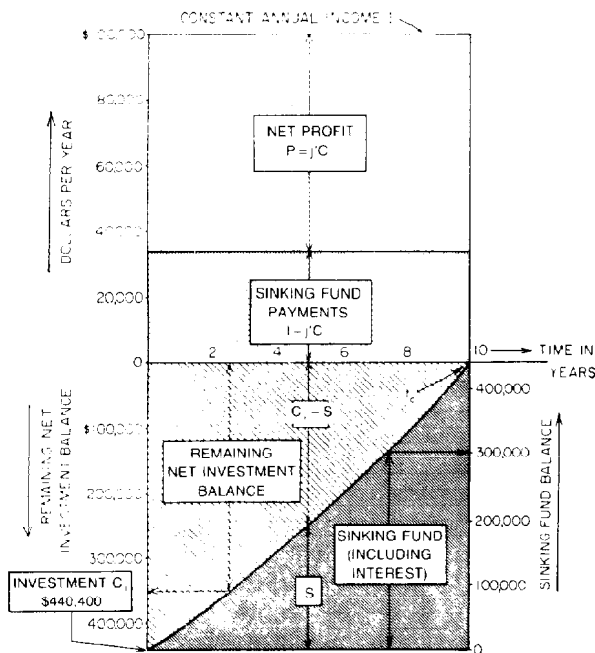

Fig. 41.3—Hoskold method. Rate of return $j' = P / C_i = \text{constant}$. At abandonment time t_a , $C_i = S$ (including interest).

attack and is being severely restricted. The government's current position is that in most instances, at the date of transfer, the taxpayer performing services recognizes taxable income. The issue is far from settled, and additional activity is expected to clarify the tax consequences of such transactions.

Different Concepts of Valuation

The literature includes many different methods that may be used to evaluate the known or estimated future projection of net income from a given venture.¹⁷⁻²⁰ One of them, the discounted-cash-flow method, illustrated in Fig. 41.2, simply reduces these future income payments to present worth or present value by a chosen rate of compound interest or rate of return. It represents the banker's approach to a stream of future income payments and is widely used in industrial work.

The *Hoskold method*, illustrated in Fig. 41.3, was specifically designed for ventures with a limited life, such as mines or oil or gas wells, and was first used in mine-evaluation work.

The *Morkill method*, illustrated in Fig. 41.4, is actually a refinement of the Hoskold method and is also mainly applicable to ventures with a limited life, such as mines and oil or gas wells.

The *accounting method*, illustrated in Fig. 41.5, represents the accounting approach to the valuation problem and takes into account the actual depletion pattern applicable to the given venture. It is particularly suited for those ventures where a specified total number of units of production is involved and where, as is the case in most extractive industries, the depletion applied to the original capital investment is on a unit-of-production basis.

Fig. 41.5—Accounting method. Rate of return $j' = \Sigma P / \Sigma C_B$. At abandonment time t_a , $C_i = \Sigma D_E$ (no interest).

Fig. 41.6—Average-annual-rate-of-return method. Rate of return $j' = \text{present worth of } \Sigma P / \text{present worth of } \Sigma C_B = \text{Area } ABCDE / \text{Area } FGHK$. At abandonment time t_a , $C_i = \Sigma D_E$ (no interest).

The *average-annual-rate-of-return method*, illustrated in Fig. 41.6, is essentially a refinement of the accounting method and, by applying the present-worth concept to both the net annual profits and the net remaining investment balances, simplifies the computations and properly weighs the time pattern of the income.

A complete summary of the basic equations for these different methods and their appraisal and rate-of-return equations will be found in Table 41.10. The top part of this table shows the equations for continuous compounding and the solution for the constant-rate case. The bottom part shows the appraisal equations and the rate-of-return equations for the general case where the cash flow, I , varies from year to year.

Discounted-Cash-Flow Method

This method, also referred to as the investors method¹⁸ or internal-rate-of-return method,^{17,18} is the one most often used in appraisal work. It is based on the principle that, in making an investment outlay, the investor is actually buying a series of future annual operating-income payments. The rate of return (with this method) is the maximum interest rate that one could pay on the capital tied up over the life of the investment and still break even. The time pattern of these future income payments is, therefore, given proper weight.

No fixed amortization pattern needs to be adopted with this method because the annual amounts available for amortization are equal to the difference between the net income and the fixed profit percentage on the unreturned balance of the investment. The computations necessary for a property evaluation are, therefore, relatively simple. They usually involve only the discounting of the pro-

jected cash flow to present value by means of the desired rate of interest.

The appraisal value is then

$$C_i = I_1(1+i')^{-1/2} + I_2(1+i')^{-1} + \dots + I_t(1+i')^{-1/2-t},$$

$$C_i = \sum_{n=1}^{n=t_a} I_n(1+i')^{-1/2-n}, \dots \dots \dots (7)$$

in which I_1, I_2, \dots, I_t represents the projection of the cash income in successive years and the compound-interest factor for the speculative effective interest rate i' is computed for the assumption that the entire income for each year is received at mid-year. Appropriate midyear compound-interest factors $(1+i')^{-1/2-t}$ will be found in Table 41.11 for speculative effective interest rates from 2 to 200%. In the case of oil-producing properties, the computed earning power by this method is not necessarily the same as the average rate of return later shown on a company's books for the net investment in the property. Most oil companies amortize their investments in producing properties in proportion to the depletion of the reserves or on a unit-of-production basis. However, no provision for such amortization pattern is made in the discounted-cash-flow method. When the production rate and the income both follow constant-percentage decline and the ratio between initial and final production rates is substantial, no serious difference will result. However, when the rate of production and the income are constant for a long period of time, a substantial difference may develop and the average rate of return, as shown later on the company's books, may be appreciably higher than the rate of return used in the evaluation by the discounted-cash-flow method.

TABLE 41.10—SUMMARY OF EQUATIONS APPLICABLE TO DIFFERENT VALUATION METHODS

Method	Discounted Cash Flow		Hoskold	
For continuous compounding, basic equation	$I dt = j' C_B dt - dC_B$ where $t=0$ $C_B = C_i$ $t=t_a$ $C_B = 0$	(8)	$I dt + jS dt = j' C_i dt + dS$ where $t=0$ $S=0$ $t=t_a$ $S=C_i$	(14)

Appraisal equation for constant annual income of I dollars per year	$C_i = \frac{(1 - e^{-j't_a})I}{j'}$	(9)	$C_i = \frac{(1 - e^{-j't_a})I}{j' - (j' - j)e^{-j't_a}}$	(15)
---	--------------------------------------	-----	---	------

Rate-of-return equation for constant annual income of I dollars per year	Solution for j' which will satisfy Eq. 9		$j' = \frac{I}{C_i} \frac{je^{-j't_a}}{1 - e^{-j't_a}}$	
--	---	--	---	--

General case: Appraisal equation	$C_i = \sum_{n=1}^{n=t_a} I_n (1 + j')^{1/2 - n}$	(7)	$C_i = \frac{\sum_{n=1}^{n=t_a} I_n (1 + i)^{t_a - n}}{1 + \frac{j'}{i} [(1 + i)^{t_a - 1}]}$	(10)
-------------------------------------	---	-----	---	------

or

$C_i = \frac{F_{PV} \Sigma I}{\frac{j'}{i} - \left(\frac{j'}{i} - 1 \right) (1 + i)^{-t_a}}$	(11)
---	------

Rate-of-return equation	Solution for i' that will satisfy Eq. 7		$i' = \frac{i \left\{ \frac{1}{C_i} \left[\sum_{n=1}^{n=t_a} I_n (1 + i)^{t_a - n} \right] - 1 \right\}}{(1 + i)^{t_a - 1}}$	(12)
-------------------------	--	--	---	------

or

$i' = \frac{i \left[\frac{F_{PV} \Sigma I}{C_i} - (1 + i)^{-t_a} \right]}{1 - (1 + i)^{-t_a}}$	(13)
---	------

The method may be illustrated with the diagram of Fig. 41.2, which shows the application of the discounted-cash-flow method to a venture that is expected to yield an income of \$100,000/yr evenly over a period of 10 yrs and where a speculative nominal rate of return j' of 15%/yr is desired. Time in years is plotted on the horizontal axis, while the constant income is represented by the horizontal line for \$100,000/yr in the upper part of the diagram. The top portion of the diagram shows how the portion of the total income, I , allocated to amortization, m_k , increases, while the net-profit portion (P) decreases with time. The bottom portion of the chart illustrates the manner in which the cumulative Σm_k gradually reduces the unreturned balance of the investment, $C_B = C_i - \Sigma m_k$, from its initial value, C_i , to zero at abandonment of the venture.

The computation of the curves for this constant-rate case is based on the basic differential equation for discounted cash flow,

$$I dt = j' C_B dt - dC_B, \quad (8)$$

where

I = yearly net income, dollars,

j' = nominal annual speculative interest rate,
fraction, and

C_B = balance of unreturned portion of
investment, dollars.

Integration of this equation for constant-rate income between the limits $t=0$, $C_B = C_i$ and $t=t_a$, $C_B=0$ leads to the appraisal value C_i for a nominal rate of return $j'=0.15$:

$$C_i = (1 - e^{-j't_a}) \left(\frac{I}{j'} \right) = [1 - e^{-(0.15)(10)}] \left(\frac{100,000}{0.15} \right) = \$517,900. \quad (9)$$

TABLE 41.10—SUMMARY OF EQUATIONS APPLICABLE TO DIFFERENT VALUATION METHODS (continued)

Morkill	Accounting	Average annual rate of return
$I dt + jS dt = j'(C_i - S)dt + dS \quad (18)$ where $t=0 \quad S=0$ $t=t_a \quad S=C_i$	$j' = \frac{\left(\frac{\Sigma I}{C_i} - 1\right) \Sigma I}{\Sigma I t_a - \int_0^{t_a} dt \int_0^t I dt}$ where $\Sigma I = \int_0^{t_a} I dt$	$j' = \frac{\left(\frac{\Sigma I}{C_i} - 1\right) \int_0^{t_a} I (1+j)^{-t} dt}{\Sigma I \int_0^{t_a} (1+j)^{-t} dt - k}$ where $k = \int_0^{t_a} dt \int_0^t (1+j)^{-t} I dt$ and $\Sigma I = \int_0^{t_a} I dt$
$C_i = \frac{[e^{(i+j')t_a} - 1]I}{j + j'e^{(i+j')t_a}} \quad (19)$	$C_i = \frac{t_a I}{1 + \frac{j' \cdot t_a}{2}} \quad (23)$	$C_i = \frac{t_a I \cdot (1 - e^{-t_a j'})}{j' t_a - \left(\frac{j'}{j} - 1\right)(1 - e^{-t_a j'})} \quad (22)$
Solution for j' that will satisfy Eq. 19 $C_i = \frac{\sum_{n=1}^{n=t_a} I_n (1+i+j')^{t_a-n}}{1 + \frac{j'}{j+i+j'} [(1+i+j')^{t_a} - 1]} \quad (16)$	$C_i = \frac{\Sigma I}{1 + j' \sum_{n=1}^{n=t_a} \left[1 - \frac{(N_p)^{n-1/2}}{(N_p)_a} \right]} \quad (20)$	$C_i = \frac{F_{PV} \Sigma I}{\frac{j'}{j} - \left(\frac{j'}{j} - 1\right) F_{PV}} \quad (24)$
Solution for j' that will satisfy Eq. 16 $j' = \frac{\frac{\Sigma I}{C_i} - 1}{\sum_{n=1}^{n=t_a} \left[1 - \frac{(N_p)^{n-1/2}}{(N_p)_a} \right]} \quad (21)$	$j' = \frac{F_{PV}}{(1 - F_{PV})} \left(\frac{\Sigma I}{C_i} - 1 \right) \quad (25)$	

Legend:

To find the rate of return corresponding to a given purchase price by the discounted-cash-flow method, no straightforward solution is possible; one has to resort to a trial-and-error procedure.

The curve for the unreturned balance, C_B , for this case is shown in the bottom portion of the graph, together with the cumulative amortization ($\Sigma m_k = C_i - C_B$). The corresponding amortization portion, m_k , of the income, I , is shown in the top portion of the graph.

It may be noted from Fig. 41.2 that the rate of return, j' , is the constant ratio of net profit ($P = I - m_k$) and the unreturned balance of investment ($C_B = C_i - \Sigma m_k$), and the balance, C_B , is declining slowly at first and faster toward the end and does not keep pace with the actual depletion of the source of income.

Hoskold's Method

Most industries and manufacturing enterprises have an indeterminate life (apparently perpetual) and are therefore not called on to replace the original investment. This does not mean that such enterprises will continue forever; it means merely that, except for competition, nothing is apparent that might cause termination. Because of this uncertainty, appraisal by the discounted-cash-flow method is generally the best method for such ventures.

Oil, gas, mining, and other extractive industries, however, differ from the foregoing enterprises. When the oil reservoir is depleted or the ore body mined out, there is no value left except possibly some equipment salvage. It is desirable to return the original capital to the investor by the time the profitable life of the enterprise is ended.

This leads to a somewhat different approach to the evaluation of enterprises in such extractive industries. One of the earliest methods, proposed by Hoskold in 1877¹⁹ for the mining industry, emphasizes complete return of the originally invested capital at abandonment time by means of a sinking fund. Hoskold's method presupposes a uniform rate of return at the speculative rate of interest i' on the original capital and provides for redemption of capital at abandonment time by annual reinvestment of the balance of the yearly earnings in a sinking fund at a safe rate of interest i . No fixed amortization pattern is used, but proper weight is given to the specific time pattern of the future cash-income payments.

The appraisal value by the Hoskold method is computed with

$$C_i = \frac{\sum_{n=1}^{n=t_a} I_n(1+i)^{t_a-n}}{1+(i'/i)[(1+i)^{t_a}-1]}, \quad \dots\dots\dots(10)$$

in which the numerator represents the combined value of the cash-income payments, I_n (no depreciation or depletion), computed at abandonment time (t_a) including compound interest at the safe rate (i) per year.

When the weighted average deferment factor or discount factor on the production rate and income projection (F_{PV}) is available at a safe interest rate of 5%/yr, this equation reduces to

$$C_i = \frac{F_{PV}\Sigma I}{(i'/i)-[(i'/i)-1](1+i)^{-t_a}}, \quad \dots\dots\dots(11)$$

The rate of return corresponding to a given purchase

price may be computed directly with the general rate-of-return equations.

$$i' = \frac{i \left\{ 1/C_i \left[\sum_{n=1}^{n=t_a} I_n(1+i)^{t_a-n} \right] - 1 \right\}}{(1+i)^{t_a} - 1}, \quad \dots\dots\dots(12)$$

or

$$i' = \frac{i[(\bar{F}_{PV}\Sigma I/C_i) - (1+i)^{-t_a}]}{1 - (1+i)^{-t_a}}, \quad \dots\dots\dots(13)$$

The interesting feature of this method is its concept of a safe or bank interest rate (i) that is used to build up the sinking fund to full return of the invested capital at the end of the project's life, while at the same time a constant speculative interest rate (i') is earned on the original capital investment (C_i) throughout the same period.

This speculative interest rate (i') is not comparable with the rate of return used in the discounted-cash-flow, accounting, or average-annual-rate-of-return methods because it applies strictly to the entire initial investment and not to the declining balances of such investment.

This method may be illustrated with Fig. 41.3, which shows what would happen to the net profit, the contributions to the sinking fund, and the sinking fund itself if the Hoskold method were applied to the same venture as before that yielded \$100,000/yr income evenly over 10 years. It was assumed that a speculative rate of return (j') of 15%/yr is desired, while the safe nominal interest rate (j) is 5%/yr. The constant-income rate (I) is again shown as the horizontal line in the top part of the diagram. This portion of the chart shows further that the net-profit portion of this annual income (P) is not declining as in the

previous case but is a constant percentage (15%) of the initial investment (C_i). The remaining portion of the income, which is diverted to the sinking fund, is also constant for this case.

The curve on the bottom part of Fig. 41.3 illustrates how the payments to the sinking fund plus interest at a safe rate build this fund up to where the entire initial investment (C_i) is available again at abandonment time.

Computation of the data for this constant-rate case is based on the basic differential equation for the Hoskold method:

$$Idt + jSdt = j'C_i dt + dS, \dots\dots\dots (14)$$

where

j = nominal annual speculative interest rate, fraction,

S = sinking fund balance, dollars, and

C_i = initial capital investment or purchase price, dollars.

Integration of this equation for constant-rate income between the limits $t=0$, $S=0$ and $t=t_a$, $S=C_i$ leads to the appraisal value C_i for a speculative interest rate ($j'=0.15$) and a safe nominal interest rate ($j=0.05$).

$$C_i = \frac{(1 - e^{-j't_a})I}{j' - (j' - j)e^{-j't_a}}$$

$$= \frac{[1 - e^{-(0.05)(10)}](100,000)}{0.15 - (0.10)[e^{-(0.05)(10)}]} = \$440,400. \dots (15)$$

Correspondingly, the constant-net-profit portion (P) of the annual income is $0.15 \times 440,400 = \$66,060$, while the annual sinking fund payment is $\$100,000 - \$66,060 = \$33,940$, as shown on the top portion of the diagram. The curve for the sinking fund (S) for this case is shown in the bottom portion of the figure together with the remaining unreturned portion of the investment ($C_i - S$).

It may be observed that the rate of return (j') is the ratio of the net annual profit (P) to the initial investment (C_i), and the remaining net investment balance ($C_i - S$) is declining somewhat more slowly in the beginning than in the end. Although the curvature is much less than in the discounted-cash-flow method, it still does not keep pace with the actual depletion of the source of income.

Morkill's Method

A variation of the Hoskold equation was proposed in 1918 by Morkill,²⁰ who felt that the risk or speculative rate of interest (i') should be expected only from the amount of capital remaining unreturned, while the security or safe rate of interest (i) should apply to the sinking fund.

The appraisal value by Morkill's method may be computed from

$$C_i = \frac{\sum_{n=1}^{n=t_a} I_n(1+i+i')^{t_a-n}}{1 + [i'/(i+i')][(1+i+i')^{t_a} - 1]}, \dots\dots\dots (16)$$

in which the numerator represents the combined value at abandonment time (t_a) of the annual cash-income payments, I_n (no depreciation), including compound interest at the total interest rate ($i+i'$).

It may be of interest to note that, if the safe interest rate (i) is zero, this equation reduces to the appraisal equation for the discounted-cash-flow method, if the compound-interest factors at the speculative rate (i') are applied at year end instead of midyear:

$$C_i = \sum_{n=1}^{n=t_a} I_n(1+i')^{-n}. \dots\dots\dots (17)$$

Appropriate year-end compound-interest factors $(1+i')^{-t}$ will be found in Table 41.11 for speculative interest rates from 2 to 200%.

To find the rate of return corresponding to a given purchase price for the Morkill method, no direct solution is possible, and one has to resort to a trial-and-error procedure. Morkill's method is illustrated in Fig. 41.4, which shows the net profit, contributions to the sinking fund, and growth of the sinking fund if this method were applied to the same venture as the other examples that yielded a \$100,000/yr income evenly over 10 years. As in the Hoskold method, it was assumed that a speculative nominal rate of return (j') of 15%/yr is desired, while the safe nominal interest rate (j) is 5%/yr.

The horizontal line in the top part of the diagram represents the constant-rate income (I) of \$100,000/yr. The other curves for this constant-rate case are computed from the basic differential equation for the Morkill method,

$$Idt + jSdt = j'(C_i - S)dt + dS. \dots\dots\dots (18)$$

Integration of this equation for constant-rate income between the limits $t=0$, $S=0$ and $t=t_a$, $S=C_i$ leads to the appraisal value (C_i) for a speculative nominal interest rate ($j'=0.15$) and a safe nominal interest rate ($j=0.05$).

$$C_i = \frac{[e^{(j+j')t_a} - 1]I}{j + j'e^{(j+j')t_a}}$$

$$= \frac{[e^{(0.20)(10)} - 1](100,000)}{0.05 + (0.15)[e^{(0.20)(10)}]} = \$551,560. \dots\dots (19)$$

The growth of the sinking fund is shown by the curve in the bottom portion of Fig. 41.4, together with the remaining unreturned portion of the investment ($C_i - S$). The net-profit portion (P) of the operating income (I) shown in the top portion is by definition equal to j' times the amount $C_i - S$. It may be noted from this chart that the rate of return (j') is the constant ratio of net profit (P) and the unreturned balance of the investment ($C_i - S$), and the sinking fund is growing slowly at first and faster toward the end and does not keep pace with the actual depletion of the source of income.

Accounting Method

This method, also referred to as the average-book method,¹⁸ is closely related to many of the concepts used in conventional oil-company accounting procedure and

computes the rate of return on a proposed investment as the ratio of the average net annual profits over the life of the venture (after depletion) to the average book investment over its life. It takes into account the actual depletion pattern and provides results that are compatible with the actual average rate of return later shown by a company's books. With amortization of an investment on a unit-of-production basis or in proportion to the depletion of the reserves, the appraisal value by this method may be expressed for the case where the net income per unit of production is constant as

$$C_i = \frac{\Sigma I}{1 + i' \sum_{n=1}^{n=t_a} \left[1 - \frac{(N_p)_{n-1/2}}{(N_p)_a} \right]}, \dots \dots \dots (20)$$

in which ΣI represents the total of the operating net income payments in successive years,

$$\sum_{n=1}^{n=t_a} I_n,$$

i' the desired speculative rate of return, $(N_p)_{n-1/2}$ the cumulative production at the midpoint of the n th year, and $(N_p)_a$ the cumulative production or estimated ultimate at abandonment time.

Although this method is comparatively simple, it has found only limited application.

The rate of return (i') for a given purchase price (C_i) may be computed directly by

$$i' = \frac{(\Sigma I/C_i) - 1}{\sum_{n=1}^{n=t_a} \left[1 - \frac{(N_p)_{n-1/2}}{(N_p)_a} \right]} \dots \dots \dots (21)$$

or for the constant-rate case by

$$j' = 2 \left(\frac{I}{C_i} - \frac{1}{t_a} \right) \dots \dots \dots (22)$$

Its principal features are illustrated in Fig. 41.5, which shows the net profit (P), the amounts reserved for depletion (D_E), and the cumulative depletion (ΣD_E) if the accounting method were applied to the same venture as before that yielded \$100,000/yr income evenly over 10 years. It was assumed that an average speculative rate of return (j') of 15%/yr is desired. The horizontal line in the top part of the figure represents the \$100,000/yr income rate. Because the income rate and the depletion of the reserves for this simplified case are assumed to be constant, the amounts reserved for depletion (D_E) are, therefore, also shown by a horizontal straight line. Simultaneously, the cumulative depletion in the bottom part of the diagram is a straight line running from zero in the beginning to the capital investment (C_i) at abandonment time (scale on right side).

By definition the rate of return (j') is the average net profit (P) divided by the average investment balance (C_B) and is also equal to the total of the annual net profits as represented by the area of Rectangle ABCD in the top

part of the diagram divided by the total of the annual investment balances as represented by the area of Triangle EFG in the bottom portion of the diagram or, algebraically,

$$t_a(I - D_E) = j' t_a \frac{C_i}{2},$$

while

$$D_E = \frac{C_i}{t_a},$$

so that, after substitution,

$$C_i = \frac{t_a I}{1 + \frac{j' t_a}{2}} = \frac{(10)(100,000)}{1 + \frac{(0.15)(10)}{2}} = \$571,400. \dots \dots \dots (23)$$

It may be noted that this method, in contrast to those previously discussed, allows for a depletion pattern that follows the actual depletion of the source of income. This is indicated for this constant-rate case by the diagonal straight line in the bottom portion of Fig. 41.5.

Average-Annual-Rate-of-Return Method

The average rate of return, computed by this method, is essentially the ratio of the present value of the future net profits (after depletion) to the present value of the net book investments over the life of a property.⁶ The method is particularly suited for investments in oil- and gas-producing properties, where amortization of the invested capital is customarily on a unit-of-production basis and, therefore, is proportional to the depletion of the reserves. The average annual rate of return used in this method corresponds closely to the one later shown by the company's books, while the time pattern of income payments is properly weighted. The equation is particularly simple in its application because the discounting to present worth needs to be done only for the safe interest rate (i). Because this interest rate is usually a fixed number, a series of weighted-average-deferment-factor charts for the most common types of production decline may be prepared in advance. Such charts for $i=0.05$ are shown in Figs. 41.7 and 41.8.

According to Arps,⁶ the appraisal value by the average-annual-rate-of-return method for the case where the net operating income per unit of production is constant may be computed from

$$C_i = \frac{\bar{F}_{PV} \Sigma I}{(i'/i) - [(i'/i) - 1] \bar{F}_{PV}} \dots \dots \dots (24)$$

where I represents the total of the operating net income payments in successive years,

$$\sum_{n=1}^{n=t_a} I_n,$$

Fig. 41.7—Lump-sum and constant-rate deferment factors for 5% interest.

and i' and i are the speculative and safe interest rates, respectively. \bar{F}_{PV} is the weighted average deferment factor on production and income at the interest rate i .

The rate of return (i') for a given purchase price (C_i) may be computed directly by means of the equation

$$i' = \frac{i\bar{F}_{PV}}{1 - \bar{F}_{PV}} \left(\frac{\Sigma I}{C_i} - 1 \right) \quad (25)$$

The relative simplicity of these equations derives from the fact that, with amortization on a unit-of-production basis, the deferment factor (\bar{F}_{PV}) for the production rate and the net operating income will be identical to the average deferment factor applicable to the annual amounts set aside for amortization. For further details of the derivation and equations, refer to Ref. 21. In cases where the deferment factor on the net operating income is not exactly equal to the deferment factor applicable to the production rates, such as when the lifting costs per barrel are increasing with time, it is customary to use the weighted average deferment factor applicable to the net operating-income projection in the equation.

The principal features of this method are illustrated in Fig. 41.6, which shows the net profit (P), the amounts reserved for depletion (D_E), and the cumulative depletion (ΣD_E) if the average-annual-rate-of-return method

Fig. 41.8—Constant-percentage-decline deferment factor for 5% interest.

were applied to the same venture as before that yielded a \$100,000/yr income evenly over 10 years. It was again assumed that an average speculative rate of return (j') of 15%/yr is desired. The horizontal line in the top part of the figure representing the annual depletion rate, and the diagonal line in the bottom portion of the diagram, representing the cumulative depletion, are the same as previously discussed for the accounting method shown in Fig. 41.5.

The average constant-rate deferment factor for continuous compounding, a safe nominal interest rate ($j=0.05$), and a total life ($t=10$ yrs) may be read from Fig. 41.7 as $\bar{F}_{CR}=0.787$ so that the initial capital investment (C_i) may be computed by means of Eq. 25 as

$$C_i = \frac{(0.787)(10)(100,000)}{(0.15/0.05) - [(0.15/0.05) - 1](0.787)} = \$551,900.$$

The present worth of the net profit, discounted at the safe interest rate ($j=0.05$) is shown by Curve ABC, while the present worth of the net remaining investment balances at the same rate of interest is shown by Curve GHK in the bottom part of the diagram. The speculative rate of return (j') with this method is then graphically represented by the ratio of Area ABCDE and area FGHK.

Interest Tables and Deferment Factors¹⁷

Simple and Compound Interest

Interest rate is the ratio between the amount paid for or gained from the use of funds and the amount of funds used.

Simple Interest. In simple interest, the interest to be paid on repayment of a loan is proportional to the length of time the principal sum has been borrowed. For example, on a loan of \$100 at a nominal interest rate of 6%/yr for a period of 2 months, the interest due upon repayment of the loan would be $0.06 \times \$100 \times \frac{2}{12} = \1.00 . Loans are rarely made at simple interest for periods of more than 1 year.

Compound Interest. In compound interest, the loan is increased by an amount equal to the interest due at the end of the interest period—e.g., on a loan of \$1,000 at an interest rate of 5%/yr for a period of 4 years, the total amount due upon repayment of the loan would be $1.05^4 \times \$1,000 = \$1,216$.

Compounding can be annually, semiannually, quarterly, monthly, or continuously, depending on the length of the stipulated interest period.

Effective and Nominal Interest

The effective annual interest rate (i) is the total compound interest over a year's time, expressed as a fraction or percentage of the amount outstanding at the beginning of the year.

The nominal annual interest rate (j) applies when the interest is compounded over M periods in a year and is equal to M times the interest rate j/M for one period. When interest is compounded once a year, the nominal (j) and effective (i) interest rates are identical.

The relationships between effective (i) and nominal (j) annual interest rate are

$$i = \left(1 + \frac{j}{M}\right)^M - 1 \quad (26)$$

and

$$j = M[(1+i)^{1/M} - 1]. \quad (27)$$

When the nominal annual interest rate is $j=0.06$ or 6%/yr and compounding is on a monthly basis ($M=12$), the monthly interest rate is

$$\frac{j}{M} = \frac{0.06}{12} = 0.005, \text{ or } \frac{1}{2}\%,$$

and the effective annual interest rate is

$$i = (1 + 0.005)^{12} - 1 = 0.06168 \text{ or } 6.168\%/\text{yr}.$$

For the case where interest is compounded continuously ($M \rightarrow \infty$), these relations reduce to

$$i = e^j - 1 \quad (28)$$

and

$$j = \ln(1+i). \quad (29)$$

Table 41.12 expresses the relationships between effective annual interest rate i and nominal annual interest rate j for annual, semiannual ($M=2$), quarterly ($M=4$), monthly ($M=12$), and continuous ($M=\infty$) compounding.

Lump-Sum Deferment Factor

A deferment factor F_{PV} , also referred to as average discount factor or present-worth factor, is defined as the ratio of the present worth of one or a series of future payments and the total undiscounted amount of such future payments. The following deferment factors are commonly used in valuation work.

The lump-sum deferment factor \bar{F}_{LS} , also known as the single-payment present-worth factor, is the ratio of the present value or present worth of a single future payment made t years hence and the amount of the single payment.

For an effective annual interest rate (i), the lump-sum deferment factor for t years is

$$\bar{F}_{LS} = (1+i)^{-t}. \quad (30)$$

Tables 41.7 and 41.11 show lump-sum deferment factors for effective annual interest rates i from 2 to 200%/yr for payments falling either at year end $(1+i)^{-t}$ or at midyear $(1+i)^{1/2-t}$, respectively; e.g., the present worth of a lump-sum payment of \$200 to be made 10 years hence, if interest is computed at 5%/yr, is $\$200 \times 1.05^{-10} = \$200 \times 0.6139 = \$122.78$.

The midyear lump-sum deferment factors are used in the discounted-cash-flow method when a future-income projection by years is to be discounted to present value. It is then customary to assume that the entire year's income is received at the midyear point. For fractional years, the lump-sum deferment factor for an interest rate of 5%/yr may also be read directly from Fig. 41.7, Curve A.

For a nominal annual interest rate j , compounded M times a year, the corresponding equation is

$$F_{LS} = \left(1 + \frac{j}{M}\right)^{-tM}. \quad (31)$$

For continuous compounding ($M=\infty$) at a nominal annual interest rate (j) this equation reduces to

$$\bar{F}_{LS} = e^{-tj}. \quad (32)$$

The lump-sum deferment factor for continuous compounding may be read directly from the graph in Fig. 41.9 for given values of tj .

Constant-Rate Deferment Factor, F_{CR}

Also known as the equal-payment-series present-worth factor, this is the ratio of the present worth of a series of Mt equal payments, made at equal intervals of $12/M$ months over a period of t years in the future, and the total amount of such payments.

TABLE 41.12—RELATIONSHIP BETWEEN EFFECTIVE ANNUAL INTEREST RATE i AND NOMINAL INTEREST RATE j FOR SEMIANNUAL, QUARTERLY, MONTHLY, AND CONTINUOUS COMPOUNDING

Nominal annual interest rate j (Decimal)	Effective Annual Interest Rate i When the Nominal Rate j is Compounded			
	Semiannually $m = 2$	Quarterly $m = 4$	Monthly $m = 12$	Continuously $m = \infty$ $e^j = 1$
	$\left(1 + \frac{j}{2}\right)^2 - 1$	$\left(1 + \frac{j}{4}\right)^4 - 1$	$\left(1 + \frac{j}{12}\right)^{12} - 1$

2.00	3.00000	4.06250	5.35860	6.38906

When the interest rate over the time interval between payments is j/M and the first payment occurs at the end of the first interest period, the constant-rate deferment factor is

$$\bar{F}_{CR} = \frac{1 - [1 + (j/M)]^{-Mt}}{tj} \quad (33)$$

When the payments are due at the end of each year, the equation reads

$$\bar{F}_{CR} = \frac{1 - (1+i)^{-t}}{ti} \quad (34)$$

When the annual payments are due at midyear, and the first payment is 6 months hence, the deferment factor is

$$\bar{F}_{CR} = (1+i)^{1/2} \frac{[1 - (1+i)^{-t}]}{ti} = \frac{(1+i)^{1/2} - (1+i)^{1/2-t}}{ti} \quad (35)$$

Constant-rate deferment factors for this case and effective interest percentages from 3 to 10% are listed in Table 41.13.

The pipeline income from oil or gas production and the operating expenses are normally accounted for on a monthly basis, and the constant-rate deferment factor for such monthly payments then takes the form

$$\bar{F}_{CR} = \frac{1 - [1 + (j/12)]^{-12t}}{tj} = \frac{1 - (1+i)^{-t}}{12t[(1+i)^{1/2} - 1]} \quad (36)$$

The constant-rate deferment factor according to this equation for an effective annual interest rate of 5%/yr, monthly payments, and monthly compounding may be read directly against the number of years t on Fig. 41.7, Curve B.

For continuous compounding ($M=\infty$) at a nominal interest rate (j) the equation reduces to

$$\bar{F}_{CR} = \frac{1 - e^{-tj}}{tj} \quad (37a)$$

The constant-rate deferment factor for such continuous compounding may be read directly from the graph in Fig. 41.9 for given values of tj . The constant-rate deferment factor for the equal monthly payments received at the end of each month during a specific interval of 1 year between $(t-1)$ and t years from now takes the form

$$\bar{F}_{CR} = \frac{(1+i)^{1-t} - (1+i)^{-t}}{12[(1+i)^{1/2} - 1]} \quad (37b)$$

This "annual deferment factor" is more accurate than the midyear lump-sum deferment factor of Eq. 30 and Table

41.7 for oil- and gas-appraisal work. Table 41.14 provides these factors for effective interest rates between 3 and 20%/yr.

Constant-Percentage-Decline

Deferment Factor \bar{F}_{CPD}

This is the ratio of the present value or present worth of a series of future payments that follow constant-percentage decline and the total amount of such income. When the pipeline income from oil and gas production and the operating expense are accounted for at the end of each month, and when the compounding of interest and the effective decline d are also on a monthly basis, the equation for the deferment factor takes the form

$$\bar{F}_{CPD} = \left\{ \frac{d}{[(1+i)^{1/2} - 1] + d} \right\} \left[\frac{F_q - (1-d)(1+i)^{t_a}}{F_q - (1-d)} \right] \quad (38)$$

where

\bar{F}_{CPD} = constant percentage-decline deferment factor; the average deferment factor applicable to a series of future payments that follow constant-percentage decline, fraction,

d = effective decline rate, drop in production rate per unit of time divided by the production rate at the beginning of the period, fraction,

F_q = ratio between initial and final production rates or payments,

i = effective annual compound safe interest rate, fraction, and

t_a = abandonment time or future life, years.

The constant-percentage-decline deferment factors according to this equation for an effective annual interest rate of 5%/yr or 0.4074%/month, monthly payments, and monthly compounding may be read directly from the graph in Fig. 41.8 for varying ratios F_q and different effective decline rates d .

For continuous compounding ($M=\infty$) at a nominal interest rate j , the equation reduces to

$$\bar{F}_{CPD} = \left(\frac{\ln F_q}{\ln F_q + tj} \right) \left(\frac{F_q - e^{-tj}}{F_q - 1} \right) \quad (39)$$

The constant-percentage-decline deferment factors for such continuous compounding may be read directly from the graph in Fig. 41.9 for given values of ratio F_q and tj .

Time t_a may be computed from Eq. 56 or 57 in Chap. 40:

$$t_a = \frac{\ln F_q}{a} = \frac{N_{pa}}{q_i} \frac{F_q \ln F_q}{(F_q - 1)}$$

Hyperbolic-Decline Deferment Factor, F_{Hy}

This is the ratio of the present value or present worth of a series of future payments that follow hyperbolic decline (decline proportional to a fractional power of the production rate) and the total amount of such payments.

For continuous compounding ($M=\infty$) at a nominal interest rate j the average deferment factor is¹⁹

$$F_{Hy} = \frac{\sqrt{F_q} - e^{-tj}}{\sqrt{F_q} - 1} - \frac{tj\sqrt{F_q} e^{(F_q-1)tj}}{(\sqrt{F_q} - 1)^2} \times \left[Ei\left(\frac{tj}{\sqrt{F_q} - 1}\right) - Ei\left(\frac{tj\sqrt{F_q}}{\sqrt{F_q} - 1}\right) \right], \dots (40)$$

where t =future life (in years) determined from Eq. 64 or 65 of Chap. 40.

$$t = \frac{N_{pa}}{q_i} \sqrt{F_q} = \frac{2(\sqrt{F_q} - 1)}{a_i}$$

The hyperbolic-decline deferment factors for such continuous compounding of interest may be read from the graph in Fig. 41.10 for given values of ratio F_q and product tj .

Harmonic-Decline Deferment Factor F_{Ha}

This is the ratio of the present value or present worth of a series of future payments that follow harmonic decline (decline proportional to the production rate) and the total

TABLE 41.14—ANNUAL DEFERMENT FACTORS $F_{CR} = (1+i)^{1-t} - (1+i)^{-t}/12[(1+i)^{1/2} - 1]$

Annual Deferral Factors are Applicable to Equal Payments Received at the End of Each Month
During a Specific Interval of 1 Year Between $(t-1)$ and t Years From Now

Year	3%	3½%	4%	4½%	5%	5½%	6%	6½%	7%	7½%	8%	8½%	9%	9½%	10%	10½%	11%	11½%

**Fig. 41.10—Deferment factors for hyperbolic decline ($n = 1/2$).**

TABLE 41.14—ANNUAL DEFERMENT FACTORS $F_{CR} = (1+i)^{1-t} - (1+i)^{-t}/12[(1+i)^{1/2} - 1]$ (continued)

Annual Deferment Factors are Applicable to Equal Payments Received at the End of Each Month
During a Specific Interval of 1 Year Between $(t-1)$ and t Years From Now

12%	12½%	13%	13½%	14%	14½%	15%	15½%	16%	16½%	17%	17½%	18%	18½%	19%	19½%	20%

amount of such payments. For continuous compounding ($M = \infty$) at a nominal interest rate (j), the average deferment factor is¹⁷

$$\bar{F}_{Ha} = \frac{e^{t_a j / (F_q - 1)}}{\ln F_q} \left[Ei \left(\frac{t_a j}{F_q - 1} \right) - Ei \left(\frac{t_a j F_q}{F_q - 1} \right) \right], \quad (41)$$

where

$$t_a = \frac{N_{pa} (F_q - 1)}{q_i \ln F_q}.$$

The harmonic-decline deferment factors for such continuous compounding of interest may be read directly from the graph in Fig. 41.11 for given values of ratio F_q and tj .

Calculation of Loan Payout

In the preparation of an engineering report, it is sometimes necessary to include a projection of future income and a payout schedule for a proposed loan. To prepare such a payout schedule, the balance of the loan at the end of each year or period must be determined.

A calculation procedure has been suggested by Wilson and Boyd²¹ based on the following assumptions: (1) the principal amount of the loan is growing by virtue of monthly compounding of interest; (2) the loan payments during any year are made in equal monthly installments that are deposited at the end of each calendar month; and (3) both the principal and the loan payments bear interest compounded monthly at the nominal annual interest rate of the loan.

Wilson and Boyd use two numerical factors to determine the balance at the end of each year. These are listed in Table 41.15.

Factor 1 is the total value of \$1, invested at the specified annual nominal interest rate, compounded monthly. Factor 2 is the total value of \$1, invested each month,

TABLE 41.15—LOAN PAYOUT CALCULATION FACTORS

Fig. 41.11—Deferment factors for harmonic decline.

with monthly compounded interest, at the end of a given number of months, divided by the number of months. The equations for the factors are

$$F_1 = \left(1 + \frac{j}{12}\right)^t$$

and

$$F_2 = \frac{(F_1 - 1)}{\left(\frac{j}{12} \times t\right)}$$

where

F_1 = Factor 1,

F_2 = Factor 2,

j = annual nominal interest rate, and

t = time, months.

The calculation steps are (1) multiply the previous year-end balance of the loan by Factor 1; (2) multiply the total annual payment by Factor 2; (3) deduct the product of Step 2 from the product of Step 1 (the difference is then equivalent to the year-end balance of the loan); and (4) for a period of time less than 1 year, the appropriate factors for the number of months involved are used instead of the 12-month period for the entire year.

TABLE 41.16—SAMPLE LOAN-PAYOUT CALCULATION

Year	Working- Interest Revenue (1)	Total Payments to Loan 80% of (1) (2)	Loan Balance Start of Period (3)	Factor 1 (4)	Loan Balance x Factor 1 (3) x (4) (5)	Factor 2 (6)	Loan Payment x Factor 2 (2) x (6) (7)	Year-End Loan Balance (5) - (7) (8)	Allocation to Principal (3) - (8) (9)	Allocation to Interest (2) - (9) (10)
9 months 1957	\$ 675,240	\$ 540,192	\$2,000,000	1.042014	\$2,084,028	1.018531	\$550,202	\$1,533,826	\$ 446,174	\$ 74,018
1958	835,200	668,160	1,533,826	1.056408	1,620,346	1.025597	685,263	935,083	598,743	69,417
1959	776,100	620,880	935,083	1.056408	987,829	1.025597	636,733	351,096	584,027	36,853
1960	632,200	358,776*	351,056	*	*	*	*	0	351,056	7,720
1961	514,000							Payout = % ₆₀		
1962	714,240									
Thereafter	1,232,090									
Totals	\$5,082,070	\$2,188,008							\$2,000,000	\$188,008

*To determine the appropriate data for the last fractional year, the procedure is as follows:

- Determine the average monthly payment from 80% of revenue for 1960. In this case, \$42,147 per month.
- Calculate the number of months to pay out the principal balance without considering interest. In this case the number of months is 8.3.
- Calculate the loan balance at the end of the nearest whole month.
 - 8 months of payments = $8(42,147) = \$337,176$.
 - Loan balance x factor 1 for 8 months = $\$351,096 \times 1.037260 = \$364,136$.
 - 8 months of payments x factor 2 = $\$337,176 \times 1.016190 = \$342,635$.
 - Loan balance after 8 months = $\$364,136 - \$342,635 = \$21,501$.
- Calculate the total payment for the ninth month, and the last 9-month period (payout = Sept. 1960).
 - Payment for ninth month = loan balance x factor 1 for 1 month = $\$21,501 \times 1.004583 = \$21,600$.
 - Total payments for last 9 months = $\$21,600$ plus $\$337,176 = \$358,776$.

A sample calculation shown in Table 41.16 deals with the problem of determining the date of payout, the total payments required, and the annual amount of interest payments for a loan of \$2,000,000 at 5½% nominal interest per year, payable out of 80% of the net runs. The calculations are shown in considerably more detail than required solely for clarity.

Nomenclature

- a = nominal decline rate; instantaneous rate of change divided by the instantaneous production rate, decimal fraction
- C_B = balance of unreturned portion of investment, dollars
- C_{dl} = depletable leasehold cost basis at beginning of tax period, dollars
- C_i = initial capital investment or purchase price, dollars
- C_l = intangible drilling and development costs, dollars
- C_{IA} = deduction if intangibles were capitalized and amortized over 120 months or depleted by use of cost depletion rates, dollars
- C_{IP} = preference intangible drilling costs, dollars
- C_{IX} = intangible costs minus C_{IA} , dollars
- C_{PT} = local production tax, dollars
- C_{WI} = working interest, decimal fraction of gross costs
- d = effective decline rate, the drop in production rate per unit of time divided by the production rate at the beginning of the period, decimal fraction
- D_A = allowable depletion, highest of D_C or lesser of V_{DE} and V_{TI}
- D_C = cost depletion; portion of leasehold cost proportional to reserves produced in a given year, dollars
- D_E = depletion; the decline of a capital value as a result of intentional piecemeal removal or gradual consumption in use
- D_{KB} = depth measurement below kelly bushing
- D_p = depreciation; the decline in value of tangible assets with use or the passage of time (obsolescence)
- e = base of natural logarithms
- $Ei(x)$ = exponential integral of x
- F_1 = total value of dollars invested at specified annual interest compounded monthly, dollars
- F_2 = total value of dollars invested each month with monthly compounded interest at end of month divided by the number of months since investment, dollars
- \bar{F}_{CPD} = constant-percentage-decline deferment factor; the average deferment factor applicable to a series of future payments that follow constant-percentage decline, decimal fraction
- \bar{F}_{CR} = constant-rate deferment factor; the average deferment factor applicable to a series of equal future payments made at equal time intervals, decimal fraction
- \bar{F}_{Ha} = harmonic-decline deferment factor; the average deferment factor applicable to a series of future payments that follow harmonic decline, decimal fraction
- \bar{F}_{Hy} = hyperbolic-decline deferment factor; the average deferment factor applicable to a series of future payments that follow hyperbolic decline, decimal fraction
- \bar{F}_{LS} = lump-sum deferment factor; the average deferment factor applicable to one single future payment, decimal fraction
- \bar{F}_{PV} = deferment factor; a factor used to reduce revenue received in the future to a present value, decimal fraction
- F_q = ratio between initial and final production rates or payments
- i = effective annual compound safe interest rate, decimal fraction
- i' = effective annual compound speculative interest rate, decimal fraction
- i_R = revenue interest; decimal fraction of gross revenue
- I = yearly net income, dollars
- I_a = net operating income; the total earned income from oil and gas sales after deduction of lease operating expenses, federal excise taxes, and production taxes, dollars/yr
- I_n = net annual operating income during Year n , dollars
- I_T = interest owner's taxable income, dollars
- j = nominal annual safe interest rate; used when interest is compounded over M periods in a year and equal to M times the interest j/M over one period, decimal fraction
- j' = nominal annual speculative interest rate, decimal fraction
- m_k = amortization; extinguishment of an intangible asset or indebtedness
- M = number of times the interest is compounded per year
- n = number of yearly payments
- N_p = cumulative oil produced, bbl
- N_r = reserves at end of tax period, bbl or Mcf
- O_a = operating expenses, including *ad valorem* taxes, dollars
- O_G = general overhead expenses, dollars
- O_t = operating expenses per well-month, dollars
- O_u = weighted average operating costs per barrel, dollars
- P = net profit; the total net operating income after deduction of capital expenditures, dollars

- P_{PV} = future net revenue or cash flow; the projection of total annually earned income from oil and gas sales after deduction of production taxes, federal excise taxes, operating expenses, and incidental capital expenditures, dollars
- q = production rate, bbl/D/month, or bbl/yr
- s = unit sales during periods
- S = sinking fund balance
- t = time, months or years
- t_a = abandonment time or future life, years
- T_{wp} = Windfall Profit Tax (WPT)
- V = gross revenue (value); the total earned income from oil and gas sales, dollars
- V_{DE} = "percent of gross" revenue, percentage depletion
- V_{TI} = "50% of net" percentage depletion, equal to 50% of taxable net income, dollars
- ΣI = total future net operating income, dollars

Subscripts

- a = abandonment
- i = initial
- t = conditions at Time t

Chapter 42

Injection Operations

W.P. Schultz, Core Laboratories Inc.*

H.M. Shearin, Suburban Propane Exploration Co. Inc.*

Introduction

The petroleum industry, like other industries, exists today because it markets desirable products at a profit. To do this, it is extremely important that every phase of an oil company's activity be conducted with this goal in mind. The specific goals and details of operation of a particular company may vary slightly or significantly from those of other companies—depending primarily on economic and marketing structure—but each desires to optimize economics of its detailed as well as its overall operations.

There are, of course, many facets to be considered in this program of optimization, and these may vary from one company to the next, from one locale to another, or even with time. No longer can companies analyze their economics considering only development and depletion of their reserves by primary means. World demand and availability of hydrocarbon products; economics of exploration, development, production, and transportation; obligations of drilling and regulation of production operations imposed by various governing authorities; taxation; and competition of other raw materials in the energy market all have had the combined effect on petroleum industry operations of demanding closer coordination and control of activities within a given company. Equally important, more detailed consideration and long-range planning must be devoted to specific projects undertaken. This chapter has been written with these general thoughts in mind.

Oilfield development and production operations constitute a major part of most oil companies' activities. More probably can be done to improve the overall economics of a company and actually shape its future by critical and thorough analysis of this phase of operations than can be done in any other activity. Every company is well aware of the high cost of finding oil, of developing a reserve, and of producing it. Experience has shown

that from most fields primary recovery is not an efficient process and that, usually, large volumes of oil are left underground as unrecoverable at the time of abandonment. The technology of oilfield operations has developed rapidly as a result of research, field application, and engineering and geological analysis. Today, in most field operations, new technology is adopted when the economics warrant it.

Petroleum reservoir engineering is by no means an exact science. Probably it never will be since so many parameters that cannot actually be measured or defined are involved; however, research and experience have yielded a substantial knowledge that is quite adequate to serve as a basis for providing management with sound recommendations regarding field development and operations, which on the basis of current technology should result in optimal economic recovery from a reservoir.

For many years it has been known that injection of either water or gas into a petroleum reservoir can improve recovery. The general history of field application of these processes is interesting to review. Many injection projects were initiated in fields before reservoir natural-energy-drive mechanisms were understood—even before there was a general awareness of what data were needed to evaluate properly either the possibilities or the results of such processes. It is not surprising, therefore, to find that some projects succeeded in substantially increasing recovery and others failed.

As the science of reservoir engineering developed, many injection projects were considered more carefully before they were actually initiated and, as a result, were on a sounder technological and economic basis from the start. Consequently, most injection operations are well engineered. In fact, the development plans of most new discoveries include the option of initiating injection operations right from the start, when feasible.

The solution of problems in any technical operation is

*These authors also wrote the original chapter on this topic in the 1962 edition.

always dependent on knowing the relevant facts. The oil industry is no exception to this rule, and many critical facts that engineers or geologists must use in their analysis of a reservoir can be obtained best early in the life of the reservoir. Some necessary facts can be obtained at later times, but only at a very large additional expense. It is therefore in keeping with sound business principles for an operator to think ahead when drilling wells and to begin planning ahead the very day a new reservoir is discovered. With this philosophy, engineers can be assured that sufficient and necessary information will be available for proper technical analysis when needed, that the best program for ultimate depletion of reserves is recognized early in the life of the reservoir, and that the development program for the reservoir is guided toward maximum use in the exploitation program best suited for optimal economic recovery. The thought process involved in this philosophy applied to development of a sound injection operation is discussed in this chapter.

Important Factors in the Design of Injection Operations

Objective

Individual oil and gas reservoirs, like human beings, are each different, and the reservoirs present a wide variety of properties for the engineer to consider. Of prime importance in making an analysis of these properties for the design of an injection program is establishing the objective of the operation.

The establishment of a proper objective for a given operator depends on the particular circumstances. An operator with limited investment opportunities might favor improvement in reserves. One with ample reserves for the current rate of production would favor an improvement or maintenance of production rate. Another, having insufficient rate and reserves, would favor improvement in each. The objective of the injection operation will likely be (1) sustaining the rate through pressure maintenance, (2) increasing ultimate recovery through a more efficient displacement process, or (3) combining improved rate and recovery to lead to the accumulation of maximum present worth.

In many instances, injection operations have been undertaken in reservoirs simply because nearby properties have responded favorably to injection. This same line of incomplete reasoning is then generally carried one step further, and it is concluded that the reservoir conditions are unknown because of variable physical properties and past production practices; therefore, no proper engineering analysis can be made and injection must be tried to see what will happen. Projects initiated with this reasoning are almost always injection operations without an objective. This "cart before the horse" philosophy is to see what will happen, then decide what is desired. Without an objective the engineering analysis will result in nebulous conclusions, for the objective influences both the timing and the choice of the injection process.

Timing

Care must be taken to ensure that the planning of the program is not delayed past the optimal time to start the injection physically. In all cases, it is desirable to

recognize the need for injection in a reservoir to obtain specific objectives as early in the life of the reservoir as possible. Early planning, even if not in great detail, will make it possible to obtain adequate basic data for proper engineering analysis at the only time such data are available. In many instances, such planning may dictate a modification of the development program so that wells will be located and completed to provide maximum efficiency to the injection program with a minimum amount of costly redrilling or workover expense.

The optimal time to start an injection project is often related to the best-suited process for the given field. For example, an immiscible displacement with gas might best be undertaken in some high-permeability sands after the reservoir reaches a low pressure, since at low pressures, the cost of compressing gas to replace a reservoir barrel of volume is low. Low-pressure waterflooding might perhaps be started when the optimal amount of free gas is present. Low-permeability reservoirs or those with high-shrinkage oil might call for the immediate use of a pressure-maintenance project in maintaining well productivity and in preventing high shrinkage losses. Some injection operations may require high reservoir pressures to accommodate the process.

For older fields, in which the optimal time to start a project may have long passed, the question becomes not one of optimal time but of the best process to employ. At times, the question is whether a change in the conditions of the reservoir, such as repressuring, can re-establish the opportunity for conducting an improved operation.

Injection Fluids

In any injection project, certain parameters are fixed and are beyond the control of engineers. These include fluid properties of the reservoir oil, rock properties, geologic stratifications, faulting, and depth. On the other hand, engineers can vary such items as injection fluid, injection pressure, pattern, and injection rate. Selection of the proper injection fluid for a given reservoir is probably the most difficult part of the design of any injection operation. Generally, air and water are the only materials considered inexpensive enough to use in large quantities for the displacement of crude oil. Current prices of natural gas make it an expensive injection fluid. However, when it exists in areas where there is no market, its greatest economic benefit may be as an injection fluid. It is in this area, however, that the knowledge, imagination, and ingenuity of the reservoir engineer can be used to develop injection programs that will greatly improve recovery and profit from most reservoirs. The project should be designed to allow for the possible use of small amounts of more expensive materials, such as propane, butane, liquefied petroleum gas, CO_2 , wetting agents, and polymers.

Projected Recovery

Data Required. Projecting oil recovery from a reservoir in which injection operations are to be conducted requires an estimation of (1) the amount of oil in place initially, (2) the recovery by any primary depletion that occurred before the start of injection, (3) the oil saturation at the start of injection and the residual oil saturation after the displacement process and how it is distributed

through the reservoir, (4) the fraction of the reservoir to be swept, and (5) the injection and production rates.

Sufficient data are needed to determine these quantities. Some sources of these data are listed in Table 42.1.

Engineering Analysis. The prediction of the performance of an injection operation is derived by (1) preparing an estimate of the oil moved as a function of the volume injected and (2) defining the injection and production rates and related volume injected to time. The details of the calculation procedures are presented in the six chapters that follow in this handbook. In general, the amount of oil recovered is determined from material-balance calculations applied to the fraction of the reservoir swept by the injected fluid. The potential injection and production rates are calculated from equations or measurements on models. The rate may be reduced through proration or through limitation in sizing equipment.

Optimizing an Injection Operation

The decision as to the optimal injection program for a given reservoir involves selection of the best process and of the best manner for conducting that process. The selection of the best process requires a study of (1) primary performance, (2) source of injection fluid, (3) cost of injecting various fluids, and (4) unit displacement efficiency of various fluids.

The selection of the best manner for carrying out the operation requires a study of (1) the time to start injection, (2) pressure maintenance, (3) partial pressure maintenance, (4) well stimulation, (5) additional drilling, and (6) pattern choice. After the best manner for conducting each process is developed, a comparison of the economics of the optimal plan for each process will show the most desirable program.

Analysis of a Reservoir for Injection Operations

Beginning the Analysis

Data Gathering and Testing. Some reservoirs may be similar in many respects but completely different in others. Because of this, it is necessary to obtain information that experienced geologists and engineers can use to define the character of each specific reservoir. Much of the information is obtained during the development portion of a reservoir's history. Some types of information are collected periodically throughout the producing life of the reservoir. Certain types of data are needed to evaluate the probable economics and producing characteristics of the reservoir by natural depletion, and additional information is necessary for proper analysis of potential recovery and economics under various injection programs. It is a responsibility of the engineer and geologist, as a team, to outline a long-range program of data requirements early in the life of every reservoir and a schedule of how and when these data are to be collected. The details of this program should be modified continuously as more knowledge of the reservoir is gained.

If conducted properly, the initial development program can contribute substantially to the early recognition of both primary and injection-operation potential of any

TABLE 42.1—DATA REQUIRED TO ESTIMATE RECOVERY FROM INJECTION OPERATIONS

<u>Oil Initially in Place</u>	
Adequate number of wells to define areal extent	
Well logs to define productive section and sometimes content	
Core measurements for porosity, interstitial water, oil saturation, and sometimes capillary properties; these data also serve as a basis for well-log calibration	
Material-balance calculations based on reservoir pressures and production history to confirm volumetric estimates of oil in place	
<u>Primary Performance</u>	
Production of oil, gas, and water by wells	
Pressures from periodic pressure-buildup tests	
Fluid properties	
Relative-permeability measurements on cores for displacing and displaced phases	
Geologic data from nonproductive wells outside the productive limits to assist in the determination of the primary drive mechanism	
<u>Fraction of the Reservoir to be Swept</u>	
Core measurements for variation in permeability and content	
Cross sections and pressure interference tests to determine the reservoir continuity between wells	
Stratification from core measurements and logs	
Orientation of permeability	
Selected injection pattern	
Fluid viscosities and relative permeabilities	
Areal sweep performance of injection pattern models	
<u>Injection Rate and Production Rate</u>	
Effective reservoir permeability from cores, pressure-buildup tests, and productivity-index tests	
Relative-permeability curves on displacing and displaced phases	
Wellbore conditions from pressure-buildup analysis	
Injection pressure	
Fluid properties	
Throughput rate from model performance or calculations	

reservoir. This program should be designed to yield (1) the broad specifications of the reservoir, such as general field limits, general reservoir geometry, (2) general rock properties of the producing formation, (3) approximate location of reservoir gas/oil and water/oil contacts if present, (4) characteristics of in-place reservoir fluids, (5) initial reservoir pressure and temperature conditions, and (6) general information pertaining to average well productivities. Quite obviously, if this program is to accomplish its economic and informative objectives, no consideration should yet be given to ultimate well spacing. In the case of large structures this initial program should consist of carefully planned, bold stepouts and, in all cases, obtaining as much information as needed to direct properly further field development and data-gathering techniques.

Often, sufficient information can be obtained from a well-planned data-gathering program conducted during the early portion of development of a reservoir to permit intelligent preliminary examination of the probable need for injection and the general feasibility of various types of injection. Early data-gathering efforts should result in the accumulation of sufficient information to permit selection of those techniques that will yield required and reliable information as other wells are drilled. Such information also can be used to refine the preliminary conclusions pertaining to probable reservoir potential under

various operating methods begun earlier on the basis of initial data. Recommendations concerning selection of the best program of operation for a particular reservoir normally should be based on behavior forecasts that involve detailed analysis of primary producing performance.

The economic potential of injection operations can suffer materially in many cases if such operations are not initiated early in the producing life of a reservoir. Thus an urgency exists to determine early the economic potential of various operating programs; one often cannot wait for primary performance information covering a majority of the reservoir's primary life and still reap the benefits that might have accrued by early initiation of some form of injection. Engineers, therefore, have quite a large responsibility to obtain sufficient information and to recognize when enough is available for making sound recommendations concerning future operations in any given reservoir. The relative timing for when this can be done in a reservoir's life may be considerably different for different reservoirs, depending primarily on the ability to recognize and define the natural forces contributing to production in each case. From a technical standpoint, full development of the field on some arbitrary spacing decided without regard to reservoir characteristics and potential should not be undertaken until it can be guided by the needs of the operating program best suited to the reservoir.

The initial-development portion of any reservoir's history is therefore a critical period. The information that should be obtained during this period includes the following.

1. Detailed routine core analysis in sufficient volume and with sufficient well logs of different types permits selection of those data-gathering techniques that when used on later wells will ensure obtaining necessary and accurate interpretations and measurements of rock properties such as porosity and permeability. Data about the initial wells should be adequate for general definition of such things as structure, gross formation thickness, net productive formation thickness, field limits, porosity, permeability, lithology, and the homogeneity and continuity of the producing formation.

2. Drillstem tests define the general productive characteristics of various zones and help establish the location of gas/oil and water/oil contacts if present.

3. Periodic static-subsurface-pressure surveys establish original reservoir pressure as well as subsequent pressure history.

4. Temperature surveys establish reservoir temperature.

5. Reservoir fluid samples establish the physical properties of hydrocarbons present in the reservoir as functions of pressure and temperature and the variation of these properties with depth and area. Also, formation-water samples establish chemical composition.

6. Controlled periodic production tests of wells provide such information as general production characteristics, GOR, and water cut.

7. Special well tests such as productivity-index measurements, pressure-buildup tests, and interference tests provide information regarding efficiency of completion techniques, average formation productivity, and formation continuity.

8. Special core-analysis tests on selected, and in some cases specially preserved, core samples help determine such things as interstitial water saturation, gas/oil and water/oil relative-permeability characteristics, residual oil saturation by waterflood, and permeability reduction caused by flooding with water of various salinities.

9. Monthly oil-, water-, and gas-production histories by well are also useful.

The engineer must use judgment with regard to exactly how much of each kind of basic data is required in any particular case. In general, the volume of data needed varies more with complexity of the reservoir system than with size. Complexity of reservoirs is often disregarded. Usually, more different types of data should be obtained early in the development period so that economy and reliability can be built into subsequent completion techniques and data-gathering programs.

Type of Injection

Many factors are involved in determining the data needed to analyze properly the potential of various injection programs for a specific reservoir. Experienced engineers with proper data at hand should be able to recognize early the types of injection programs that might prove worthy of detailed consideration. Often, new reservoirs are discovered in the same formation and in close proximity to existing fields for which detailed performance information already exists. Unless factors point to differences between the two, in his preliminary thoughts, the engineer usually can consider that the new field probably will behave in a manner similar to the other. If existing injection projects are successful or if they are failing, the preliminary thinking on a new reservoir, unless obvious differences exist, will be that similar projects in the new reservoir probably would behave in about the same manner. This thought process is a normal one but can be dangerous in that the results of a specific injection project many times are actually a function of the original thought, evaluation, and planning of the project as well as the engineering control exercised throughout its life. Proper engineering control of injection projects in practice varies considerably, and for this reason, thinking based on analogy is good for preliminary screening but should not be the prime consideration in evaluating the need for or the potential of various injection programs. Prime consideration should be given to the physical characteristics of the particular reservoir being evaluated.

Reservoir Fluid and Rock Characteristics. One of the first questions that should be answered by engineers concerns the technical feasibility of various forms of injection. This involves preliminary analysis of reservoir rock and fluid characteristics and early interpretations of reservoir geometry. Engineers should be on the lookout continuously for characteristics such as high interstitial water content, unfavorable water/oil or gas/oil relative-permeability properties, unfavorable mobility ratios, indications of natural formation fracture and fault systems, unusual areal and vertical variations of porosity and permeability, and lack of vertical and areal formation continuity. None of these situations rule out the technical possibilities of injection projects, but they are warning signals to engineers and may complicate their problems.

Engineers know, for example, that if (1) the reservoir appears to have fair continuity and shape, (2) permeability is reasonably distributed, and (3) relative-permeability relations and oil properties are favorable, then either water-, gas-, or enhanced-recovery injection projects are possibly feasible from a technical standpoint. If the reservoir oil is viscous, then mobility-ratio characteristics normally favor water over gas injection, and thermal processes might increase recovery. If a high interstitial water saturation exists, then under certain conditions this can be more of a disadvantage for water than for gas injection. Benefits often can be derived through enhanced-recovery operations in reservoirs containing highly undersaturated oils. Through experience engineers have learned that low formation permeability in itself is not a factor that eliminates injection possibilities but that often a more critical factor can be extreme variation of permeability. All these factors, along with others, can be available for the engineer's scrutiny early in the development period and, if used properly, can guide the early thinking about overall plans for a reservoir.

Availability of Injection Fluids. In viewing the possibilities of injection operations, engineers must also consider the availability of fluids for injection. This factor alone can sometimes eliminate further evaluation of some particular form of injection or, in other cases, materially affect the economics of a project. A water-injection operation might appear very attractive from a technical standpoint; yet if water cannot be made available in required quantities and at reasonable cost, further consideration of the process would be only academic. Engineers should certainly consider the possibilities of gas-injection and miscible-drive projects when gas or liquid plant products are available in the area. Of course it is impossible to set forth a checklist of factors that could be used early in the life of every reservoir to determine the absolute need or feasibility of injection projects. Each factor discussed here is important, and variations of any one or of all the pertinent parameters can affect results to various degrees.

Predicted Reservoir Performance During Primary Operations

Another important consideration that must be an integral part of the engineer's appraisal of possible injection projects is the need for the project. This can be a very complicated part of the overall analysis and should involve not only technical aspects of the project itself but also the effect that the project's results might have from an overall company standpoint. The latter is treated in more detail along with a discussion of economics in this chapter. Technical need for injection projects involves analysis of past reservoir performance, recognition and definition of the natural energy forces contributing to primary production, and evaluation of the efficiency and forecast of performance of the primary production operations.

Other chapters in this handbook deal with the types of drive mechanisms that can be present individually or in combination in any given reservoir. Engineers must have a detailed understanding of these natural processes before they can recognize the need for application of supplemental recovery processes to a reservoir. General-

ly speaking, the depletion- or solution-gas-drive process is an inefficient one, but coupled with good segregation and oil and gas counterflow, the process can be much more efficient. In general, better recovery efficiency is usually expected by a natural water drive than by any other natural process, and gas-cap expansion-drive processes are usually intermediate in effectiveness.

Engineers know, however, that these are generalizations and that the existence and effectiveness of each must be evaluated for each reservoir. They can make reasonable guesses of possible future primary performance on the basis of behavior of analogous fields and on preliminary evaluation of data acquired early in a reservoir's life, but these guesses can be translated into sound engineering conclusions only through a detailed study of the particular reservoir's performance. When they are able through intelligent use of available information concerning basic properties of the reservoir system to calculate accurately and match the actual past performance of a reservoir, then they gain confidence in any predictions they might make of future primary performance.

An experience factor is involved, however, that cannot be overlooked. Engineers must be able to recognize whether a match of calculated and actual performance is a real match such that the solution is reasonably unique and their understanding of the primary production process is good or whether there actually could be several widely different solutions that could result in equally good matches of performance. In the latter case there is either a lack of understanding of basic reservoir parameters and a need for more basic data, or there is insufficient production performance available for analysis at that time.

Often, it might be possible to plan early production from the reservoir in such a manner as to aid in reservoir evaluation. Extreme changes in production rate (upward or downward or both) and maintenance of those rates at reasonably constant levels for a period of time can often result in changes in observed reservoir pressure or well performance that are extremely useful in early recognition of prevailing natural-energy forces. Since treatment of the various methods of analysis appears in other chapters, there is no need to discuss them at this point. Emphasis, however, should again be placed on the urgency of early recognition and definition of the efficiency of the primary production process because it is of prime importance in ascertaining the need for injection.

Predicted Reservoir Performance During Injection Operations

The next step in the process of determining the best method of operation for a given reservoir is the prediction of performance for various injection programs that are considered technically and practically feasible on the basis of preliminary examination of available information. Normal methods of accomplishing this objective are discussed in later chapters; however, the following philosophy should be a normal part of engineers' thinking processes. An injection program is not to be designed for the reservoir at hand because a similar project appeared successful in some other reservoir; it is not developed simply because the process is one that has been used extensively in the past; it does not follow that,

just because a certain pattern of injection and production was good for one reservoir, it should also be the best or even good in another reservoir. Each reservoir must be examined in the light of its character and needs.

Many injection projects are hampered by inadequate programs borrowed from yesterday (a period when reservoir fluid-flow processes were not well understood) and applied to reservoirs without appreciation of differences in reservoir detail or other pertinent circumstances. Engineers should strive to be current in thinking and original in ideas. A surface map showing location of injection and production wells for a project might appear to be extremely radical on first examination; however, if sound technical procedures show that it could result in better economic recovery than any other scheme, the plan is not radical. Programs are developed for obtaining desired results in underground reservoirs and not to be symmetrical, uniform, or appealing with regard to topography or property lines. At the time engineers make detailed analyses of the potential of injection operations, they should have already answered, by means of the planned data-gathering program, as many pertinent details as possible about characteristics of the reservoir rock, reservoir fluids, reservoir geometry and continuity, and well-behavior characteristics.

Economics

Although technical analyses of possible future operations in a reservoir must be thorough and sound, an equally important consideration during overall evaluation is economics. Any project might be an outstanding success from a technical standpoint, but its real value is measured in terms of income and expense. In designing the general specifications of an injection program, engineers should first recognize or ascertain some of the overall objectives of their company. Usually engineers find that there is considerable latitude with regard to some important considerations in a study that are well within the limits of sound technology but that with varying assumptions could represent quite a spread in the economic results of a given project. This is particularly true of factors that influence production rate.

As stated earlier, it might be more desirable from an economic and marketing standpoint in one company to recover as much oil as possible and as fast as possible whereas in another company the interest may be for long-term maintenance of stabilized high production rates. Knowledge of this is important in designing an injection project. Engineers should be cautious in their economic analysis and not permit conclusions to be drawn that on the basis of the project alone might be reasonable but that with broader consideration could be invalid. An example of such a case might be the prediction of a water-injection project that would recover large volumes of additional oil. The economics of such a proj-

ect might appear to be very favorable; however, if the company cannot market the additional oil at the forecasted rates and values, such a project could not possibly result in the indicated benefits from an overall company standpoint.

Wells are often drilled that are not needed from the standpoint of producing reserves. The surplus wells are there because economic and marketing differences exist between companies, because of regulations concerning drilling requirements, because wells drilled for primary operations are not suitable for later operations, and in some cases because of false economic reasoning. Many wells have been drilled simply because they pay out in a fairly short period of time. Some of these wells may have benefited companies from a current-income standpoint, a lesser number from a present-worth standpoint, and probably very few from an ultimate-recovery standpoint. Unnecessary drilling is a waste of money and should be eliminated; engineers can be very instrumental in such a program through efforts to appraise the potential of reservoirs early in their life and to forestall complete development until the future plan for the reservoir is known. At that time only the necessary additional wells can be drilled and they can be located strategically according to need. The benefits of additional oil recovery and reduced costs that can be obtained through cooperative or unitized operations should be uppermost in engineers' minds.

Many times variables exist in the engineers' technical analyses that seem to defy definition. Engineers must know how critical reasonable variation of such parameters is in the overall analysis. Sometimes results pertaining to such cases can be derived only through pilot applications. These pilot operations serve the primary purpose of reducing risk that might be involved in a fieldwide program. This is particularly true for EOR projects where injection of expensive chemicals, steam, or oxygen is involved. In those cases where it is necessary to resort to a pilot program, it should first of all have specific objectives, detailed engineering control to ensure early attainment of the objectives, and planning to make it an integrated part of the expanded fieldwide program.

Petroleum engineers today are no longer just professionals with technical experience or background relating to oil production. They must also understand principles of finance. They not only must be able to know what "yardsticks" are used by their company and by others to evaluate the benefits of a specific project, but also must be able to design the project so that maximum benefits can result. Engineers can play a major role in the future of the oil industry. Rewards will certainly come to individuals who recognize the existing challenge and who, with "know-how," good judgment, and new ideas, are always striving to improve the specific facets as well as the overall complexion of the industry.

Chapter 43

Gas-Injection Pressure Maintenance In Oil Reservoirs

I.F. Roebuck Jr., Roebuck-Walton Inc.*

Introduction

The first recorded deliberate attempt to stimulate recovery from an oil reservoir by hydrocarbon gas injection was in the Macksburg field, Washington County, OH,¹ long before water injection was used for secondary recovery purposes. For almost 60 years, most secondary recovery projects included some form of immiscible gas injection, and its use continued even after the advent of new methods and materials. In spite of this, it was the late 1940's before serious attempts were made to develop quantitative techniques for describing reservoir performance under gas-injection operations, especially with regard to depleted oil reservoirs. Before then, such efforts were directed primarily toward describing the water displacement process.

As a result, techniques used to describe the performance characteristics of immiscible gas injection consist of modifications to methods originally developed for describing performance of water-injection operations, even though there is a fundamental difference in the basic displacement mechanisms of the two fluids. Such modifications, therefore, include the effects of gas solution in the reservoir oil, vaporization of lighter hydrocarbons from oil, or both.

Physical criteria for successful gas-injection operations are basically the same as for other types of fluid injection; the same physical and thermodynamic variables control the displacement process. As in all engineering investigations, pertinent variables must be defined, evaluated, and applied by the investigative techniques available and with a knowledge and awareness of the limitations of the techniques and the accuracy and reliability of the data and information at hand.

Gas injection has been used to maintain reservoir pressure at some selected level or to supplement natural

reservoir energy to a lesser degree by reinjection of a portion of the produced gas. Complete or partial pressure-maintenance operations can result in increased hydrocarbon recovery and improved reservoir production characteristics.

The quantity of additional liquid hydrocarbons that can be recovered from a reservoir is influenced by several characteristics of the particular reservoir, including reservoir rock properties, reservoir temperature and pressure, physical and compositional properties of the reservoir fluids, type of reservoir drive mechanism, reservoir geometry, sand continuity, structural relief, rates of production, and fluid saturation conditions.

Basically, increased hydrocarbon recovery can be attributed to the oil displacement and vaporization action of the injected gas and, in some cases, to the prevention of losses in recovery that would occur if pressure were not maintained. The conservation aspects of gas-injection pressure-maintenance operations can be particularly important with reservoirs containing volatile high-shrinkage crude oils and with gas-cap reservoirs containing large quantities of retrograde condensate gas. Gas injection has also been employed frequently to prevent migration of oil into a gas cap in oil reservoirs with natural water drives, with downdip water injection, or both. Other uses of gas injection in high relief reservoirs have been to enhance gravity drainage processes and to recover so-called attic oil residing above the uppermost oil-zone perforations.

Improvements in reservoir producing characteristics may, in some cases, be sufficient justification to initiate gas-injection operations even though a competitive recovery process might be used to achieve greater ultimate hydrocarbon recovery. Decreased depletion time resulting from pressure-maintenance operations can have a significant influence on the economic justification for gas injection. Decreased reservoir oil viscosity and gas saturation in the vicinity of the wellbore tend to

*Original chapter in 1962 edition, Part 1, *Gas-Injection Pressure Maintenance*, was written by I.F. Roebuck Jr. and Kenneth M. Garms. Part 2, *Miscible Displacement*, is now a separate chapter (see Chap. 45).

maintain individual well productivities, and producing wells are generally more able to maintain their desired producing rates or allowables. Further advantages can be obtained by elimination of penalties imposed by regulatory agencies for excessive net gas production where produced gas is not reinjected. Thus, many times it is possible to maintain full-field allowables over most of the producing life of the project, thereby reducing the depletion time of the reservoir, with attendant savings in operating costs and increased present value of future revenues.

Since 1978 and the passage of the Natural Gas Policy Act, the increasing value of sales gas has resulted in a decline in the numbers of new gas-injection projects. However, some opportunities still exist in remote areas where recovery considerations are augmented by the storage aspects of such projects and by specialized applications in connection with gravity drainage systems and attic oil recovery projects.

Concurrent with this, CO_2 and nitrogen injection for miscible displacement of crude oil have been of increasing interest and application. On the basis of both economic and technical considerations, it is not unreasonable to expect that immiscible nitrogen-injection projects will see increasing application in many oil reservoirs that in the past would have been subjected to hydrocarbon-gas injection. In general, calculation techniques previously developed for hydrocarbon-gas injection and displacement can be used for the design and application of nitrogen-injection projects under conditions of immiscible displacement.

It is the purpose of this chapter to point out the physical criteria for successful gas-injection operations, to describe the variables that must be defined and evaluated, and to demonstrate some of the techniques available for the prediction and evaluation of field performance under immiscible gas-injection operations.

Most of the calculations described are now accomplished with hand calculators or digital computers; many of them can be applied with relatively basic varieties of today's generation of microcomputers. At the same time, the physical and mathematical relationships described have been incorporated into a wide variety of mathematical reservoir simulation models. The formulation and application of such models is beyond the intended scope of this chapter, but a few selected references to technical articles describing models for gas-injection processes are included in Appendix B.

The calculation techniques described here are the classical methods for describing immiscible displacement with complete pre-equilibrium between the injected and displaced phases, gas and oil, while accounting for the effects of reservoir heterogeneities, injection/production well configurations, and differing physical characteristics of the fluids. The reservoir is treated in terms of the average properties of a unit volume of rock, and production performance is described on the basis of an average well.

The simplest types of so-called reservoir simulation models employ essentially these same techniques but, by means of one-, two-, or three-dimensional cell arrays, account for areal and vertical variations in rock and fluid properties, well-to-well gravity effects, and individual well characteristics.

More complex component or compositional models allow also for nonequilibrium conditions between injected and displaced fluids and can be used to describe individual well streams in terms of the compositions of the produced fluids.

The accuracy and reliability of the results obtained generally increase with each of these methods, or models, in the order described, depending on the quantity and quality of the reservoir and fluid data available, the internal variations in reservoir properties, the fluid characteristics, and the ability to describe the overall physical system. The time and worker requirements, and hence the cost of the study, also increase in the same order.

Therefore, the choice of a method for describing project performance is a matter of judgment, considering economics, the time available, and the requirements for accuracy in a practical sense. Obviously, these requirements will vary with the phase of work undertaken and the overall purpose of the study at hand. Certainly, early feasibility studies usually can and should be made with nothing more than the simple, classical techniques. Such is also the case for many detailed studies where the effects of gravity and phase equilibrium are negligible or when the quantity and quality of data are inadequate to support more complex full-scale simulation studies.

Types of Gas-Injection Operations

Gas-injection pressure-maintenance operations are generally classified into two distinct types depending on where in the reservoir, relative to the oil zone, the gas is introduced. Basically, the same physical principles of oil displacement apply to either type of operation; however, the analytical procedures for predicting reservoir performance, the overall objectives, and the field applications of each type of operation may vary considerably.

Dispersed Gas Injection

Dispersed gas-injection operations, frequently referred to as internal or pattern injection, normally use some geometric arrangement of injection wells for the purpose of uniformly distributing the injected gas throughout the oil-productive portions of the reservoir. In practice, injection-well/production-well arrays vary from the conventional regular pattern configurations (e.g., five-spot, seven-spot, nine-spot) to patterns seemingly haphazard in arrangement with relatively little uniformity over the injection area. The selection of an injection arrangement is usually based on considerations of reservoir configuration with respect to structure, sand continuity, permeability and porosity variations, and the number and relative positions of existing wells.

This method of injection has been found adaptable to reservoirs having low structural relief and to relatively homogeneous reservoirs having low specific permeabilities. Because of greater injection-well density, dispersed gas injection provides rapid pressure and production response—thereby reducing the time necessary to deplete the reservoir. Dispersed injection can be used where an entire reservoir is not under one ownership, particularly if the reservoir cannot be conveniently unitized.

Some limitations to dispersed-type gas injection are: (1) little or no improvement in recovery efficiency is derived from structural position or gravity drainage, (2)

areal sweep efficiencies are generally lower than for external gas-injection operations, (3) gas "fingering" caused by high flow velocities generally tends to reduce the recovery efficiency over that which could be expected from external injection, and (4) higher injection-well density contributes to greater installation and operating costs.

External Gas Injection

External gas-injection operations, frequently referred to as crestal or gas-cap injection, use injection wells in the the structurally higher positions of the reservoir—usually in the primary or secondary gas cap. This manner of injection is generally employed in reservoirs having significant structural relief and average to high specific permeabilities. Injection wells are positioned to provide good areal distribution of the injected gas and to obtain maximum benefit of gravity drainage. The number of injection wells required for a specific reservoir will generally depend on the injectivity of each well and the number of wells necessary to obtain adequate areal distribution.

External injection is generally considered superior to dispersed-type injection, since full advantage can usually be obtained from gravity drainage benefits. In addition, external injection ordinarily will result in greater areal sweep and conformance efficiencies than will similar dispersed injection operations.

Optimal Time to Initiate Gas Pressure-Maintenance Operations

Generalizations as to the optimal time to initiate gas pressure maintenance are of limited practical value because of the exceedingly large number of variables that must be considered from an economic and reservoir mechanics standpoint. Obviously, there is no method of calculating directly the optimal time from an economic standpoint; instead, several calculations of future performance, assuming initiation of injection at various stages of reservoir depletion, must be made and compared on an economic basis.

Considering only hydrocarbon recovery and improvements in producing characteristics, it can be stated that generally more favorable reservoir conditions for gas-injection operations are present when the reservoir is at or slightly below the reservoir fluid saturation pressure. Within this range of reservoir pressures, the initial free-gas saturation in the oil zone is at a minimum—a condition favorable to obtaining maximum recovery efficiency from the gas displacement process.

Efficiencies of Oil Recovery by Gas Displacement

It is convenient to analyze and evaluate the recovery efficiency obtainable by gas displacement operations in terms of three efficiency factors, generally referred to as (1) unit-displacement efficiency, (2) conformance efficiency, and (3) areal sweep efficiency. Each recovery efficiency may be considered as one component element that accounts for the influence of certain parameters on the overall recovery efficiency of the displacement process. The product of the three efficiency factors provides an estimate of the percentage oil recovery that can be expected with this recovery process in a particular reservoir

under specified conditions. Analytical procedures are available for evaluating each efficiency factor individually. In certain instances, such analytical procedures are combined to determine two or more of the factors as a unit; for example, the term "volumetric efficiency" is sometimes employed where the conformance and areal sweep efficiencies are combined into one factor. Similarly, the term "displacement efficiency" is sometimes used where the unit displacement and conformance efficiencies are evaluated in combination. For the purpose of this chapter, the three components describing the overall recovery process are defined as follows.

1. *Unit displacement efficiency* is the percentage of oil in place within a totally swept reservoir-rock volume that is recovered as a result of the displacement process.

2. *Conformance efficiency* is the percentage of the total rock or pore volume within the swept area that is contacted by the displacing fluid.

3. *Areal sweep efficiency* is the percentage of the total reservoir or pore volume that is within the swept area, the area contacted by the displacing fluid.

Each of the three efficiencies increases with continued displacement; therefore, each is a function of the number of displacement volumes injected. The rate of increase in recovery efficiency in a given portion of a reservoir diminishes as gas breakthrough occurs. Therefore, the maximum value of each component efficiency and, consequently, the ultimate recovery efficiency is limited by economic considerations.

Methods of Evaluating Unit-Displacement Efficiency

Equations

Unit-displacement efficiency is normally determined by analytical procedures developed from the two fundamental equations reported by Buckley and Leverett.² These equations essentially characterize the mechanics of steady-state, two-phase fluid flow encountered in oil displacement by an immiscible fluid. These equations were developed by means of relative-permeability concepts and are based on Darcy's law describing steady-state fluid flow through porous media.

The so-called *fractional-flow equation* describes quantitatively the fraction of gas flowing in terms of the physical characteristics of a unit element of porous media. In customary units, using a unit area, this equation is as follows.

$$f_g = \frac{1 + 1.127[k_o A / (\mu_o q_t)] \left[(\partial P_c / \partial L) - 0.433(\rho_o - \rho_g) \sin \alpha \right]}{1 + (k_{ro} / k_{rg})(\mu_g / \mu_o)} \quad \dots \dots \dots (1)$$

where

- f_g = fractional flow of gas,
- q_t = total flow rate, B/D,
- A = cross-sectional area, sq ft,
- P_c = oil/gas capillary pressure $(\rho_o - \rho_g)$, psi
- L = distance, ft,

Fig. 43.1—Schematic representation of saturation distribution during gas-displacement process.

Fig. 43.2—Fluid saturation distribution at four time periods during gas displacement process.

- ρ_o = oil density, g/cm³,
 ρ_g = gas density, g/cm³,
 α = angle of dip, positive down-dip, degrees,
 k_o = effective permeability to oil, darcies,
 k_{ro} = relative permeability to oil, fraction,
 k_{rg} = relative permeability to gas, fraction,
 μ_o = oil viscosity, cp, and
 μ_g = gas viscosity, cp.

To relate the fraction of gas flowing to time, Buckley and Leverett developed the following material-balance equation.

$$L = \frac{5.615 q_i t}{\phi A} \left(\frac{\partial f_g}{\partial S_g} \right), \dots \dots \dots (2)$$

where

- t = time, days,
 ϕ = porosity, fraction, and
 S_g = gas saturation, fraction.

The value of the derivative $\partial(f_g)/\partial(S_g)$ may be obtained for any value of gas saturation by plotting f_g from Eq. 1 vs. S_g and determining slopes at various points on the resulting curve.^{3,4} This graphical procedure is generally considered to be sufficiently precise for most reservoir engineering calculations. It is especially suited where the calculations are to be made by hand calculators. A more precise mathematical procedure for evaluating the function $\partial(f_g)/\partial(S_g)$ was presented by Kern⁵ and is particularly adaptable for use with digital computers.

Figs. 43.1 and 43.2 illustrate the displacement process described by Eqs. 1 and 2. Calculated oil- and gas-saturation distributions for a hypothetical example of gas displacement after successive periods of injection are shown in Fig. 43.2. The area beneath any curve represents the gas-invaded zone, whereas the area to the right of the "gas front" at any time represents the uninvaded zone.

Modifications of Displacement Equations

Eqs. 1 and 2 were developed on the basis of the following simplifying assumptions.

1. Steady-state flow conditions prevail.
2. Displacement takes place at constant pressure.
3. The displacing and displaced phases are in compositional equilibrium.
4. None of the injected gas is dissolved in the oil.
5. There is no production of fluids from behind the gas front.
6. The advancing gas moves parallel to the bedding planes of the formation.
7. The gas front moves uniformly through laminated sands.
8. The interstitial water present is immobile.

The applicability of the basic displacement equations to a given reservoir is, of course, governed to a large extent by the restrictions imposed by the basic assumptions. Several authors have reported modifications to the displacement equations that eliminate the need for making certain of the assumptions. Modifications that take into consideration the swelling effects experienced from injection into an undersaturated reservoir and production of fluids from behind the gas front have been presented by Welge,³ Kern,⁵ Shreve and Welch,⁶ and others. Jacoby and Berry,⁷ Attra,⁸ and others have presented equations and analytical procedures for calculating per-

formance where there is significant compositional interchange of components between the displacing gas phase and the reservoir oil. The influence of deviations from the conditions described in Assumptions 6 and 7 is generally taken into consideration in the determination of conformance efficiencies.

Influencing Factors

Eqs. 1 and 2 provide a means for investigating the relative influence of the various parameters affecting unit-displacement efficiency. These factors are (1) initial saturation conditions, (2) fluid viscosity ratios, (3) relative-permeability ratios, (4) rate and formation dip, (5) capillary pressure, and (6) reservoir pressure and fluid properties.

Initial Saturation Conditions. Frequently, gas-injection operations are initiated after reservoir pressures have declined to such an extent as to permit the accumulation of free gas released from solution in the oil. If the free-gas saturation exceeds the breakthrough or critical saturation determined from the fractional-flow curve, an oil bank ahead of the front will not be formed; consequently, oil production will be accompanied by immediate and continually increasing free-gas production.² This influence of initial mobile gas saturation on gas displacement performance has been demonstrated by laboratory investigations and mathematical analyses.⁹ Fig. 43.3 shows a comparison of calculated and experimentally determined gas displacement performance. It will be noted that approximately 10% oil recovery was attained prior to gas breakthrough where the initial gas saturation was zero, whereas with an initial gas saturation of 18.1% PV, a period of gas-free production was not observed.

The magnitude of the interstitial water saturation present in a reservoir, of course, influences the quantity of oil subject to gas displacement. It apparently does not have an influence on the breakthrough unit-displacement efficiency as determined by the fractional-flow equations, however.¹⁰ If the interstitial water saturation is a mobile phase, the displacement equations are not directly applicable since they were developed from concepts of two-phase flow. Approximations of gas displacement performance can usually be made where three phases are mobile by treating the water and oil phases as a single liquid phase. Displacement calculations can then be made with k_{rg}/k_{ro} data determined from core samples containing interstitial water saturation. Oil recovery can be differentiated from total liquid recovery on the basis of k_{rw}/k_{ro} data or by material-balance calculations incorporating an estimated minimum interstitial water saturation.

Fluid Viscosity Ratios. The effects of variations in oil viscosity on calculated unit-displacement efficiency can be seen from an examination of the curves presented in Fig. 43.4. Note that the oil recovery is significantly improved as the viscosity of the oil approaches that of the displacing gas. This indicates that the most efficient displacement will occur where the oil-to-gas viscosity ratio is unity or less.

Fig. 43.3—Comparison of calculated and experimental gas-injection performance for two conditions of initial gas saturation.

Rate and Formation Dip. Note from Eq. 1 that several factors influence the magnitude of the gravity term. Since the fractional flow of gas decreases as the magnitude of the gravity term increases, maximum benefits from gravity segregation are obtained when the following occur.

1. Specific permeabilities and relative permeabilities to oil are high.
2. Reservoir oil viscosities are low and densities are high.
3. The cross-sectional area to flow is large.
4. The angle of dip is high (Fig. 43.5).
5. Injection and production rates are low.

Frequently, the design of a gas-injection program can have an appreciable effect on whether maximum advantage is obtained from gravity drainage in a given reservoir. For example, proper location and distribution of injection wells along the structurally high portions of the reservoir may in some cases increase the cross-sectional area to flow and take full advantage of maximum reservoir dip. Cap oil viscosities and relative oil permeabilities are favorable when pressures are highest. In addition, injection and production rates, in terms of reservoir withdrawals, are generally lowest at high reservoir pressures, indicating that maximum benefits from gravity drainage can be achieved by initiating gas-injection operations early in the life of a reservoir.

Relative-Permeability Ratios. It has been shown that the concepts of relative permeability can be applied equally well to complete or partial pressure-maintenance operations.¹¹ Since relative-permeability ratio, along

Fig. 43.4—Effect of oil viscosity on fractional flow of gas.

with viscosity ratio, fixes the relative portions of gas and oil flowing at any given saturation condition, it is one of the more important factors influencing unit-displacement efficiency. Relative permeability is a characteristic of the reservoir rock and is a function of fluid-saturation conditions; therefore, an operator has no control over the relative-permeability characteristics of a given reservoir. However, because of the significant influence that this factor has on the performance of gas-displacement operations, it is important that calculations be based on dependable data obtained from laboratory analyses of core samples. If possible, the laboratory-determined data should be supplemented by relative permeabilities calculated from field performance data.

Capillary Pressure. Capillary-pressure forces tend to oppose the forces of gravity drainage and, as a result, tend to decrease unit gas displacement efficiency. At extremely low rates of displacement where frictional factors become negligible, the saturation distribution may be controlled to a large extent by the balance between capillary and gravitational forces. However, at the rates of displacement normally employed in practice, it is generally considered that in most cases capillary forces, or capillary-pressure gradients, can be neglected without seriously detracting from the utility of the analysis.

Reservoir Pressures and Fluid Properties. In certain highly undersaturated reservoirs, particularly those containing high-gravity crude oils that are to some degree volatile, the unit-displacement efficiency can be increased by initiating pressure-maintenance operations at the highest pressure possible. Under the proper conditions of pressure and fluid composition and at the proper degree of undersaturation, a miscible-fluid displacement can be achieved by use of relatively "dry" injection gas. The mechanics of this process, which reportedly achieves unit-displacement efficiencies approaching

Fig. 43.5—Effect of formation dip on fractional flow of gas.

100%, will be considered more in detail in Chap. 45. Recovery efficiency often can be improved by gas injection at high reservoir pressures even though miscibility is not achieved. This improvement in recovery may be a result of (1) swelling or expansion of the undersaturated reservoir oil resulting from addition of dissolved gas, (2) reduction of the oil viscosity from addition of dissolved gas, and (3) vaporization of the residual oil and subsequent recovery from the produced gas.¹²

Laboratory data obtained from tests using samples of reservoir fluid and injection gas are necessary to evaluate quantitatively the degree of swelling and vaporization that will take place under specified reservoir conditions. These data may be used in conjunction with conventional material-balance, compositional-balance, and displacement equations to arrive at an estimate of unit-displacement efficiency.

Calculation Procedures

Example procedures for calculating displacement efficiency are included in Appendix A for the cases of horizontal and vertical (down dip) flow of displacing gas.

Methods of Evaluating Conformance Efficiency

Several methods have been advanced for evaluating the conformance efficiency for a given reservoir. Generally, all the methods are somewhat empirical and are based on either comparisons of calculated and observed past displacement performance or statistical analyses of core-analysis data.

If a displacement process such as gas-cap expansion or pilot injection operations has been operative in a reservoir long enough to yield sufficient and reliable data concerning the position of the gas front and recovery as a function of time, past reservoir performance can be used to calculate conformance efficiency. The basic premise

for this type of analysis is that the conformance efficiency is the predominant factor responsible for deviations between actual displacement performance and the ideal or theoretical. On this basis, the conformance efficiency is calculated by dividing the observed recovery at various time intervals by theoretical recovery for corresponding time periods. Theoretical recovery may be determined from unit-displacement-efficiency calculations including an appropriate areal sweep efficiency. The conformance efficiencies thus determined may then be empirically correlated with either rate of production or percent recovery to determine an average value or trend for use in making future performance predictions.

Several authors have presented methods for determining conformance efficiencies based on statistical treatments of core-analysis data. Perhaps the most frequently used is an adaptation of the method presented by Stiles¹³ for evaluating the effect of permeability variations on waterflood performance (see Chap. 44). Conformance-efficiency calculations for miscible-fluid displacement using this analytical technique are presented in Chap. 45. The same calculation procedures may be used when immiscible gas displacement is considered, except that the relative-permeability ratio k_{rg}/k_{ro} must be considered for immiscible gas displacement, whereas it is not applicable to miscible displacement. The relative-permeability ratio used in such calculations is considered to be constant and is generally taken to be the relative permeability to gas at residual oil saturation divided by the relative permeability to oil at initial gas saturation.

Influencing Factors

The conformance efficiency for a given reservoir is largely controlled by the influence of (1) variations in rock properties, (2) mobility ratios, and (3) gravity segregation.

Variations in Rock Properties. Reservoir-rock porosity and permeability vary from one pore channel to the next. In addition, reservoir rock almost universally is formed in layers—stratified—either to a small extent or over large distances. Stratification can be merely differences in porosity and permeability of layers in capillary equilibrium or can be separations caused by impermeable shale or other rock streaks. Variations in porosity and permeability can be both vertical and horizontal. All these rock heterogeneities tend to decrease the effective size of the reservoir as far as displacement operations are concerned. Therefore, the degree of heterogeneity controls to a large extent the conformance efficiency attainable from gas-injection operations in a given reservoir.

Mobility Ratios. The mobility of a fluid is an index of the ease with which the fluid will flow under specified conditions. Herein, mobility is defined as the relative permeability to a fluid at a given saturation divided by the fluid viscosity. Mobility ratio, M , is an index of the ease with which one fluid will flow relative to another fluid. It is defined herein as the ratio of the gas mobility to the oil mobility or, in equation form,

$$M = \frac{k_{rg}}{k_{ro}} \frac{\mu_o}{\mu_g}, \dots\dots\dots (3)$$

with permeabilities and viscosities as before.

If the mobility ratio is equal to unity, it indicates that, for a given pressure differential, oil and gas will flow with equal ease; values greater than unity indicate that gas will be the more mobile fluid, etc. During the gas displacement process, mobility ratio can vary from essentially zero during periods of low gas saturation to values approaching infinity during the periods of high gas saturation.

In heterogeneous reservoir-rock systems, relative-permeability characteristics may be extensively variable both laterally and vertically. As a result, the displacing gas will not form a uniform front as it advances but will tend to “finger” ahead in the layers or areas having higher mobility ratios. As the displacement progresses, the mobility ratio continues to increase in the portions of the reservoir previously contacted by displacing gas. As a result, there is a decreasing tendency for gas to enter regions of low permeability or regions of low gas saturation. These volumes are therefore bypassed and little or no oil is recovered from them. It can be seen that the factors tending to increase the mobility ratio also tend to accentuate the detrimental effects of sand heterogeneity on conformance efficiency.

High localized injection and production rates in the presence of adverse mobility ratios and sand heterogeneity can add to the severity of gas channeling and resultant bypassing of oil. The possibility of creating this adverse effect frequently can be reduced through proper selection of the number and location of injection wells and proper scheduling of fluid withdrawals so that minimum pressure drawdown is created in the vicinity of the advancing gas front.

Gravity Segregation. As was previously mentioned, gravity forces tend to improve unit-displacement efficiency. Gravity drainage has essentially the same influence on conformance efficiency, and its effectiveness is controlled by the same factors—i.e., rate, angle of dip, vertical permeability, etc. Under favorable conditions, gravity drainage tends to maintain a more uniform gas front and therefore tends to offset the effects of adverse mobility ratios and permeability variations.

Under certain conditions, gravity segregation of the displacing and displaced fluids has an adverse effect on the conformance efficiency. In reservoirs having relatively good vertical communication, low formation dips, and slow displacement rates, the gas tends to segregate to the top of the formation, bypassing oil in the lower portions and creating a so-called umbrella effect, which causes premature breakthrough of the gas and a lowering of conformance efficiency.

Methods of Evaluating Areal Sweep Efficiency

Several investigators have shown that the areal sweep efficiency for a given reservoir is controlled to a large extent by (1) injection/production well arrangements with respect to reservoir geometry, (2) mobility ratio of the fluids involved, and (3) number of displacement volumes injected.

Fig. 43.6—Sweep efficiency as a function of mobility ratio.

Applied mathematical techniques have been used to investigate the influence of these factors on regular geometrical reservoir units of constant thickness. On the other hand, various types of laboratory and numerical models have been used to study the effects on areal sweep efficiencies of irregular reservoir boundaries, irregular well arrangements, variable formation thicknesses, and variable mobility ratios. From these investigations, it generally can be concluded that the areal sweep efficiency at gas breakthrough will be a maximum in a given reservoir when the mobility ratio is low and when the distance from injection to production well is large. After gas breakthrough, areal sweep efficiencies are improved as the number of injected displacement volumes increase. The influence of mobility ratio and displacement volumes injected on the areal sweep efficiency of a regular five-spot reservoir unit may be seen in Fig. 43.6. The data presented in this illustration were obtained from model studies that used miscible fluids of various viscosities to study the influence of various mobility ratios. These data are generally considered to be applicable to reservoir analyses for either water or gas displacement when actual model studies for a given reservoir are not available.

Areal sweep efficiencies, calculated at gas breakthrough and at successive periods thereafter until the economic limit is reached, are required for estimating reservoir performance under pressure-maintenance operations. If the injection/production well arrangements and the fluid mobility ratios for a given reservoir closely approximate those that have been studied in the laboratory, the data on this subject reported in the literature may be used as a basis for estimating the areal sweep efficiencies. Data reported by Dyes *et al.*¹⁴ have been found particularly useful since consideration was given to the influence of production after gas breakthrough. Note that the quantitative applicability of laboratory data is inherently questionable because of uncertainties in model scaling, laboratory techniques, and associated simplifying assumptions. Nevertheless, laboratory-model studies still offer the most convenient means of determining quantitative data concerning areal

Fig. 43.7—Areal sweep efficiency as a function of injection fluid volume for a mobility ratio of unity.

sweep efficiencies. For this reason, if mathematical model studies are not practical for the particular reservoir under consideration, published data (tempered by experience) must generally be resorted to as a basis for predicting areal sweep efficiencies even though the well arrangements being investigated do not duplicate those reported in the literature.

For application to performance predictions, it is frequently desirable to construct a curve showing the areal sweep efficiency for a given mobility ratio as a function of the fractional gas flow, f_g , or the displacement volumes injected. For example, Fig. 43.7 shows a replot of the data presented in Fig. 43.6 for a mobility ratio of unity. If necessary, the trend established from these data may be adjusted up or down depending on the judgment of the engineer as to the applicability of the model to the reservoir under consideration.

As was discussed in a previous section of this chapter, during gas displacement operations there is a significant gradient in mobility ratios behind the gas front. Therefore, an average mobility ratio must be selected to determine areal sweep efficiencies from published data. Probably the most representative, and certainly the most conservative, value for this purpose is the mobility ratio determined at the average gas saturation behind the front according to the methods presented in connection with unit-displacement efficiencies.

Calculation of Gas Pressure-Maintenance Performance

Estimates of gas-injection performance are generally based on the simultaneous solution of one or more forms of the conventional material-balance equations and the displacement equations previously discussed. The manner in which these equations are applied will vary depending on the scope of the investigation, the type of reservoir under consideration, and whether dispersed or external injection is to be used for complete or for partial pressure maintenance. Rigorous treatment of all factors influencing production performance and the displacement processes in a given reservoir can result in the development of calculation procedures that are quite

complex. Specific analytical techniques and procedures as applied to various types of reservoirs have been the subject of numerous articles in the technical literature and several reservoir engineering textbooks. A selected bibliography of technical articles dealing with specific analytical techniques and procedures that can be used for estimating reservoir performance under gas-injection operations is included in Appendix B. Note that these references are indexed according to the type of reservoir under consideration, the major influencing factors, and the type of injection-well arrangement. These references can be used as a basis for developing suitable analytical techniques to estimate future pressure-maintenance performance in any given reservoir. However, since each petroleum reservoir is unique, in the final analysis engineers must rely upon imagination and experience to develop techniques, based on fundamental theory, for the particular reservoir under consideration.

Although the equation forms and specific details of estimating reservoir performance will vary somewhat for each reservoir considered, certain general analytical procedures are common to most investigations and can be used as a basis for developing specific calculation techniques. A complete engineering analysis of a reservoir for the purpose of evaluating gas-injection operations will usually consist of four major phases: (1) assembly, preparation, and analysis of basic data; (2) analysis of past performance; (3) projection of future performance of current operations; and (4) estimation of gas pressure-maintenance performance.

Basic Data

The need for adequate and comprehensive basic data has been emphasized in other chapters of this book and is apparent when it is realized that the validity and therefore the utility of any engineering analysis is determined primarily by the quality and quantity of basic data. The data requirements for analysis of gas-injection operations are, with few exceptions, the same as the requirements for analysis of other types of fluid-injection operations. Appendix C includes an outline of the usual data requirements for engineering analyses as presented by Patton,¹⁵ with certain additions and modifications.

Analysis of Past Performance

The methods used to evaluate past reservoir performance will, of course, vary depending on the active reservoir drive mechanisms present, the quantity of suitable basic data available, and the amount of detail or scope of the investigation. Procedures for analyzing past reservoir performance are discussed in detail in other chapters. The results of such analyses will determine to a large extent the methods used for predicting gas-injection pressure-maintenance performance and will provide the current reservoir pressure and saturation distribution conditions for use in such predictions. Further, proper analysis of past performance will aid in supplementing and establishing the reliability of data required for the projection of reservoir performance under injection operations.

Projection of Future Performance of Current Operations

Decisions regarding the installation of gas-injection

operations must be made on the basis of the relative benefits to be derived from such operations compared with competitive recovery techniques. Therefore, any complete analysis of gas-injection operations would include the projection of future reservoir performance under the current production operations. Methods of projecting future primary production performance and other types of injection operations are discussed in detail in other chapters.

Estimation of Gas Pressure-Maintenance Performance

Generally, projections of partial pressure-maintenance performance, for either external or dispersed-type gas injection, can be made by use of conventional material- and volumetric-balance techniques in combination with recovery efficiency determinations previously discussed. On the other hand, if complete pressure maintenance is being considered, the project performance can be estimated by only the displacement equations and other analytical procedures presented previously in connection with the discussions of unit displacement, conformance, and areal sweep efficiency.

Procedures for calculating the future performance of both external and dispersed-type gas-injection operations are included in Appendix A. These example calculations include the determination of displacement efficiency and pressure, producing gas/oil ratio, and recovery performance for primary operations and for various degrees of gas-injection pressure maintenance for two idealized reservoirs.

Performance-Time Predictions. Predictions of future gas-injection performance are necessary for making economic comparisons of various types of future operations. Such predictions will usually include estimates of functions of time such as (1) reservoir pressures; (2) oil-, gas-, and water-production rates; (3) gas- and water-injection rates; (4) GOR's; (5) cumulative oil, gas, and water recovery; (6) cumulative gas and water injected; (7) number of producing, injecting, and shut-in wells; and (8) recoverable plant products, if applicable.

To estimate these quantities, it is necessary to develop relationships between the hydrocarbon distribution of the subject reservoir and the positions of injection and production wells. Once this is done and with a given injection rate, Eq. 2 can be used to calculate the time necessary for the gas front to reach incrementally selected points in the reservoir.

In gas-cap-drive reservoirs and where external injection is being considered for reservoirs having significant structural relief, it is frequently convenient to relate hydrocarbon PV, cross-sectional area, and well completion intervals to subsea depth within the reservoir. If such relationships are used and if the advancing gas front is assumed to conform to structural depth, displacement equations and fluid inventory equations can be used to predict the rate of advance of the gas front, taking into consideration changes in cross-sectional area and reservoir productivity.

Until the gas front reaches the top of the perforations in the structurally highest well, oil and gas production is controlled by the productivities or allowables of the producing wells ahead of the front; and producing GOR's

Bubblepoint pressure at gas/oil level p_b , psig	1,375

are controlled by gas-saturation conditions ahead of the front. If it is assumed that each producing well is shut in as gas breakthrough occurs, the producing GOR will remain a function of oil-zone gas saturation, and the total oil-producing rate and gas-injection rate will decline as the front reaches each successively lower-producing well. The oil-producing rate at any position of the gas front can be determined from the productivities or allowables of the wells in the uninvaded portions of the reservoir. If it is assumed that each well is produced to an economically limiting GOR prior to being shut in, production from behind the front must be accounted for by use of the modified displacement equations referred to previously. In such cases, a comprehensive fluid inventory is required to account for the portion of the injected gas being produced at any time and the portion that is advancing down structure. If partial-pressure-maintenance operations are being considered, it is necessary to introduce material-balance equations to calculate, by trial-and-error methods, the pressure decline and relative positions of the advancing gas front.

With complete pressure maintenance in reservoirs having low structural relief or where the gas front is likely to advance parallel to the bedding planes of the formation,

the cumulative hydrocarbon distribution, cross-sectional area, and reservoir productivity can be related to distance from injection to production wells. Where dispersed gas injection is being considered, calculations can be made for a typical pattern element of the reservoir and the results applied to the total number of patterns present. Care should be taken to select a method of reservoir representation that will conform as nearly as possible to the anticipated frontal advance in a given reservoir.

APPENDIX A

Example Calculations of Future Performance

I. Basic Data

The basic reservoir rock and fluid data used throughout are presented in Tables 43.1 and 43.2 and in Figs. 43.8 and 43.9.

II. Unit Displacement

A. Horizontal Gas Flow

1. Equation

$$f_g = \frac{1}{1 + (k_{ro}/k_{rg})(\mu_g/\mu_o)}$$

where

- f_g = fractional gas flow,
- k_{ro} = relative permeability to oil at S_g ,
- k_{rg} = relative permeability to gas at S_g ,
- μ_o = oil viscosity at p , cp, and
- μ_g = gas viscosity at p , cp.

2. Procedure

a. Calculate and construct a fractional-flow curve for selected increments of gas saturation, S_g , as indicated in Table 43.3 and Fig. 43.10.

TABLE 43.2—SUMMARY OF RESERVOIR-FLUID PROPERTIES

b. Construct the tangent to the f_g curve from the equilibrium gas saturation, S_g (equal to zero in this case), and read the average gas saturation behind the front at breakthrough from the intercept where $f_g = 1.0$. This average gas saturation \bar{S}_g corresponds to the oil recovery as a fraction of total pore volume behind the front.

c. Construct other tangents as required to obtain the average gas saturations and oil recoveries at various other values of f_g or frontal gas saturations S_g .

B. Downdip Gas Flow

1. Equation

$$f_g = \frac{1 + 0.489[k_o(\rho_g - \rho_o)\sin \alpha / (q_t \mu_o)]}{1 + (k_{ro}/k_{rg})(\mu_g/\mu_o)}$$

where

- f_g = fractional gas flow,
- k_o = effective permeability to oil, darcies,
- ρ_g = gas density at p , g/cm³,
- ρ_o = oil density at p , g/cm³,
- α = angle of gas flow (-90°),
- q_t = rate of frontal gas movement, B/D-sq ft,
- k_{ro} = relative permeability to oil at S_g ,
- k_{rg} = relative permeability to gas at S_g ,
- μ_o = oil viscosity at p , cp, and
- μ_g = gas viscosity at p , cp.

2. Procedure

a. By using a unit flow, calculate and construct a fractional-flow curve for selected increments of gas saturation, S_g , as indicated in Table 43.4 and in Fig. 43.11.

b. Construct the tangent to the f_g curve from the equilibrium gas saturation, S_{ge} (equal to zero in this case), and read the average gas saturation behind the front at breakthrough from the intercept where $f_g = 1.0$. This average gas saturation \bar{S}_g corresponds to the oil recovery as a fraction of the total swept pore volume.

c. Construct the tangent to the f_g curve where f_g becomes asymptotic to 1.0 and read the ultimate or maximum value for \bar{S}_g .

III. Dispersed Gas-Injection Pressure Maintenance

A. Partial Pressure Maintenance

1. Equations

$$\Delta N_p = \frac{(1 - N_{pi}) \Delta[(B_o/B_g) - R_s] - B_{ob} \Delta(1/B_g)}{[(B_o/B_g) - R_s] + \bar{R}(1 - \Delta G_i)}$$

$$S_L = S_w + (1 - S_w) \left(\frac{B_o}{B_{ob}} \right) (1 - N_p),$$

and

$$R = R_s + \left(\frac{k_{rg}}{k_{ro}} \right) \left(\frac{\mu_o}{\mu_g} \right) \left(\frac{B_o}{B_g} \right),$$

Fig. 43.8—Reservoir volume and area as functions of height.

Fig. 43.9—Relative-permeability data.

where

- ΔN_p = incremental oil production, fraction of OIP,
- N_p = cumulative oil production, fraction of OIP,
- N_{pi} = cumulative oil produced from previous step, fraction of OIP,
- R = instantaneous GOR, scf/STB,
- \bar{R} = average GOR, scf/STB,
- R_s = solution GOR, scf/STB,
- S_L = total liquid saturation, fraction,
- S_w = interstitial water saturation, fraction,
- k_{rg} = relative permeability to gas at S_L ,
- k_{ro} = relative permeability to oil at S_L ,
- μ_g = gas viscosity at p , cp,
- μ_o = oil viscosity at p , cp,
- B_o = oil FVF, RB/STB,
- B_{ob} = oil FVF at p_b , RB/STB,
- B_g = gas FVF, bbl/scf, and
- ΔG_i = incremental gas injection, fraction of produced gas.

2. Procedure

a. Select pressure increments such that any one increment $\leq 10\%$ of the initial or bubble-point pressure and obtain fluid properties as indicated in Table 43.2.

b. Perform material-balance calculation as shown in Table 43.5, with no gas injection, by assuming an incremental oil production ΔN_p and verifying this value by the trial-and-error procedure indicated. This procedure can be shortened by use of previous calculated ΔN_p for the second and third trials at each pressure. (Note that subscript i in Col. 13 refers to previous step.)

c. Repeat this procedure for various values of gas injection as shown in Table 43.6.

d. Construct performance curves as indicated in Fig. 43.12.

* Calculated at corresponding rate and pressure of 1,375 psig (9480.3 kPa).

** Calculated at corresponding rate and pressure of 900 psig (6205.3 kPa).

e. For cases where the gas saturation, S_g , exceeds the critical gas saturation as determined from an f_g vs. S_g curve at the appropriate pressure, performance from that point to abandonment must be determined by the frontal-advance method illustrated in III-B, which follows. Abandonment recovery to a limiting GOR can be determined directly from the f_g relationship.

B. Pressure Maintenance

1. Equation is same as II-A in preceding section.
2. Procedure
 - a. Construct f_g curve and tangents as shown in II-A.
 - b. Calculate performance as shown in Fig. 43.10.
 - c. Construct performance curves as indicated in Fig. 43.12.
 - d. Calculate injection requirements for complete pressure maintenance at the bubble-point by the equation

$$\Delta G_i = 1 + \frac{(B_o/B_g) - R_s}{R_s}$$

IV. External Gas-Injection Pressure Maintenance

A. Partial Pressure Maintenance

1. Equation

$$\Delta N_p =$$

$$\frac{(1 - N_{pi})\Delta[(B_o/B_g) - R_s] - (1 + m)B_{ob}\Delta(1/B_g)}{[(B_o/B_g) - R_s] + \bar{R}(1 - \Delta G_i)}$$

where

ΔN_p = incremental oil production, fraction of OIP,

N_{pi} = cumulative oil production from previous step, fraction of OIP,

\bar{R} = average GOR, scf/STB,

R_s = solution GOR, scf/STB,

B_o = oil FVF, RB/STB,

B_{ob} = oil FVF at p_b , RB/STB,

Fig. 43.13—External gas-injection pressure-maintenance performance.

B_g = gas FVF, bbl/scf,
 ΔG_i = incremental gas injection, fraction of
 produced gas, and
 m = ratio of gas-cap to original oil-zone volume,
 fraction.

(Note that subscript i refers to previous step.)

2. Procedure

- Select pressure increments such that any one increment $\leq 10\%$ of the initial or bubble-point pressure and obtain fluid properties as indicated in Table 43.2.
- Perform depletion drive material-balance calculation with $\Delta G_i = 0$, as described in III-A.
- Perform material-balance calculation as shown in Table 43.7, using \bar{R} as determined from depletion drive calculation in Point b and \bar{S}_g as determined from unit-displacement calculations.
- Determine positions of gas/oil level and abandonment conditions, using data in Fig. 43.8 and calculations in Table 43.7.
- Construct performance curves as indicated in Fig. 43.13.

B. Pressure Maintenance

- Equation is the same as II-B.
- Procedure
 - Construct f_g curve and tangents as in II-B.
 - Calculate recovery and construct performance curves as indicated in Fig. 43.13.
 - Calculate injection requirements for complete pressure maintenance at the bubble-point by the equation

$$\Delta G_i = 1 + \frac{[(B_o/B_g) - R_s]}{R_s}$$

APPENDIX C

Data Requirements for Engineering Analysis of Gas-Injection Operations¹³

Analytical Data

1. Core analyses from a representative number of wells

- a. Porosity
 - b. Permeability
 - c. Water saturation
2. Special core analyses on a sufficient number of samples to cover permeability range of the reservoir
 - a. Capillary-pressure data (for determining interstitial saturations)
 - b. Gas/oil relative permeability, k_{rg}/k_{ro}
 - c. Relative permeability to oil, k_{ro}
 3. Hydrocarbon compositional analysis
 - a. Gas-cap, casing-head, and trap samples
 - b. Reservoir-fluid samples
 4. Reservoir-fluid property analyses
 - a. Solubility
 - (1) Flash
 - (2) Differential
 - b. Relative oil volume
 - (1) Flash
 - (2) Differential
 - c. Oil viscosity
 - d. Oil density
 - e. Gas viscosity
 - f. Gas density

Field Data

1. Development history
2. Abandonment history, if any
3. Production history
 - a. Oil
 - b. Water
 - c. Gas
4. Injection history, if any
 - a. Gas
 - b. Water
5. Pressure history
6. Well productivity data
7. Gas/oil and oil/water contacts (original and present)
8. Well and test data
 - a. Drillstem tests
 - b. Production tests
 - c. Sample cuttings
 - d. Core descriptions
 - e. Electrical and radioactivity logs
9. Average reservoir temperature
10. Well completion data

Interpretive Data (prepared from preceding data)

1. Structure maps
 - a. Top of zone
 - b. Base of zone
2. Isopachous maps
 - a. Total net sand
 - b. Net gas sand
 - c. Net oil sand
3. Reservoir volume distribution
 - a. Volume vs. subsea depth, and/or
 - b. Volumes by injection/production units
4. Cross-sectional area
 - a. Area vs. subsea depth, and/or
 - b. Area perpendicular to bedding planes for injection/production units

5. Volume-weighted reservoir datum
6. Average reservoir fluid properties (as functions of pressure)

Nomenclature

- A = cross-sectional area
 B_g = gas FVF
 B_o = oil FVF
 B_{ob} = oil FVF at p_b
 f_g = fractional gas flow
 ΔG_i = incremental gas injection
 k_o = effective permeability to oil
 k_{rg} = relative permeability to gas
 k_{ro} = relative permeability to oil
 L = distance
 m = ratio of gas-cap to original oil-zone volume
 M = mobility ratio
 N_p = cumulative oil production
 ΔN_p = incremental oil production
 p = pressure
 p_b = bubblepoint pressure
 p_c = oil/gas capillary pressure ($\rho_o - \rho_g$)
 q_t = total flow rate
 \bar{R} = instantaneous GOR
 \bar{R} = average GOR
 R_s = solution GOR
 S_g = gas saturation
 S_L = total liquid saturation
 S_w = interstitial water saturation
 t = time
 α = angle of dip, positive downdip
 μ_g = gas viscosity
 μ_o = oil viscosity
 ρ_g = gas density
 ρ_o = oil density
 ϕ = porosity, fraction

Key Equations in SI Metric Units

$$f_g = \frac{1 + (8.639 \times 10^{-5})[k_o A / (\mu q_t)] \left[\left(\frac{\partial P_c}{\partial L} \right) - 9.795(\rho_o - \rho_g) \sin \alpha \right]}{1 + \left(\frac{k_{ro}}{k_{rg}} \right) \left(\frac{\mu_o}{\mu_g} \right)} \quad \dots \dots \dots (1)$$

where

- f_g = fractional flow of gas,
 q_t = total flow rate, m³/d,
 A = cross-sectional area, m²,
 P_c = oil/gas capillary pressure, $\rho_o - \rho_g$, kPa,
 L = distance, m,
 ρ_o = oil specific gravity (water = 1) or density, g/cm³,
 ρ_g = gas specific gravity (water = 1) or density, g/cm³,
 α = angle of dip, positive downdip, degrees,
 k_o = effective permeability to oil, μm^2 ,
 k_g = effective permeability to gas, μm^2 ,
 μ_o = oil viscosity, Pa·s, and
 μ_g = gas viscosity, Pa·s.

$$L = \frac{q_t t}{\phi A} \left(\frac{\partial f_g}{\partial S_g} \right), \quad \dots \dots \dots (2)$$

where

- t = time, days,
 ϕ = porosity, fraction,
 S_g = gas saturation, fraction,

and others are as in Eq. 1.

$$f_g = \frac{1 + 0.848 \times 10^{-3} [k_o (\rho_g - \rho_o) \sin \alpha / (q_t \mu_o)]}{1 + \left(\frac{k_o}{k_g} \right) \left(\frac{\mu_g}{\mu_o} \right)} \quad \dots \dots \dots (\text{A.II.B})$$

where

- f_g = fractional gas flow,
 k_o = effective permeability to oil, μm^2 ,
 k_g = effective permeability to gas, μm^2 ,
 ρ_g = gas specific gravity at p (water = 1),
 ρ_o = oil specific gravity at p (water = 1),
 α = angle of gas flow (-90°),
 q_t = rate of frontal gas movement, m³/d·m²,
 μ_o = oil viscosity at p , Pa·s, and
 μ_g = gas viscosity at p , Pa·s.

Note: All other material-balance, saturation, and GOR equations that follow are correct for standard SI units, where B_o and B_g are volume factors (in m³/m³) and \bar{R} , R_s , and R_p are GOR's (in m³/m³).

Chapter 44

Water-Injection Pressure Maintenance and Waterflood Processes

C.E. Thomas, Core Laboratories Inc.*

George W. Winter, Core Laboratories Inc.

Introduction

Many factors that are important to waterflooding are also important in water-pressure maintenance, so it is difficult to define the point of separation between the two processes. Accordingly, a major portion of the information presented in this chapter applies to both waterflooding and water-pressure-maintenance operations. For our purposes, waterflooding and water-pressure maintenance are defined as follows.

Waterflooding is a secondary-recovery method by which water is injected into a reservoir to obtain additional oil recovery through movement of reservoir oil to a producing well, after the reservoir has approached its economically productive limit by primary-recovery methods.

Water-pressure maintenance is a process whereby water is injected into an oil-producing reservoir to supplement the natural energy that is indigenous to the reservoir and to improve the oil-producing characteristics of the field before the economically productive limits are reached.

General History and Development of Waterflooding

The first recognition of the benefits that can be obtained from water injection came as a result of accidental flooding when water was inadvertently admitted to producing oil sands through abandoned wells. In 1880, Carll¹ reported increased oil production following accidental flooding in the Pithole City (PA) area, and suggested the use of intentional flooding. Although waterflooding was illegal in Pennsylvania before 1921 and in New York before 1919, water-injection operations in these areas were reported as early as the 1890's.² Since it was illegal, limited information is available on operations before 1922;

however, increased production was noted in 1907 in Pennsylvania's Bradford field and in 1912 in New York.³ The linedrive pattern was introduced in 1922 and the five-spot pattern in 1924. The use of pattern injection programs, when combined with surface pressure injection, provided a more effective and efficient method of moving oil to the producing wells.

The initial success of waterflooding in the Bradford area can be attributed to a number of favorable factors. The Bradford sand generally had no natural water encroachment, contained a relatively low-viscosity crude, and had a low initial gas saturation. As a result, primary recovery was limited, and the oil recovery by water injection was significantly larger than that achieved by natural pressure depletion.

Waterflooding was slow to expand outside the Pennsylvania-New York area. The first waterflood was initiated in Oklahoma in 1931 in a shallow Bartlesville sand in Nowata County. In 1936, waterflooding was introduced in Texas when injection was applied to the Fry pool in Brown County. Within 10 years, waterflooding was in operation in most of the oil-producing areas. However, it was not until the early 1950's that the general applicability of waterflooding was recognized.⁴

There are no generally reliable records of water-injection operations in areas outside the U.S. during this developmental period, but sufficient data have been published to indicate a comparable growth pattern in other parts of the world.

Waterflooding currently is accepted worldwide as a reliable and economic recovery technique; almost every significant oil field that does not have a natural water drive has been, is being, or will be considered for waterflooding.

*Original chapter in the 1962 edition was written by H.C. Osborne, C.E. Thomas, J.F. Armstrong, L.L. Crain, C.F. Mahoney, F.C. Kelton, Bill Lafayette, and J.E. Smith.

Important Factors in Waterflooding or Water-Injection Pressure Maintenance

In determining the suitability of a given reservoir for waterflooding or pressure maintenance, these factors must be considered: (1) reservoir geometry, (2) lithology, (3) reservoir depth, (4) porosity, (5) permeability (magnitude and degree of variation), (6) continuity of reservoir rock properties, (7) magnitude and distribution of fluid saturations, (8) fluid properties and relative-permeability relationships, and (9) optimal time to waterflood.

Generally, the influence of all these factors on ultimate recovery, rate of return, and ultimate economic return must be considered collectively to evaluate the economic feasibility of conducting waterflood and/or water-pressure-maintenance operations in a particular reservoir. Factors other than reservoir characteristics also will have a great influence. These include the price of oil, marketing conditions, operating expenses, and availability of water.

Reservoir Geometry

One of the first steps in organizing reservoir information to determine whether water injection is feasible is to establish the geometry of the reservoir. The structure and stratigraphy of the reservoir control the location of the wells and, to a large extent, dictate the methods by which a reservoir may be produced through water-injection practices.

Structure is a principal factor in governing gravitational segregation. In the presence of high permeabilities, recovery by gravity segregation, particularly in old pools, may reduce oil saturation to a value at which the application of water injection may be uneconomical. If a suitable structure exists and the remaining oil saturation proves sufficient for secondary operations, the adaptation of a peripheral flood may result in a higher areal sweep efficiency than would the conventional pattern or linedrive floods. High relief also would suggest investigation of a companion gas-injection program. The shape of the field and the presence or absence of a gas cap would also influence this decision.

Most water-injection operations conducted to date have taken place in fields that exhibit only moderate structural relief. Many floods are located in pools where the oil accumulation occurs in reservoirs of the stratigraphic-trap type. Since these pools, as a rule, have been produced by dissolved-gas drive and have not received any benefits from natural-water encroachment or other displacement-energy mechanisms, high oil saturations usually remain after primary-recovery operations, making these reservoirs most attractive for secondary-recovery operations.

In such pools, the dip of the strata may be so slight as to have no noticeable effect on secondary-recovery operations. Thus, the location of the injection and producing wells may be made to conform to property lines and to known sand conditions. Whether such a practice would prove successful in pools where oil and gas distribution has been controlled by a high-relief structure is questionable.

An analysis of reservoir geometry and past reservoir performance is often important in defining the presence and strength of a natural-water drive and, thus, in defining the need for supplementing injection. If a natural-water

drive is determined to be strong, injection may be unnecessary. Structural features such as faults, or stratigraphic features such as shale-outs, or any other permeability barrier usually will influence these decisions. An otherwise suitable reservoir may be so highly faulted as to make any injection program economically unattractive.

Lithology

Lithology has a profound influence on the efficiency of water injection in a particular reservoir. Lithological factors that affect floodability are porosity, permeability, and clay content. In some complex reservoir systems, only a small portion of the total porosity, such as fracture porosity, will have sufficient permeability to be effective in water-injection operations. In these cases, a water-injection program will have only a minor impact on the matrix porosity, which might be crystalline, granular, or vugular in nature. Evaluation of such effects requires an extensive laboratory investigation and a somewhat comprehensive reservoir study. Evaluations can be supplemented by experimental pilot injection operations.

There is laboratory evidence that a difference between the mineralogical compositions of the sand grains and cementing material of various oil-producing formations may account for differences in the residual oil saturation (ROS) that have been observed subsequent to waterflooding. These differences in oil saturation are indicated to be dependent not only on the mineralogical composition of the reservoir rock but also on the composition of the hydrocarbons within the rock. Benner and Bartell⁵ have shown that, under certain conditions, the basic constituents of some types of petroleum cause quartz to become hydrophobic because of the adsorption of these constituents by the surface of the sand grains. In a similar manner, the acidic constituents of other types of petroleum render calcite hydrophobic. At present, there are not enough data available to permit valid predictions regarding the effects on recovery when the pore walls are made wet to various degrees by water and petroleum, but it appears probable that there is some effect.

Although there is evidence that the clay minerals that are present in some oil sands may clog the pores by swelling and deflocculating when waterflooding is used, no exact data are available as to the extent to which this may occur. The effect depends on the nature of the clay minerals; however, an approximation of the pore-clogging impact may be determined through laboratory investigations. The montmorillonite group is most likely to cause a reduction in permeability by swelling; kaolinite is least likely to cause a reaction. The extent to which such a reduction in permeability will occur also depends on the salinity of the water that is injected. Brines are usually preferable to fresh water for flooding purposes.

Reservoir Depth

The depth of the reservoir is another factor that should be considered in waterflooding. If the depth of the reservoir is too great to permit redrilling economically and if old wells have to be used as injection and producing wells, lower recoveries may be expected than in cases in which new wells can be drilled. This is particularly true in old fields where regular well spacings were not observed and where infill development was not as extensive as lease-line development. Also, after primary operations, ROS's

in most deep pools probably are lower than in shallow pools, because a greater volume of solution gas was generally available to expel the oil and because shrinkage factors are higher. Therefore, less oil remains. Greater depth, on the other hand, permits the use of higher pressures and wider well spacings, provided the reservoir rock possesses a sufficient degree of lateral uniformity.

Caution should be exercised in shallow-depth fields since the maximum pressure that can be applied in a secondary-recovery operation is limited by the depth of the reservoir. In waterflood operations, it has been found that there is a critical pressure (usually approximating that of the static pressure of the column of rock overlying the productive sand, or about 1 psi/ft of sand depth) which, if exceeded, apparently permits the penetrating water to expand openings along fractures or other planes of weakness, such as joints and, possibly, bedding planes. This results in the channeling of the injected water or the bypassing of large portions of the reservoir matrix. Consequently, an operational pressure gradient of 0.75 psi/ft of depth normally is allowed to provide a sufficient margin of safety to prevent pressure parting. However, to remove as much doubt as possible, information regarding fracture pressures or breakdown pressures in a given locality should be studied. Either pressure should be considered as an upper limit for injection. These considerations will also influence equipment selection and plant design, as well as the number and location of injection wells.

Porosity

The total recovery of oil from a reservoir is a direct function of the porosity, because the porosity determines the amount of oil that is present for any given percent of oil saturation. Since the fluid content of reservoir rock varies from 775.8 to 1,551.6 bbl/acre-ft for porosities of 10 and 20%, respectively, it is important that reliable porosity data be assembled. Porosities sometimes vary from 10 to 35% in an individual zone. In limestones and dolomites, pinpoint and fractured porosities may vary from 2 to 11%; honeycombed and cavernous porosities may vary from 15 to 35%. In establishing an average porosity, the arithmetic average of the porosities determined from core samples has proved acceptable. If there are sufficient data, isoporosity maps are used when the distribution of porosity is important—as, for instance, when some fields are unitized. These maps may be areally or volumetrically weighted to give a very good total porosity value. If enough core data are available, statistical analyses of porosity and permeability may be used to improve the use of these data.

To date, the most satisfactory method of measuring this important property has been through laboratory measurements of core samples. Various logging methods have been quite satisfactory in many cases. The logs may include a "microlog" or "contact log," neutron log, density log, or sonic log.

Permeability (Magnitude and Degree of Variation)

The magnitude of the permeability of the reservoir rock controls, to a large degree, the rate of water injection that can be sustained in an injection well for a specific pressure at the sandface. Therefore, in determining the suitability of a given reservoir for waterflooding, it is necessary to determine (1) the maximum permissible injection pres-

sure from depth considerations, and (2) the rate vs. spacing relationships from the pressure/permeability data. This should indicate roughly the additional drilling that would be required to complete the proposed flood program in a reasonable length of time. An approximation of the expected recovery then can be compared with the monetary expenditure for this development program, so as to indicate quickly the suitability of the reservoir as a flood prospect. If the project profitability is favorable, more detailed work may be warranted.

The degree of variation in permeability has justifiably received much attention in recent years. Reasonably uniform permeability is essential for a successful waterflood, because this determines the quantities of injected water that must be handled. If great variations in the permeability of the individual strata within the reservoir are noted, and if these strata maintain continuity over substantial areas, injected water will break through early in high-permeability streaks and will transport large quantities of injected water before the low-permeability streaks have been swept effectively. This, of course, will influence the economics of the project and thus the suitability of the reservoir for flooding. Not to be overlooked is that continuity of these streaks or strata is as important as the permeability variation. If there is no correlation between the permeability profiles of the individual wells, the chances are good that the high-permeability zones are not continuous and that the channeling of injected fluids will be less severe than indicated by performance calculations.

Continuity of Reservoir-Rock Properties

The importance of reservoir-rock continuity in relation to permeability and vertical uniformity in determining the suitability of a reservoir for waterflooding has been mentioned previously. Since the flow of fluids in a reservoir is essentially in the direction of bedding planes, horizontal (along bedding planes) continuity is of primary interest. If the reservoir body is split into layers by partings of shale or dense rock, a study of a cross section of the producing horizon should indicate whether individual layers have a tendency to shale out in relatively short lateral distances, or whether sand development is uniform. Also, evidence of crossbedding and fracturing should be collected from core data. These features should be considered in determining well-spacing and flood patterns, and in estimating the volume of the reservoir that will be affected during the injection program. The presence of shale partings is not necessarily detrimental, provided the individual layers of reservoir rock exhibit a reasonable degree of continuity and uniformity with respect to permeability, porosity, and oil saturation. When vertical discontinuities exist (i.e., when there is a water- or gas-bearing stratum in the producing formation), shale partings will sometimes permit a selective completion; such a completion allows the exclusion or reduction of water or gas production and permits selective water injection.

Fluid Saturations and Distributions

In determining the suitability of a reservoir for waterflooding, a high oil saturation certainly would be considered more suitable than a low oil saturation. Usually, the higher the oil saturation at the beginning of flood operations, the higher the recovery efficiency will be. Also, ultimate

recovery will be higher, the bypassing of water will be less, and the economic return per dollar risked will be greater. Also involved in the suitability determination is the ROS after passage of the water front. Methods for ascertaining this saturation are discussed later in this chapter. The more this value can be reduced, the greater the ultimate oil recovery and economic gain. Most of the newer, more specialized displacement techniques that are currently under development and experimentation are aimed solely at reducing the value of ROS behind the displacing medium (see Chap. 42).

Also of great interest is the initial saturation measurement of the interstitial water. A knowledge of this quantity is essential in determining the initial oil saturation. Leverett and Lewis⁶ and other investigators^{7,8} have shown experimentally that, as a fraction of PV, oil recovery by solution-gas drive is essentially independent of connate-water saturations. Therefore, the amount of residual oil after the solution-gas depletion varies inversely with the water saturation. Worthy of mention here is the effect that initial water saturation has on the formation of an oil bank in front of the advancing water front. If the water saturation exceeds some critical value, an oil bank may not form; although substantial oil recovery may be achieved, oil will be produced at high water cuts. The water saturation that would preclude the formation of an oil bank may be determined from the fractional-flow equation, as illustrated later. This value may vary greatly from field to field. The fractional-flow equation also will indicate the amount of water that may be expected in the total flow stream at any particular saturation.

In the U.S. midcontinent area, waterflood programs have resulted in substantial oil recoveries being obtained from sands that have water saturations ranging from 22 to 40%. The average saturation in the Bartlesville sand of Oklahoma is about 30%. In the Bradford field, gas injection has proved unprofitable with oil saturations of 40% and water saturations of 30%; however, waterflooding has been very successful.

The Venango fields of Pennsylvania have responded more favorably to gas injection than to waterflooding because of high interstitial-water saturations. Oil saturations in cores range from 20 to 35%, with interstitial water varying from 40 to 60%. Waterflood oil recoveries have been uneconomical in these fields, but gas injection has resulted in additional recoveries of up to 100 bbl/acre-ft.⁹

An exception to the rule concerning the uneconomical flooding of sands with high water content occurred in the Woodsen Shallow field, Throckmorton County, TX; a successful waterflood program was carried out in this field where the sands have an average water saturation of 54%.¹⁰

Interstitial water content may be estimated from cores that are obtained with an oil-based mud system, through electrical log interpretations, laboratory restored-state floods, or capillary-pressure tests.

Another factor that is instrumental in determining the susceptibility of a reservoir to waterflood operations is the free-gas saturation. The pore space occupied by free gas in the reservoir is dependent on the voidage created by the produced stock-tank oil and gas, provided no influx of edge water has occurred. If accurate production data are known, the pore space depleted by the produced oil and gas may be determined. For solution-gas-drive

reservoirs, the portion of pore space occupied by gas may be determined by

$$S_g = (100 - S_w) \frac{NB_{oi} - (N - N_p)B_o}{NB_{oi}}, \dots\dots\dots (1)$$

where

- S_g = gas saturation, fraction,
- S_w = water saturation, fraction,
- N = initial oil in place, STB,
- N_p = oil produced, STB,
- B_{oi} = initial oil FVF, RB/STB, and
- B_o = oil FVF, RB/STB.

Several authors have shown through experiments that, for a given oil saturation, the percent of recovery by waterflood increases as gas saturations increase to about 30%, but the benefits decline as gas saturations go beyond the 30% level. The effect of free gas has been to cause lower ROS's behind the front than could be obtained by waterflooding the same systems in the absence of such gas. The increased recovery obtained because of the presence of gas during a waterflood has been variously attributed to changes in the physical characteristics of the oil, to the selective plugging action of the gas, to inclusion of oil mist in the free-gas phase, and to replacement of residual oil by residual gas. The degree of improvement in recovery has not been established in the field; however, an investigation¹¹ into the influence of a free-gas saturation on recovery by water drive indicated that the optimal gas saturation could be determined for maximum oil recovery by water displacement. Some operators who have injected gas ahead of water have reported that floods have benefited in one way or another. Besides the advantages of increased oil and gas production, benefits such as increased water-injection rates, more efficient flooding, and decreased paraffin problems have been reported.

The effects of free-gas saturations on oil recovery in waterflooding remain an academic problem. Until the merits of injecting gas ahead of (or with) water can be proved practicable in both the laboratory and in the field, caution should be used in applying this method to any large field operation.

Fluid Properties and Relative-Permeability Relationships

The physical properties of the reservoir fluids also have pronounced effects on the advisability of waterflooding a given reservoir. Of major importance among these effects is the viscosity of the oil. The viscosity of the oil affects the mobility ratio. The relative permeability of the reservoir rock to the displacing and displaced fluids is also a factor in the mobility ratio, as is the viscosity of the displacing fluid—water, in this case (refer to Chap. 43). The mobility of any single phase (e.g., oil) is the ratio of the permeability of that phase to its viscosity, k_o/μ_o . The mobility ratio, M , is the ratio of the mobility of the displacing fluid to that of the displaced fluid. The larger the mobility ratio, the lower will be recovery at breakthrough; hence, more water must be produced to recover a fixed amount of oil. This is because (1) a smaller area is swept at breakthrough, and (2) the stratification effect is enhanced.

With high-viscosity (low-gravity) crudes, primary recovery normally is lower and shrinkage is less than with low-viscosity crudes. This tends to offset the bad effects of high-viscosity crudes since it often results in higher oil saturations at the beginning of water-injection operations.

Optimal Time to Waterflood

The optimal time to waterflood a particular reservoir depends on the operator's primary objective in waterflooding. Among these objectives might be (1) maximum oil recovery, (2) maximum number of dollars of future net income, (3) maximum number of dollars of future net income per dollar invested, (4) stabilized rate of monetary return, or (5) maximum discounted present worth. Certainly all these objectives are desirable, and all seem to call for an early beginning of water-injection operations; however, that is not always the case. The most common way to determine the optimal time to begin flooding is to compute the anticipated oil recovery, production rate, monetary investment, and income for several assumed times of initiation—and then observe the effect of these factors on the most desirable goal.

In a homogeneous reservoir, maximum oil recovery can be expected if flooding is begun at the precise time bubblepoint pressure is reached. This is because residual oil after waterflooding will have the maximum amount of gas in solution and, at the bubblepoint, oil viscosity is most favorable. If the effect of a free-gas saturation on ROS is ignored, heterogeneity causes the optimal pressure for highest recovery to be lower than the bubblepoint pressure. If the bubblepoint pressure is quite low, production rates may have substantially declined and the operator may prefer an earlier flood. Water-injection operations initiated above the bubblepoint in a heterogeneous recovery may ultimately result in less oil recovery but may be justified economically.

Objective 1, maximum oil recovery, is important to all operators or agencies who are concerned primarily with the best interests of the public. Objectives 2, 3, and 5, involving certain financial goals, are most important to privately owned companies, either independent or major; in these cases, the choice would depend on a company's size and financial position and on whether it is planning to sell the property. Objective 4, stabilized rate of monetary return, becomes important when financing, such as production loans and oil payments, and federal taxes are considered. This last point, federal taxes, is particularly important to small operators who are subject to large variations in a tax rate that depends on their tax bracket. Also, some money-lending agencies are particularly interested in properties that are anticipated to have long producing lives—i.e., to have a production rate that has been stabilized somewhat below the attainable rate. Other agencies are more interested in a fast return on investment.

In summary, then, the optimal time to begin water-injection operations depends on which of the objectives is of primary concern.

Determination of Residual Oil After Waterflooding

Perhaps the most commonly used technique for calculating total waterflood recovery is to subtract the ROS after waterflooding from the oil saturation before flooding, then

to multiply the difference by the appropriate factors to convert the displaced portion to barrels of stock-tank oil, after making adjustments for such things as areal pattern efficiency and vertical conformance. If original reservoir saturation conditions and fluid properties are known or can be determined, current saturation conditions may be computed at any time from the pressure and production history. The determination of the ROS resulting from displacement by an advancing water front can be determined satisfactorily only from laboratory measurements made on representative samples of the reservoir rock. These samples must be subjected to a displacement process that is similar to that expected under waterflood. Such tests of waterflood susceptibility, or potential, are run on both fresh cores and on restored-state samples. Interpretation of the data is often difficult, particularly when fresh-core techniques are used or when there are not enough data available to establish its reliability.

Fresh-Core Techniques

The fresh-core technique has the advantage of being quicker and cheaper than the restored-state technique. In applying this technique, a core sample that is fresh from the field is subjected to waterflooding and the residual oil is determined. This procedure is meaningful only when coring conditions have ensured that flushing and contamination by drilling fluid has been virtually eliminated, as is the case when a depleted sand is cored with cable tools. Contamination of cores by the drilling fluid, which often contains surface-active agents and other chemicals as well as contaminating solids, can drastically change wettability characteristics and reduce ROS's to considerably below the naturally occurring value. Any ROS that has been determined in this manner should be regarded suspiciously and be used only if the reported values can be verified by other means.¹²

Interpretation of Conventional Core-Analysis Data

In the absence of more dependable data, some authors recommend that the oil saturation measurement that is derived from conventional core analysis of cores taken with water-based drilling fluids be used as a reasonable estimate of the ROS after waterflooding. This procedure is valid only after the saturation value is increased by the FVF at the existing reservoir pressure. The resulting measurement is believed to be more dependable than the saturation value that is determined from further flooding this same core sample with more water, as is done with the fresh-core technique.

Laboratory tests¹³ indicate that an additional correction should be made for the reduction in oil saturation that results from gas expansion as the core is being pulled. The actual reservoir ROS would be represented by the term $S_{or} B_{oR} C_{ge}$, where S_{or} is the residual oil measured at the surface, B_{oR} is the oil FVF at current reservoir conditions, and C_{ge} is the correction for gas expansion. (A value for C_{ge} of 10.0% is acceptable in the absence of measured data.)

Restored-State Technique

Probably the most dependable means of determining the ROS behind an advancing front is to study the results of waterflood susceptibility tests that are performed by the

restored-state technique on representative samples of the reservoir rock. This requires the obtaining of enough data to establish dependably that the core samples represent all the permeability ranges contained in the reservoir. This ideal situation is very rarely available to the engineer, so interpretations must be made with less than the ideal data. In the restored-state technique, the sample is first extracted and then dried in an effort to remove all contaminants. Then, the irreducible water saturation is determined by the capillary-pressure method. After this, the sample is saturated with brine, which is usually of approximately the same composition as that of the reservoir. All mobile water then is displaced with an oil of about the same viscosity as the reservoir oil, leaving the core sample in its original condition. Then the core sample is subjected to a water-displacement process until the effluent is essentially 100% water. At this point, the oil saturation is determined in the normal manner and called the ROS.

Relative-Permeability Curves

ROS's also may be determined from relative-permeability curves, but the normal purpose of these curves is to give more data for the area that lies between the two extreme conditions of interstitial water and ROS. Since the measurements for the area between those two conditions are made on rather small samples of the reservoir rock, they are normally performed with an oil of substantially greater viscosity than that of the reservoir oil. The more viscous oil facilitates accurate measurement of the pressure gradients that are necessary for dependable relative-permeability determination. Therefore, relative-permeability curves should be used primarily for fractional-flow and rate/pressure calculations, with more weight being given to the middle saturation range than to those on either end. This view seems to support the practice of arbitrarily reshaping the experimental k_{rw} curve in the vicinity of the ROS and the experimental k_{ro} curve in the vicinity of the irreducible water saturation so as to confirm more dependable determinations of these saturations. Further, it seems to indicate that considerable error might be introduced by using an ROS taken from relative-permeability measurements alone.

Effect of Initial Saturations

Initial saturations of water, oil, and gas on reservoir suitability have been discussed previously in this chapter. The effect of these saturations on the ROS behind the water front will be considered here.

As previously mentioned in the discussion of fluid saturation and distributions, an initial water saturation that is above the "critical" value will cause the displacement mechanism to be of the "subordinate-phase" variety that normally prevails after breakthrough. This means that a frontal displacement will be impossible; still, considerable quantities of oil may be recovered if it is economical to use large volumes of water. For predictions of this type of performance, a fractional flow evaluation is necessary—rather than reliance on the concept of an ROS behind an advancing front, or "piston," of water.

The effect of an initial gas saturation has been investigated by several authors, most of whom report increasing beneficial results in reducing the ROS left by the displacing water when an initial gas saturation up to 30% has been found.¹⁴⁻¹⁶ Some authors^{14,17} have reported

substantial benefits from an initial gas saturation of more than 30%; however, these benefits begin to decline as the gas saturation increases. True benefits were also found to vary with the properties of the reservoir rock as well as with the properties of the reservoir fluids. All authors report substantial increases in ROS's as the oil/water viscosity ratio increased. Accurate predictions of the amount by which the ROS may be reduced as a result of any initial gas saturation is a matter for laboratory determination or for calculation from field performance data.¹⁷ Craft and Hawkins¹² state that the total residual hydrocarbon saturation will be about the same value, whether for oil or gas, or a combination of oil and gas. This view is not rigidly supported by laboratory data but the value may be used as an approximation.

Influence of Wettability

It has been shown that wettability has an influence on the interstitial water saturation, ROS, capillary pressure, relative permeability, waterflood performance, and the resistivity index of oilfield cores. In short, any property that is influenced by saturation conditions and/or interfacial relationships also will be influenced by wettability. This indicates the importance of assuring that all measurements of such properties are made under the correct conditions. Any laboratory measurements that are made under improper wettability conditions will give results that will differ to a potentially large degree from the true magnitude of the property as it exists in the reservoir. The importance of wettability in reservoir-rock-fluid behavior has been increasingly emphasized in recent literature.¹²⁻¹⁵

In most cases, the laboratory data, engineering calculations, and field experience will indicate that water is generally more efficient than gas in displacing oil from reservoir rocks. There are two primary reasons for this: (1) the viscosity of water is much nearer that of oil than is the viscosity of gas, and (2) the water occupies the less conductive portions of the pore spaces whereas the gas occupies the more conductive portions. Thus, in water displacement, the oil is left to the central and more conductive portions of the pore channels. This circumstance is true only for reservoir rocks that are preferentially water-wet (hydrophilic), as is the case for most reservoir rocks. Where the rock is preferentially oil-wet (hydrophobic), the displacing water will invade the more conductive portions first (just as the gas does), thus resulting in lower displacement efficiencies. However, the efficiency by water displacement still exceeds that by gas displacement because of the viscosity advantage. This effect is accounted for in capillary-pressure and relative-permeability measurements only if the rock samples in the laboratory exhibit the same number and degree of hydrophilic and/or hydrophobic qualities as those that prevail in the reservoir. Waterflood oil-recovery predictions that were based on core-analysis data have shown recoveries from water-wet rock to exceed recoveries from oil-wet rock by as much as 15% of the original oil in place (OOIP).¹⁸ Apparently, coring fluids and core-handling techniques can disturb the native wettability characteristics of reservoir rock surfaces and may render undependable the laboratory measurements that are made on any particular core. However, a few coring fluids, brine in particular, have been found not to affect core wettability, and core handling and preserving procedures have been

developed to preserve wettability characteristics during storage and laboratory testing.

Predicting Water Injection Oil Recovery and Performance

Predictions of future oil recovery and reservoir performance for waterflood and water injection projects provide the basis for the economic evaluation of the profitability of proposed projects. These performance and recovery projections should be made in sufficient detail to define the economic viability of the project. This definition should be made after consideration is given to the investment requirements, cost of operations, projected recovery, and the return that is expected on the investment. In some cases, an estimate of the ultimate oil recovery that is expected from the operation may be sufficient; in fact, it may be the only estimate possible if basic reservoir and past production data are limited or are of questionable reliability. However, in most cases, detailed projections are required for making economic evaluations. These include the projection of future well requirements and recompletions, individual well injection and producing rates, reservoir and injection pressures, producing WOR's, and oil recovery throughout the course of the project. Detailed projections require complex predictive methods and complete and detailed reservoir data. It is the responsibility of the reservoir engineer to choose the detail and complexity of the performance projections—following consideration of the management requirements, the cost of developing the projections, and the amount and reliability of the basic reservoir and economic data that are available.

Displacement Calculation Procedures

There are a number of methods presented in the literature for calculating the performance of a waterflood project. Two of the early methods that were developed for application in stratified reservoirs are the Stiles¹⁹ and Dykstra-Parsons.¹⁵ The Stiles method is based on the assumptions that fluid displacement occurs in a piston-like manner, in a linear bed of a specific permeability, and that the rate of advance of the flood front is proportional to the permeability of the bed. The Dykstra-Parsons method for predicting waterflood performance includes

consideration of actual fluid mobilities rather than an assumption of equal mobility for the displacing and displaced fluids. With this exception, the basic assumptions made in the development of both techniques are essentially the same.

For the description of water/oil displacement in homogeneous reservoirs, two methods are of primary importance: the Buckley-Leverett²⁰ frontal advance theory, and a subsequent extension of this work by Welge.²¹ These two techniques provide the fundamental basis for describing the water/oil displacement characteristics of a linear reservoir segment with homogeneous properties.

Stiles Calculation. In the Stiles¹⁹ method, the following assumptions are made. The rate of flood advance in a linear bed is proportional to the permeability of that bed. After breakthrough, the water/oil production rates are governed by, respectively, the water and the oil mobility ratios of the beds that produce the water and oil in the output well. This latter point is equivalent to the assumption that the rate of fluid movement in each bed is proportional to the oil mobility if breakthrough has not occurred, or proportional to the water permeability if breakthrough has occurred, and that there is no crossflow between beds. The Stiles method involves a calculation procedure that gives recovery values for a "unit" of the total reservoir.

The data needed for the calculations are the individual, measured, permeability values for the reservoir unit being considered, the water/oil mobility ratio, and the oil FVF at flood conditions. The Stiles calculations give the values of produced watercut vs. oil recovery as a fraction of the total recoverable oil. In practical applications, the total recoverable oil is determined independently, as the difference between the amount of oil in the reservoir at the start of the waterflood and the amount of oil remaining after the flood has been completed (to 100% water cut); this difference is then adjusted by an areal coverage factor for the flood unit.

For convenience in calculating, the permeability values are arranged in a numerically descending sequence. If there are a great many values, they may be grouped by permeability ranges and the total millidarcy-foot capacity and footage for each range is computed. In the case of such grouped values, it is preferable to set the ranges

Fig. 44.1—Log-normal permeability distribution.

so that there will be approximately equal capacities in the middle permeability ranges and somewhat smaller capacities in the high and low permeability ranges.

Values for cumulative capacity and cumulative thickness, as well as the average permeability for each group, then are calculated. The fractional cumulative capacity may be plotted vs. fractional cumulative thickness; the result of this procedure is referred to as a capacity-distribution curve. In the original Stiles method, the permeability data are plotted at the midpoint values of cumulative thickness, a smooth curve is drawn through the points, and a new set of permeability values are read at the thickness values to be used in the final calculations. In the equivalent calculation method presented in this chapter, the plotting may be eliminated because the smoothing of permeability values is accomplished by forward interpolation between successive permeability values. The calculation of fractional capacity and thickness also may be eliminated if the capacity-distribution curve is not required.

An example of a water-cut recovery calculation is shown in Table 44.1. In that table, the letters h and kh , in Cols. 3 and 5, represent cumulative foot and millidarcy-foot capacity, respectively; h_i and $(kh)_i$, in Cols. 2 and 4, represent the corresponding totals; and \bar{k} , in Col. 7, designates the interpolated average permeability in millidarcies. The equations for the fractional water cut and recovery, at the time when h feet are producing water, are as follows.

$$f_w = \frac{khM_{wo}}{khM_{wo} + (kh)_i - kh} \quad (2)$$

and

$$N_{pa} = \frac{1}{h_i} \left[h + \frac{(kh)_i - kh}{\bar{k}} \right] \quad (3)$$

where M_{wo} equals the water/oil mobility ratio multiplied by the FVF of the reservoir oil at the time of flooding:

$$M_{wo} = \frac{k_{rw}}{k_{ro}} \frac{\mu_o}{\mu_w} \times B,$$

where

k_{rw}/k_{ro} = water/oil relative permeability ratio,

μ_o/μ_w = oil/water viscosity ratio,

B = FVF,

N_{pa} = recovery to depletion (abandonment),

kh = capacity of flowing water, and

$1 - kh$ = capacity of flowing oil.

The resulting recovery vs. water-cut data may be used as the starting point for further calculations in connection with the flood unit. For example, if the unit is a five-spot in a depleted field and an estimate of the gas space in the reservoir is available, calculations of the time behavior of the flood may be made for an assumed injection-rate schedule. These calculations would involve determination of the fill-up time and a subsequent application of the water-cut recovery curve so as to calculate the oil production rate vs. time.

As noted previously, the Stiles method gives recovery vs. water-cut data for a hypothetical flood unit, in which breakthrough into various producing wells of the unit occurs at the same time. The information could be expected to approximate that for the behavior of a five-spot pattern or that for a group of five-spots, provided an appropriate areal coverage factor is applied.

Dykstra-Parsons Calculation. Dykstra and Parsons¹⁵ performed a series of laboratory waterflooding tests on field core samples and concluded that oil recovery by waterflooding is a function of both mobility ratio and permeability distribution, with the mobility ratio being defined as follows.

$$M = \frac{k_w}{\mu_w} \frac{\mu_o}{k_o}, \quad (4)$$

where k_w is the permeability to water in the water-contacted portions of the reservoirs, and k_o is the permeability to oil ahead of the waterfront (or mobility of swept to unswept region).

On the basis of the laboratory test results, and calculations made on a layered linear model in which it was assumed there was no crossflow, a correlation that related waterflood recovery to both mobility ratio and permeability distribution was developed. Permeability distribution was measured by the efficiency of permeability variation E_K , as follows.

$$E_K = \frac{\bar{k} - k_o}{\bar{k}}, \quad (5)$$

where \bar{k} is the mean permeability and k_o is the permeability value at 84.1% of the cumulative sample, as shown in Fig. 44.1.⁴

Fig. 44.2—Permeability variation vs. mobility ratio, showing lines of constant $E_R(1 - S_{wi})$ for a producing WOR of 1.

Fig. 44.3—Permeability variation vs. mobility ratio, showing lines of constant $E_R(1 - 0.72S_{wi})$ for a producing WOR of 5.

The correlations developed by Dykstra and Parsons were for WOR's of 1, 5, 25, and 100, with recovery related to permeability variation, interstitial water saturation, ROS, and mobility ratio. The basic equations used in developing the correlations were based on the following approach.

At the beginning of injection, the mobility in a layer is determined by the oil and gas phases. As water advances into a layer, the mobility is a composite of oil, gas, and water mobilities; after fill-up, the mobility is determined by the relative permeability and the viscosity ratios. The varying nature of the overall mobility results in a continuously changing injectivity. This method assumes that the permeability distribution is log-normal.

By use of the linear Darcy flow equation for incompressible fluids, the following equations for "coverage" or "conformance efficiency" and WOR were developed:

$$E_C = \left\{ n_{BT} + \frac{(n - n_{BT})M}{(M - 1)} - \frac{1}{(M - 1)} \sum_{i=(n_{BT}+1)}^n \left[\sqrt{M^2 + \frac{k_i}{k_x}(1 - M^2)} \right] \right\} \div n \quad (6)$$

and

$$F_{wo} = \frac{\sum_{i=1}^{n_{BT}} k_i}{\sum_{i=(n_{BT}+1)}^n \left[\frac{k_i}{\sqrt{M^2 + \frac{k_i}{k_x}(1 - M^2)}} \right]} \quad (7)$$

where

- E_C = fractional coverage or conformance efficiency,
- F_{wo} = WOR,
- n = number of layers,
- k_i = permeability of layer,
- k_x = permeability of x layer, or the layer that has just been flooded,
- M = mobility ratio, and
- n_{BT} = number of layers in which water has broken through (varies from 1 to n).

When the coverage and F_{wo} are known, it is possible to predict oil recovery and water cut as a function of time, provided the injection rates can be determined adequately.

To develop the relationship between the producing WOR and coverage, or fractional oil recovery, the equations must be solved for breakthrough conditions in each layer of the system, or at least for a substantial number of layers. This method is laborious for hand calculations and, in a later paper, Johnson²² presented a graphical technique for applying the Dykstra-Parsons method that was based on the plots shown in Figs. 44.2 through 44.5, where E_R is the fractional recovery of OIP at a given producing WOR. An example of the manner in which these plots were used in applying the Dykstra-Parsons technique was presented by Craig.⁴

Both the Stiles and the Dykstra-Parsons methods were developed for linear, piston-like displacement in a stratified system, and the results that are obtained when applying these techniques must be interpreted within the context of the limitations imposed by the basic assumptions. However, the concepts established as a result of this early work provided the basis for a number of predictive techniques that have since been developed.

Frontal Advance Calculation. The frontal advance calculation was derived from the concept of fractional flow presented by Leverett²³ in his classic 1941 paper. The fractional flow equation was developed from Darcy's law for water and oil and, in generalized form, it is as follows.

Fig. 44.4—Permeability variation vs. mobility ratio, showing lines of constant $E_R(1 - 0.52S_{wi})$ for a producing WOR of 25.

Fig. 44.5—Permeability variation vs. mobility ratio, showing lines of constant $E_R(1 - 0.40S_{wi})$ for a producing WOR of 100.

$$f_w = \frac{1 - (k_o/\mu_o q) \left(\frac{\partial P_c}{\partial L} - g \Delta \rho \sin \theta \right)}{1 + \frac{\mu_w}{\mu_o} \frac{k_o}{k_w}}, \quad \dots \dots (8)$$

where

- f_w = fraction of water in the flowing stream,
- k_o, k_w = effective formation permeability to the specific phase, kk_{ro} and kk_{rw} ,
- μ_o = oil viscosity,
- μ_w = water viscosity,
- q = fluid volumetric flow rate per unit cross-sectional area,
- P_c = capillary pressure, $p_o - p_w$,
- L = distance along direction of measurement,
- $\Delta \rho$ = density difference between water and oil, $\rho_w - \rho_o$,
- θ = angle of formation dip referenced to horizontal, and
- g = acceleration caused by gravity.

In practical units, the equation becomes

$$f_w = \frac{1 + 0.001127 \frac{k_o A}{q_i \mu_o} \left(\frac{\partial P_c}{\partial L} - 0.434 \Delta \rho \sin \theta \right)}{1 + \frac{\mu_w}{\mu_o} \frac{k_o}{k_w}}, \quad \dots \dots (9)$$

where

- f_w = fractional flow of the displacing fluid,
- k_o = effective permeability to oil, md,
- k_w = effective permeability to water, md
- A = cross-sectional area of flow, sq ft,
- q_i = total flow rate, $(q_w + q_o)$, B/D,
- P_c = capillary pressure, $p_o - p_w$, psi,
- $\Delta \rho$ = density difference, g/cm^3 , $\rho_w - \rho_o$,
- θ = dip angle, positive updip,
- μ = phase viscosity, cp, and
- L = distance, ft.

In the case of a water drive, neglecting the effects of the capillary pressure gradient and the dip of the reservoir, the terms $\partial P_c / \partial L$ and $g \Delta \rho \sin \theta$ become insignificant. The fractional flow equation then reduces to

$$f_w = \frac{1}{1 + (k_o/k_w)(\mu_w/\mu_o)}, \quad \dots \dots (10)$$

which states that the fraction of water in the flow stream is a function of the relative-permeability relationships in which μ_o and μ_w are constant for a given reservoir pressure. Since k_o/k_w is a function of saturation, Buckley and Leverett²⁰ derived the following frontal-advance equation on the basis of relative-permeability concepts.

$$L = \frac{5.615 q_i}{\phi A} \left(\frac{\partial f_w}{\partial S_w} \right)_{S_w}, \quad \dots \dots (11)$$

where

- L = distance, ft,
- q_i = total flow rate, B/D,
- ϕ = porosity,
- A = cross-sectional area, sq ft, and
- t = time, days.

This states that the distance a plane of constant saturation (S_w) advances is directly proportional to time and to the derivative $(\partial f_w / \partial S_w)$ at that saturation. The value of the derivative may be obtained for any value of water saturation by plotting f_w from Eq. 9 vs. S_w and graphically taking the slopes at values of S_w . Fig. 44.6 shows a plot of f_w vs. S_w in addition to the resultant df_w/dS_w vs. S_w relationships for the S_w vs. k_o/k_w data at a viscosity ratio of water to oil of 0.50 (see Table 44.2).

If the df_w/dS_w values found in Fig. 44.6 are substituted into Eq. 11, the distance that a given water-saturation plane or front will advance for any time t can be calculated for the known throughput q in barrels per day, fractional porosity, and cross-sectional area (in sq ft).

Fig. 44.7 represents the water-saturation profile or frontal-advance curves for a bed that is 1,320 ft wide and 20 ft thick, and has a porosity of 20% and a throughput of 900 B/D for 60, 120, and 240 days with the f_w , $\partial f_w / \partial S_w$ vs. S_w relationship shown in Fig. 44.6 The curves shown in Fig. 44.7 are characteristically double-valued or triple-valued. For example, the water saturation after 240 days at 400 ft is 20, 36, and 60%. The saturation can have only one value at any place and time, and the difficulty is resolved by dropping perpendiculars so that the areas to the right (A) equal the areas to the left (B).

Fig. 44.8 represents the initial water and oil distributions in the example reservoir and also the distributions after 240 days. The area to the right is the flood front or "oil bank," and the area to the left is the water-invaded zone. The area above the 240-day curve and below the 90% water-saturation curve represents oil that may be recovered by the displacement of additional volumes of water through the area. The area above the 90% water saturation curve represents unrecoverable oil because the ROS is 10%.

Welge Calculations. In 1952, Welge²¹ extended the earlier work of Buckley and Leverett²⁰ to derive a simplified method for calculating fractional flow and recovery performance after water breakthrough. The basic equations developed by Welge are as follows:

$$\bar{S}_w - S_{w2} = W_i f_{o2} \quad (12)$$

and

$$W_i = \frac{1}{\left(\frac{dS_w}{dS_w} \right)_{S_{w2}}} \quad (13)$$

where

\bar{S}_w = average water saturation, fraction of PV,

S_{w2} = water saturation at the producing end of the system,

W_i = cumulative PV's of water injected,

fraction, and

f_{o2} = fraction of oil flowing at the producing end of the system.

An example of the use of the Welge technique for calculating waterflood displacement performance was presented by Craig.⁴ Basic data used in the example calculation are average permeability, 50 md; porosity, 20%; irreducible water saturation, 10% of PV; oil viscosity, 1.0 cp; and water viscosity, 0.5 cp (see Table 44.3).

By Eq. 10,

$$f_w = \frac{1}{1 + \frac{k_{ro} \mu_w}{k_{rw} \mu_o}}$$

The fractional flow vs. water saturation relationship is calculated from basic data, such as those given in Table 44.4.

The fractional flow curve from this calculation is shown in Fig. 44.9. For water breakthrough, the tangent to the fractional flow curve from the point of irreducible water saturation defines (1) \bar{S}_w , the average water saturation behind the front, (2) S_{w2} , the water saturation at the producing end of the system, and (3) f_w , the fractional flow of water at the downstream end of the system.

$$\bar{S}_w = 0.563 \text{ PV,}$$

S_{wBT} = average water saturation at water breakthrough, % PV,

S_{wsz} = water saturation at upstream end of the stabilized zone, % PV,

S_{w2} = 0.469 PV, and

f_{w2} = 0.798.

From the fractional flow curve, df_w/dS_w is determined for water saturations that are higher than S_{w2} at water

breakthrough conditions, and the df_w/dS_w vs. S_w curve is developed, as shown by Fig. 44.10. From Eq. 13, W_i is calculated for increasing values of S_{w2} and f_{w2} and corresponding values of \bar{S}_w are calculated from Eq. 12.

The results for the calculations of the example problem are shown in Table 44.5.

Areal Sweep and Pattern Efficiency

The previous discussion dealt with fundamental techniques for defining water/oil displacement characteristics in linear reservoir segments in stratified reservoirs and in homogeneous reservoir rock systems. However, from a practical standpoint, a truly linear displacement is never used in waterflood operations. In practice, water is injected into some wells and oil and water are produced from others, and often portions of the reservoir are never contacted by the injected water. Therefore, it is necessary to consider the areal sweep efficiency so as to make esti-

mates of recoverable oil for a particular project and to predict reservoir performance for waterflood operations.

The purpose of this section is (1) to present methods for determining areal sweep efficiency for pattern flood projects, (2) to discuss factors that affect areal floodout patterns, and (3) to present correlating factors that are used to define areal sweep efficiency.

Methods of Determining Areal Sweep Efficiency. To conduct waterflood operations in a continuous reservoir with a relatively large areal extent, it is common practice to locate injection and producing wells in a regular geometric pattern so that a symmetrical and interconnective network is formed. Five of these basic patterns will be discussed: (1) direct line drive, (2) staggered line drive, (3) five-spot, (4) seven-spot, and (5) nine-spot.^{24,25} Figs. 44.11A through 44.11E are diagrammatic representations of these basic waterflood patterns. The dashed areas represent the basic symmetrical elements that are used in both analytical and model determinations of sweepout patterns.

It is often impractical or even impossible to design waterflood operations that correspond to one of the standard geometrical flood patterns. In such a case, the operator must select a less sophisticated well network—the choice being either a peripheral or random injection pattern.

The random flood pattern will not be considered specifically in this work because that type of flood is required only in certain explicit cases; it is used only when it is impossible to arrive at an arrangement of the peripheral or geometric type of pattern. Most of the material dealing with peripheral floods will apply generally to random waterflood networks. Fig. 44.12 is an illustration of the typical peripheral flood network.²⁶ It is obvious from this figure that there is no symmetrical element that could be considered for analysis, and that reservoir simulation techniques are necessary to obtain reliable future performance predictions for random or peripheral injection patterns.²⁷

Mathematical Analysis of Areal Pattern Efficiency.

Most practical mathematical analyses of flood coverage are based on Darcy's law when it is assumed that steady-state single-phase flow occurs through large areas of homogeneous reservoir rock.

Muskat²⁴ presents a comprehensive review of this theory in his early discussions of the steady-state flow ca-

Fig. 44.11A—A diagrammatic representation of a direct-line-drive well network. Dashed segment represents basic symmetry element.

capacity of the various pattern networks. As early as 1934, Muskat and Wyckoff²⁸ presented a theoretical means of calculating areal sweep efficiency for basic flood patterns. Fig. 44.13 is taken from their early work and it shows the variation in calculated steady-state homogeneous-fluid sweep efficiencies for linedrive networks with different values of d/a , where d is the distance between rows of

wells and a is the difference between adjacent wells in a single row. The graph shows a curve for both direct linedrive and staggered linedrive patterns with d/a values from 0.45 to 4.0. Even though the absolute values of pattern efficiency presented in this illustration apply to a simplified system, there are two conclusions that can be drawn from the information: (1) at breakthrough, the staggered

techniques. Figs. 44.14 through 44.17 are taken from Muskat and Wyckoff²⁸ and represent steady-state isopotential contours and streamlines for systems with homogeneous fluids that have direct linedrive, staggered linedrive, five-spot, and seven-spot networks, respectively. When the isopotential lines and streamlines are known,

it is easy to determine the fluid interface position at any time during the flood by using the methods described by Craft and Hawkins.¹² In the particular case analyzed for a five-spot pattern and a mobility ratio of 1.0, depicted by Fig. 44.18, the calculated breakthrough sweep efficiency is 72%. This corresponds to a value of 71.5% that

was computed by Muskat as the steady-state breakthrough sweep efficiency for the five-spot pattern at a mobility ratio of 1.0.

Analog Methods for Investigating Areal Sweep Efficiency. Several types of analog models have been used in the petroleum industry to study the shape of injection-fluid fronts and to evaluate areal sweep efficiencies. All the models depend on the analogy between Darcy's law and Ohm's law for a conductive medium that is scaled to represent the reservoir geometry. One of the earliest of these analogs is an electrolytic model designed by Wyckoff *et al.*²⁹ Its operation is based on the movement of copper ammonium and zinc ammonium ions in a medium such as blotting paper or gelatin. Figs. 44.19 through 44.22 are photographic histories of various pattern floods under steady-state, homogeneous-fluid flow conditions, as obtained by using a blotter-type electrolytic model. Fig. 44.23 shows the same type of photographic history but it represents an irregular well network and was obtained with the gelatin type of electrolytic model.³⁰

The potentiometric model was introduced to the industry in 1939 by Swearingen³¹ as a method for studying sweep efficiency in gas-cycling operations; the model has been further refined for waterflood studies by Hurst and McCarty³² and Lee.³³ The potentiometric model is based on the same basic principle as the electrolytic model except that electron flow, rather than ionic flow, is measured.

Porous Reservoir Models. The approach presented by Slobod and Caudle³⁴ is another that has been used by the petroleum industry for studying areal pattern efficiency; this involves scaled porous models of the reservoir element. The model initially is saturated with a fluid that rep-

resents the reservoir oil. Injected fluid in this case contains an X-ray-absorbing material and the displacing front can be followed on a fluorescent screen or X-ray film. Fig. 44.24 is an X-ray shadowgraph study of the five-spot model by Slobod and Caudle.³⁴ An areal sweep efficiency at breakthrough for the 1:1 mobility system is indicated as 69%.

Two-Dimensional (2D) Numerical Models. In an early paper describing the use of numerical models in predicting flood coverage for a peripheral, or random, water injection program, McCarty and Barfield²⁶ presented results obtained for two typical field studies, as shown in Figs. 44.25 and 44.26. In this approach, the computer is used to perform essentially the same calculations as those described by Muskat, with the reservoir defined by a grid network. A valid method of numerical analysis is used to allow solution of the basic differential equations that describe the simultaneous flow of oil and water. As is true of the methods described by Muskat and Wyckoff,²⁸ Stahl,³⁵ and Craft and Hawkins,¹² the digital computer calculates the pressure distribution in the reservoir and then tracks the progress of the interface between the displacing and displaced phases.

This calculation can be done for any combination of injection and producing rates. The approach will allow the calculation of the optimal sweep efficiency under a particular pattern as a function of reservoir injection and producing rate distribution.

Mobility-Ratio Effects. In the previous discussion of various methods of studying areal sweep efficiency, it is important to realize that each technique is based on the assumption that isopotential lines remain fixed during the advance of the front; that is, that the mobility of the dis-

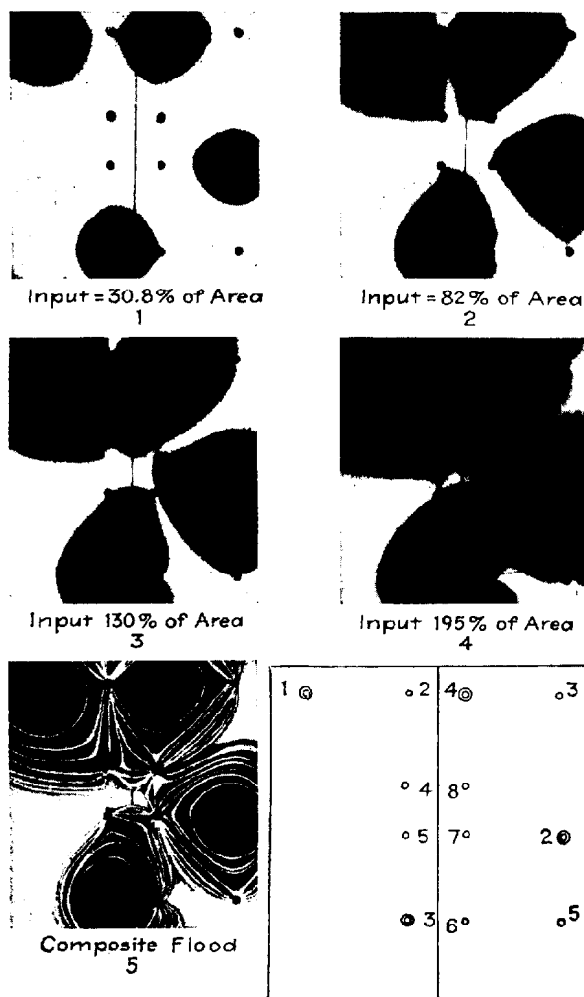

Fig. 44.23—The photographic history of the injection-fluid fronts in an injection project of limited area and with an irregular well distribution, under steady-state, homogeneous-fluid-flow conditions as obtained with a gelatin electrolytic model. Double circles indicate injection wells.

Fig. 44.25—Typical flood pattern resulting from field study.

placing fluid is the same as that of the displaced phase. However, it is well known that isopotential lines change constantly during most injection operations. Consequently, the actual pattern efficiency that will result in the reservoir can be quite different from that indicated by a simplified analysis that assumes a mobility ratio of 1.

The mobility ratio is probably the most important factor involved in determining pattern efficiency. Even though the methods previously cited were based on the assumption of a mobility ratio of unity, it does not mean that they are not of practical use, and the resulting information has served as a basis for further experimental investigations of certain geometrical characteristics that come into play during waterflood operations.

Although the early analog models that were used for studying pattern efficiency did not take into consideration the mobility-ratio effects, later investigations have made use of ingenious ideas to circumvent this restriction. Burton and Crawford³⁶ described an electrolytic model that has been used to estimate flood coverage by mobility ratios of 0.5, 0.85, 1.2, and 3. In that work, the

Fig. 44.26—Typical flood pattern resulting from field study.

adjustment for mobility ratios was accomplished through the use of metallic complex ammonium ions other than the copper and zinc compounds used by Wyckoff *et al.*²⁹ Aronofsky³⁷ has been able to include mobility ratios other than unity in a special adaptation of the potentiometric model. Nobles and Janzen³⁸ have presented a variation of the potentiometric model by replacing the liquid with a system of interconnecting resistors; by changing the values of these resistors, they were able to introduce mobility-ratio effects.

The most logical model with which to study mobility-ratio effects is a porous model, or, specifically, a porous model that uses X-ray shadowgraph techniques. In this type of analysis, the injection and displaced phases may be selected so that almost any mobility ratio can be fixed in the reservoir model. Experimental studies by Slobod and Caudle³⁴ take advantage of this feature of the X-ray shadowgraph technique, so that liquids of different viscosities can be used as the displaced and displacing phases and the effect of mobility ratios can be evaluated. Their original work has been extended by Caudle *et al.*³⁹ Fig.

Fig. 44.27—Areal sweepout patterns, five-spot well spacing.

Fig. 44.28—Sweepout pattern efficiency vs. reciprocal of mobility ratio for the five-spot well spacing.

44.27 is an X-ray shadowgraph that shows the effects of the reciprocal of mobility ratio on sweep efficiency at breakthrough for three different reciprocals of mobility ratios. Fig. 44.28 is a plot of the reciprocal mobility ratio vs. five-spot pattern sweepout efficiency at breakthrough. It is apparent from these illustrations that there is little change in breakthrough efficiency for reciprocal mobility ratios that are greater than 7.

In his monograph, Craig⁴ has summarized the areal sweep efficiency studies that have been presented in the literature for various flooding patterns. These summaries are listed in Tables 44.6 through 44.12.

Fig. 44.29 is a plot of the areal sweep efficiencies at breakthrough that were developed as a function of mobility ratio by the various investigations referenced in Table 44.7. As indicated, there is good agreement in the region below a mobility ratio of 1.0; however, considerable deviation exists at higher mobility ratios. Craig⁴ points out that potentiometric model data obtained for high mobility ratios may yield high sweep efficiency values and that miscible displacement methods may give low re-

sults because of mixing. As a result, he concluded that the most probable value of sweep efficiency at high mobility ratios for the five-spot pattern is represented by the solid line of Fig. 44.29. Breakthrough sweep efficiencies obtained later, from investigations with numerical methods conducted in 1979 by Martin and Wegner,⁵⁶ are in agreement with this conclusion.

There are insufficient data for patterns other than the five-spot to allow a comparison of the results obtained by various investigators; however, the correlations shown

in Figs. 44.30 through 44.48 are standards in the industry for determining areal sweep efficiency relationships for the normal patterns. In these figures,

V_d = displaceable PV's injected, fraction,
 f_s = fraction of total flow coming from the swept portion of the pattern,
 f_{icw} = corner well producing water cut, and
 f_{isw} = side well producing water cut.

Effect of Reservoir Dip. The effect of reservoir dip on five-spot sweep patterns has been investigated by Matthews and Fischer.⁵⁷ It was found that distortion would occur in the normal sweepout patterns in dipping reservoirs. Most of this distortion was attributed to gravitational effects. The conclusion reached in this study was that pattern flooding is practical for dipping reservoirs but that the pattern should be shifted to allow for dip. Figs. 44.49 through 44.52 are charts that show how to locate wells correctly for pilot and field five-spot floods in reservoirs that have substantial dip. In these figures,

N = ratio of square root of production rates,

S_F = position of center of unflooded area at moment of fill-up (correct drilling location) fraction of length of side or diagonal,

F_F = ratio of viscous to gravity forces defined by

$$F_F = \frac{(F_{og} + 1)q\mu khL}{g\Delta\rho \sin \alpha}$$

μ = fluid viscosity, poise,

q = injection rate before interference,

$$F_{og} = \frac{S_o - S_{or}}{S_g - S_{gr}},$$

S_o = oil saturation at start of flood, fraction,

S_{or} = ROS, fraction,

S_g = gas saturation at start of flood, fraction, and

S_{gr} = residual gas saturation, fraction.

Prats *et al.*⁵⁸ have made analytical studies of the same problem. Van der Poel and Killian⁵⁹ have made analytical and analog studies to investigate the area that can be swept out in dipping reservoirs by using water drive around the structurally highest wells.

Effect of Directional Permeability. Some formations exhibit differences in reservoir permeability in one horizontal direction relative to another. When this situation is encountered, it is apparent that pattern sweep efficiencies will be affected adversely when the direction of high permeability is between an injector and a producing well. The initial study to determine the effect of directional permeability on the areal sweep performance of a five-spot pattern flood was made by Hutchinson.⁶⁰ If the X-ray shadowgraph technique is used and a directional permeability difference of 16 to 1 is considered, the data shown in Figs. 44.53 and 44.54 are obtained for mobility ratios varying from 0.1 to 10. It is apparent from these data that improved sweep efficiency results when the pattern is oriented with the direction of maximum permeability, parallel to a line passing through the injection wells. In later investigations, Landrum and Crawford⁶¹ and Mortada and Nabor⁶² also studied the effects of directional permeability on five-spot and linedrive patterns. The results of their studies confirm the data obtained by Hutchinson.⁶⁰

Effect of Reservoir Fractures

In 1958, Dyes *et al.*⁶³ presented one of the most comprehensive studies of the effect of vertical fractures on sweepout pattern efficiencies. Their investigations showed that relatively long and highly conductive vertical fractures, not usually obtained from fracturing operations, are required to affect sweep efficiencies substantially. Other investigations⁶⁴⁻⁶⁷ have confirmed the results of Dyes *et al.*; these show that vertical fracturing can affect breakthrough sweep efficiency significantly, but that sweep efficiency at higher water cuts is influenced to a much lesser degree. Table 44.13 is a summary of the results obtained by Dyes *et al.*⁶³

Landrum and Crawford⁶⁸ have investigated the effect of horizontal fractures on sweep efficiency in thick reservoirs. The results of their studies, along with those of other investigators,^{36,69,70} show that the adverse effect

Fig. 44.49—Correct location of production well in pilot five-spot—side along strike.

Fig. 44.50—Correct location of production well in pilot five-spot—diagonal along strike.

of horizontal fractures on areal sweep efficiency is a direct function of fracture radii; that is, only small effects were observed on sweep efficiency when the fractures had small radii. However, as the fracture radius increases, sweep efficiency will be reduced drastically.

Methods for Predicting Waterflood Performance

There are many papers and articles in the petroleum industry literature that present or discuss methods for predicting waterflood or water-injection performance. Most

of the classic prediction techniques that have been developed since the early work by Muskat,²⁴ Stiles,¹⁹ Buckley-Leverett,²⁰ Dykstra-Parsons,¹⁵ and others have been modifications, enhancements, or extensions of those pioneering techniques, which were discussed in the initial part of this section. In many cases, those techniques, when combined with data obtained from areal sweep investigations, provided the basis from which several of the methods were conceived and developed.

Fig. 44.51—Correct location of production wells in a field of five-spots—side along strike.

Fig. 44.52—Correct location of production wells in a field of five-spots—diagonal along strike.

In his monograph, Craig⁴ has described and compared the classic prediction methods that were presented before 1971, and has included recommendations for selecting the appropriate waterflood prediction technique to obtain the desired results. The methods that were considered were categorized into five groups, which may be summarized as follows: (1) reservoir heterogeneity (Refs. 15, 19, 22, and 71 through 80), (2) areal sweep methods (Refs. 25, 28, 34, 37, 40, 50, 55, and 81 through 85), (3) displacement mechanism (Refs. 20, 21, 45, and 86 through 97), (4) numerical methods (Refs. 98 through 103), and (5) empirical approaches (Refs. 104 through 107).

Craig's monograph is certainly the most comprehensive review and evaluation of the techniques for predicting waterflood performance that has appeared in the petroleum industry literature.

Craig compared the capabilities of each method that was evaluated to the capabilities of the "perfect method," in which the calculation procedures would allow consideration of all pertinent fluid-flow, well-pattern, and heterogeneity effects—i.e., the influence of relative permeability characteristics, wettability, pore size distribution, and initial and final water and oil saturations; the effect of different well arrangements and mobility ratio on injection rate

Fig. 44.53—Sweepout pattern efficiency in a five-spot pattern of anisotropic horizontal permeability. The most favorable arrangement has the direction of maximum permeability parallel to lines through injection wells, as illustrated here.

Fig. 44.54—Sweepout pattern efficiency in a five-spot pattern operating under the least favorable arrangement; i.e., with the direction of maximum permeability parallel to a line from an injection well direct to a producing well.

and areal sweep efficiency; and the effect of the heterogeneity of the reservoir rock recovery and performance.

Table 44.14 shows Craig's evaluation of these techniques, as compared to the "perfect method."

Of the many classic methods that were evaluated, Craig has concluded that the three that most closely meet the requirements of the "perfect method" are Higgins-Leighton,^{93-95,97} Craig *et al.*^{4,108} and Prats *et al.*^{58, 108}

The Higgins-Leighton method can be used for various flooding patterns or for irregular well patterns, while the other two can be applied only for the five-spot pattern. Computer programs for the Higgins-Leighton and Craig *et al.* techniques are available in the literature. Examples of the calculation procedures and complete descriptions of the techniques also can be found in the literature. The

best, detailed description of the Higgins-Leighton technique is given in Ref. 97. Complete and detailed calculations for an example waterflooding problem that was solved by the Craig *et al.* technique are presented in Craig's monograph⁴ and by Timmerman.¹⁰⁸ An example of the use of the Prats *et al.* technique is also presented by Timmerman.¹⁰⁸

Other authors have compared results obtained by a number of the classic methods with actual field performance. Abernathy¹⁰⁹ compared the observed performance of five-spot waterfloods in three carbonate reservoirs in west Texas with the performance predicted by the Stiles,¹⁹ Craig *et al.*,⁴⁵ and Hendrickson⁹⁰ techniques. Figs. 44.55 through 44.57 show these comparisons.

Fig. 44.58—Comparison of actual and predicted recovery history, Flood 1.

Fig. 44.59—Comparison of actual and predicted oil recovery, Flood 1.

Guerrero and Earlougher¹⁰⁶ compared the actual and predicted performance of two floods. The predictive methods that were compared included Stiles', modified Stiles', Dykstra-Parsons', Prats *et al.*'s, and the empirical approach developed by Guerrero and Earlougher. The results of these comparisons are shown in Figs. 44.58 through 44.61. (Also see Ref. 4, Figs. 8.16 through 8.19.) Higgins and Leighton⁹⁴ compared the results obtained by using their method with actual field performance and with predicted performance obtained by the methods of Prats *et al.* and Slider.⁷⁴ This comparison is shown in Fig. 44.62. (Also see Ref. 4, Fig. 8.20.)

It is obvious from these comparisons that the fields do not always perform as predicted regardless of the method that is used to estimate future performance. This is true for many reasons, including (1) an incorrect or inadequate description of the reservoir rock, fluid, and water/oil flow properties, (2) a prediction technique that does not have the capability to consider all the factors that affect water-flood performance, and (3) the fact that there is always a question of the reliability of the estimates of the interwell character of the reservoir rock and the vertical and horizontal variations that exist in reservoir rock and fluid properties.

Fig. 44.60—Comparison of actual and predicted recovery history, Flood 2.

Fig. 44.61—Comparison of actual and predicted oil recovery, Flood 2.

The prediction techniques selected as most promising by Craig⁴ appear to deserve primary consideration when one of the classic techniques is being selected for projecting future reservoir performance under waterflood operations. The comparisons made by Abernathy¹⁰⁹ show the Craig-Stiles multilayer method to be capable of making predictions that yield a good match with actual reservoir performance. In the Guerrero and Earlougher comparison, the Prats *et al.* method performed very well in the case of Flood 2 but erred badly with respect to oil recovery in the prediction of the behavior of Flood 1. The Higgins and Leighton method gave a good comparison with respect to actual performance in the case presented.

Since the time when Craig made his evaluation and comparison of the classic prediction methods that were available, reservoir simulation models have continued to be improved and expanded to the point that, today, there are models available for prediction of waterflood or water-injection performance under a variety of conditions. The reservoir simulation models that are available to the industry at present are capable of considering any type of flooding pattern, as well as gravity, capillary, and viscous forces, with virtually any type of three-dimensional (3D) reservoir description. The initial developments of the numerical methods were made by Douglas *et al.*⁹⁸ in 1958, and this work was later extended to two dimensions by Douglas *et al.*¹⁰⁰ in 1959. Since that time, numerical models and reservoir simulation techniques have improved continuously, in step with the increased speed and storage capacity of the computing systems that have become available.

Although the subject of reservoir simulator development and application has been covered in another section of this handbook, it is important to emphasize that the simulation models and techniques that are presently available to the industry are capable of modeling the most complex reservoir systems. With the use of these tools, predictions of waterflood and water-injection performance can be made in such detail that almost every factor that affects reservoir and individual well behavior can be considered and simulated.

Selection of the Waterflood Prediction Method

When choosing the appropriate waterflood prediction method, the engineer must bear in mind the objective in

Fig. 44.62—Comparison of field behavior with predicted performances by the Prats *et al.*, Slider, and Higgins-Leighton methods.

making the recovery predictions, the amount and quality of basic data that are available, and the resources that are available for performing the calculations in light of both the manpower that will be necessary and the actual costs for computer use or data processing. In some instances, a simple estimate of ultimate oil recovery may be sufficient and, in fact, it may be the only reliable estimate possible because of data limitations. However, in most cases, more detailed projections will be required to evaluate the economic potential of the proposed project; and a method must be used that will allow the estimation of future well requirements, producing WOR's, producing rates, oil recovery, injection well requirements, and injection rates and distribution, all as functions of time.

The methods available to the reservoir engineer range in complexity from those that provide an estimate of ultimate recovery to those that use sophisticated reservoir simulation models that are capable of predicting both reservoir and individual well performance for water injection operations. However, the time requirements and costs for making the calculations are in direct proportion

Fig. 44.63—Viscosity of water at oilfield temperatures and pressures.

to the complexity of the technique used. The engineer must choose the method for predicting performance while taking into account the availability of time and resources and the reliability and quantity of the basic data at hand.

The most basic evaluation is that of defining the ultimate oil recovery to be expected from the project. This can be determined by using the Welge²¹ technique or by estimating ROS's and conformance. Empirical approaches are also available to provide these estimates if data are limited. Guthrie and Greenberger¹⁰⁴ have developed an equation, based on waterflooding experience in a number of sandstone reservoirs, that has proven effective for estimating the ultimately recoverable oil. The equation is as follows:

$$E_R = 0.2719 \log k + 0.25569 S_w - 0.1355 \log \mu_o - 1.5380\phi - 0.0003488h + 0.11403, \dots (14)$$

where E_R is the oil recovery efficiency, fraction, and h is the formation thickness, ft.

Another equation that is applicable in estimating the ultimate recoverable oil was developed by an API committee.¹⁰⁷ The relationship developed by this committee is as follows.

$$E_R = 0.54898 \left[\frac{\phi(1-S_w)}{B_{oi}} \right]^{0.0422} \left(\frac{k\mu_{wi}}{\mu_{oi}} \right)^{0.077} \times (S_w)^{-0.1903} \left(\frac{p_i}{p_a} \right)^{-0.2159}, \dots (15)$$

where p_i is the initial pressure and p_a is the pressure at depletion (abandonment).

When a projection of producing WOR as a function of oil recovery is required, the basic methods that are available are those developed by Stiles,¹⁹ Slider,⁷⁴ and others. These procedures allow a prediction of the water-cut performance of the waterflood as well as the ultimate recovery. The published correlation charts of Johnson,²² based on the data developed by Dykstra-Parsons,¹⁵ will allow a quick prediction of future waterflood performance.

For a more detailed projection of future performance, Craig⁴ has suggested the techniques proposed by Higgins-Leighton,⁹³⁻⁹⁷ Craig *et al.*,⁴⁵ and Prats *et al.*⁸⁰ These techniques require considerably more engineering time and more reservoir data than do the basic calculations, but they will enable projections to be made in sufficient detail so that an economic analysis of the project can be made for comparison with the projected return that might be expected as a result of alternative operational programs.

The complex reservoir simulation models that are available to the industry today can produce projections of water injection performance that consider all the factors that influence the behavior of the injection operation. Their use requires a detailed description of the reservoir rock, fluid, and fluid-flow properties, as well as the characterization of individual wells. When the basic data are available for future performance predictions, there is no doubt that the simulation approach will produce the highest confidence level that is attainable with today's technology. When compared to the other alternatives that are available, reservoir simulation approaches are expensive; however, if used properly, these techniques will enable a complete evaluation of the potential of a proposed water injection project.

The engineer has many choices available in selecting the approach that he will use to evaluate a prospective water injection operation. To repeat, the selection should be made while bearing in mind the overall objectives of the evaluation, the resources that are available, and the data that are either immediately available or that can be obtained within the imposed time or monetary limitations.

Water-Injection Well Behavior

The initial water-injection rate of a well depends on the (1) effective permeability, (2) oil and water viscosity, (3) sand thickness, (4) effective well radius, (5) reservoir pressure, and (6) injection pressure at the sandface. As water begins to fill the reservoir, other factors are introduced to affect the behavior of the injection well. These factors are influenced by the increase in flow resistance as water extends into the reservoir and by the quality of the injection water.

The fundamental equation²⁴ for the rate of water injection into a well is expressed as

$$i_w = \frac{0.00708 k_w h (p_{iwf} - p_e)}{\mu_w \ln(r_e/r_w)}, \dots (16)$$

There are numerous uncertainties that make quantitative applications of the equation difficult. They do not, however, impair its usefulness in explaining the relative importance of each of the factors.¹¹⁰

1. **Effective Permeability.** The symbol k_w denotes the effective permeability (millidarcies) of the sand to water. According to laboratory work on clean sands, the relative permeability to water ranges from 30 to 60% of the dry permeability as the water saturation varies from 70 to 85%. Tests on virgin and artificially oil-saturated cores show that the effective permeability of the sand to water is often less than one-tenth of the dry permeability. Whenever possible, the effective permeability to water should be determined on representative cores from the field.

2. **Viscosity.** The viscosity (centipoise) of the injected water, μ_w , can be measured, or a value approximated, from Fig. 44.63.

3. **Sand Thickness.** The sand thickness, h , is the net effective sand thickness (feet) of the interval that is open for injection.

4. **Pressure.** The bottomhole flowing injection pressure, p_{iwf} , (pounds per square inch) at the sand face can be estimated from the wellhead pressure, the depth of the well, the density of the water, and the flowing pressure gradients. p_e is the effective reservoir pressure (external boundary pressure).

5. **Well Radius.** The effective radius of a well, r_w , (feet) may vary from a few inches to several feet, depending on the type of completion.

6. **Pressure Radius.** The pressure radius (external boundary radius), r_e , can be estimated, at least roughly, from the amount of water that is injected and from the available pore space, and is the distance from the injection well where the pressure is p_e . The available pore space is defined as the total PV less that occupied by interstitial water and oil. As more and more water is injected, the pressure radius, r_e , in Eq. 16 increases and, therefore, the injection rate, i_w , must decrease with time.

The pressure radius, r_e , depends on the cumulative volume of water that is injected into the space that is available, in accordance with the equation

$$r_e = \left(\frac{5.61 W_i}{\pi h \phi S_g} \right)^{1/2}, \quad (17)$$

where W_i is the cumulative water injected, bbl.

The oil may or may not be moved by the advancing water. If the oil is not moved, the water will fill the gas space. If the oil is moved ahead of the water bank, the volume of injected water that is required to fill the reservoir with liquids (oil and water), for a given distance (to external radius), will still be the same as that which was originally necessary to fill the gas space.

If a large percentage of oil is being moved, Eq. 16 does not hold strictly true, and a more exact expression prior to interference is

$$i_w = \frac{0.00708 h k_w (p_{iwf} - p_e)}{(\mu_w/k_w) \ln(R_w/r_w) + (\mu_o/k_o) \ln(R_e/R_w)}, \quad (18)$$

where R_w is the outer radius of the waterflood front and R_e is the outer radius of the oil bank.

As a rule, the width of the oil bank is small in comparison to the radius of the encroached water so that very little error will be introduced by considering the simpler

Fig. 44.64—Five-spot pattern computed input well history.

case. The change in intake rate with time can be calculated by Eq. 19.

$$\frac{0.0253 k \Delta p t}{\mu_w \phi S_g (r_w)^2} = 1 + \left(\frac{0.0142 k h \Delta p}{\mu_w i_w} - 1 \right) \times 10^{0.00617 k h \Delta p / (\mu_w i_w)} \quad (19)$$

Eqs. 16, 18, and 19 can be applied to a single-well system (radial flow); however, they are not valid for pattern floods after interference has occurred between injection wells. When interference occurs, the advancing liquid converges on the producing well and, for mobility ratios near unity, finally stabilizes at the steady-state conductivity of the specific pattern. The effect of interference on a five-spot pattern for a system with a favorable mobility ratio ($M \leq 1$) is as shown in Fig. 44.64.

Muskat²⁴ and Deppe⁸⁴ have developed equations for calculating the steady-state injectivities for the normal flooding patterns when a mobility ratio of one is considered. These equations are as follows.

Five-spot pattern²⁴:

$$i_w = \frac{0.001538 k_w h \Delta p}{\mu_w \left(\log \frac{d}{r_w} - 0.2688 \right)} \quad (20)$$

Direct line drive²⁴:

$$\text{for } \frac{d}{a} \geq 1,$$

$$i_w = \frac{0.001538 k_w h \Delta p}{\mu_w \left(\log \frac{a}{r_w} + 0.682 \frac{d}{a} - 0.798 \right)} \quad (21)$$

Fig. 44.65—Conductance ratio as a function of mobility ratio and the pattern area swept (E_A), five-spot pattern.

Staggered line drive²⁴:

for $\frac{d}{a} \geq 1$,

$$i_w = \frac{0.001583k_w h \Delta p}{\mu_w \left(\log \frac{a}{r_w} + 0.682 \frac{d}{a} - 0.798 \right)}, \quad \dots (22)$$

where d is the distance between rows of wells, ft and a is the distance between wells in a row, ft.

Seven-spot pattern⁸⁴:

$$i_w = \frac{0.002051k_w h \Delta p}{\mu_w \left(\log \frac{d}{r_w} - 0.2472 \right)}, \quad \dots (23)$$

Inverted nine-spot pattern⁸⁴:

$$i_w = \frac{0.001538k_w h \Delta p_{ic}}{\mu_w \left(\frac{1+F_p}{2+F_p} \right) \left(\log \frac{d}{r_w} - 0.1183 \right)}, \quad \dots (24)$$

$$= \frac{0.003076k_w h \Delta p_{is}}{\mu_w \left[\left(\frac{3+F_p}{2+F_p} \right) \left(\log \frac{d}{r_w} - 0.1183 \right) - \frac{0.301}{2+F_p} \right]}, \quad \dots (25)$$

where

d = distance between rows of wells,

F_p = corner-to-side-well producing-rate ratio,

Δp_{ic} = pressure differential between injection well and corner well, and

Δp_{is} = pressure differential between injection well and side well.

These equations allow the determination of the steady-state injectivities for the normal patterns if it is assumed the system is completely filled with liquid and has a mobility ratio of one.

There are a number of papers that report the results of investigations to define the variation of injectivities for the five-spot pattern at mobility ratios that are other than one. Various techniques were used. Deppe⁸⁴ and Aronofsky and Ramey⁵⁵ used potentiometric model techniques; Caudle and Witte⁸² used the X-ray shadowgraph technique and a porous model of the reservoir element. In the Caudle and Witte study,⁸² one-eighth of the five-spot pattern was modeled. Nobles and Janzen³⁸ used resistance networks to simulate mobility differences, and Prats *et al.*⁸⁰ used an analytical solution. Qualitatively, all investigators arrived at the same conclusion—i.e., if the mobility ratio is favorable ($M \leq 1$), injectivities will decline continuously during the entire operation; however, if the mobility ratio is unfavorable ($M > 1$), injectivities will increase continuously.

In their work, Caudle and Witte determined the variation in injectivity for the five-spot pattern as a function of the mobility ratio that exists before and after water breakthrough. Fig. 44.65 shows the results of their studies, in the form of the relationships between the conductance ratio, the mobility ratio, and the fractional areas of the reservoir that are contacted by the injected fluid.

Craig⁴ points out that, subsequent to fill-up, the relationships developed by Caudle and Witte can be used along with Eq. 20 to calculate water injection rates for the five-spot pattern:

$$i_w = F_C \times i_b,$$

where

i_w = water-injection rate,

F_C = Caudle and Witte conductance ratio, and

i_b = the injection rate of fluid that has the same mobility as the reservoir oil in a liquid-filled (base) pattern, as calculated from Eq. 20.

As the intake rate declines in the early stages of injection, it is important to be able to tell whether the decline results from the plugging of the sand (a situation that requires remedial work), from natural reservoir fill-up, or from mobility ratio effects. Consequently, a method is required to determine the intake capacity of the well itself without regard to the conductivity of the well system surrounding it. Such a method would be achieved by conducting periodic tests on certain selected wells scattered across the flood area. A close check of the efficiency of the input of the wells could then be maintained.

One practical method of determining the efficiency of the input wells is to use the calculated injectivity index

Fig. 44.66—Composite type log, Hewitt field, Carter County, OK.

Fig. 44.67—Hewitt unit, Chubbee structure map.

of the well. The injectivity index is defined as the number of barrels per day of gross liquid that is pumped into an injection well per pound per square inch of pressure differential between the mean injection pressure and the mean formation pressure associated with a specific subsurface datum, usually the mean formation depth. To be most valuable in a study of the behavior of the individual input wells, use of the injectivity-index concept should be restricted to defining the conductivity of an individual well; it should not be used to determine the general conductivity of the well system. This restricted injectivity index, which may be called a "localized injectivity index," is best used in measuring the conductivity of the cylinder of sand surrounding the well—most of the pressure drop takes place in this cylinder, whose inside wall is the sandface.

The localized injectivity index can be calculated from a modified Eq. 16:

$$i_w = \frac{0.00708 k_w h (p_{iwf} - p_{bp})}{\mu_w \ln(r_i/r_w)} \quad (26)$$

where p_{bp} is the transient backpressure and r_i is the distance from the well to the point of pressure equalization at p_{bp} .

Differentiating, the localized injectivity index, with p_{bp} being constant, is expressed as

$$I = \frac{di_w}{dp_{iw}} = \frac{0.00708 k_w h}{\mu_w \ln(r_i/r_w)} \quad (27)$$

Experimentally, it has been found that, for small volumes of injected water, di_w/dp_{iw} is constant. If small volumes of water are injected during the course of a test, r_i changes only slightly; r_i is considerably greater than r_w and the logarithm of r_i/r_w is practically constant. If, however, larger volumes are injected during the course of the test, the $\ln r_i/r_w$ will no longer be constant and the localized injectivity index, di_w/dp_{iw} , will not be constant. If large enough volumes are injected so that equi-

librium conditions are obtained, the corresponding pattern formula is applicable. In the case of a five-spot pattern, the change in intake rate for each change in pressure can be approximated by

$$I = \frac{di_w}{dp_{iw}} = \frac{0.00354 k_w h}{\mu_w [\ln(d/r_w) - 0.6190]} \quad (28)$$

where d is the distance between unlike wells.

The transient backpressure, p_{bp} , is a pressure phenomenon that occurs when the intake rate of an injection well is changed. Theoretically, the flow of water from a well into the surrounding formation will continue until the intensity of the sandface pressure is reduced to that of the reservoir pressure. In practice, if the pressure on an input well suddenly is reduced to the atmospheric pressure at the surface, the well backflows for a period of time that varies from a few minutes to several hours. The pressure that caused the backflow of water from the well is defined as the transient backpressure. This pressure, which occurs near the wellbore, is greater than the average reservoir pressure and has been attributed qualitatively to the compressibility of water and gas near the wellbore. When the injection is terminated, the backflow is caused by the expansion of the water and gas that results from the decrease in pressure. Quantitative treatment of this phenomenon has been given by Nowak and Lester¹¹¹ and Hazebroek *et al.*¹¹² The transient backpressure gradually dissipates and approaches the reservoir pressure. The localized injectivity index should be determined after the transient pressure has started falling very slowly or is in equilibrium with the reservoir pressure.

A comparison of the injectivity indices for injection wells in the waterflood will give an indication as to the wells that are not performing satisfactorily, and investigations should be made to determine whether the remedial measures are necessary to improve the injectivity rate. The intake rate of a normal well declines during its life, at least until a constant steady-state pressure distribution is established in the part of the reservoir affected by the well. In addition to the normal well decline, the sandface

gradually becomes plugged by suspended solids in the injected water. These suspended solids include materials like clay, silt, iron oxide, and hydroxides. In addition to suspended solids, dissolved and organic growths may contribute to the plugging of the formation sandface. Plugging of the sandface by these materials may be minimized with the proper treatment of the injection water. This treatment is covered in this chapter under the heading Water Treating.

By means of rate/pressure curves established at intervals of a few months, it is possible to distinguish between the decrease in intake rate caused by plugging and that caused by fill-up of the reservoir as mobility ratio effects. Rate/pressure curves are helpful also in indicating the value of the critical breakthrough pressure at which rupture of the formation occurs. If plugging is occurring and the injection rate declines, backflow of the well may be induced to remove the material from the sandface. Or if the plugging material on the sandface cannot be removed by backflowing, then perhaps it can be dissolved through the use of various types of acids. If necessary, fracturing may be used to increase the injectivity rate in the well.

Water-Injection Case Histories

Many examples of field case histories of water-injection projects can be found in the literature. Seven case histories of waterfloods in both sandstone and limestone reservoirs, using pattern as well as peripheral injection, are detailed in SPE Reprint Series No. 2a, *Waterflooding* (1973). SPE Reprint Series Nos. 4 (1962) and 4a (1975), *Field Case Histories* and *Oil and Gas Reservoirs*, also describe the history of several typical waterflood and pressure-maintenance projects.

For this chapter, three recently reported water-injection-project case histories were selected from the literature as a means of illustrating the use of contemporary technolo-

gy and reservoir engineering methods to solve some of the more complex problems encountered in many oil fields today. Summarized in the following discussion are results of projects involving (1) an older field with multiple sands, (2) a deep carbonate reservoir, and (3) an offshore field.

The effects of extensive waterflooding operations in the Hewitt field unit, Carter County, OK, were reported in 1982 by Ruble.¹¹³ The project described in that paper is a pattern waterflood in multiple sands that had been essentially depleted through 50 years of primary operations. The project is a good example of a simultaneous waterflooding of numerous sands containing relatively high-viscosity oil at shallow depths, as shown in Fig. 44.66. A structure map of the Hewitt unit is shown in Fig. 44.67. A summary of the reservoir performance data is given in Table 44.15. The additional oil recovery by waterflooding has been estimated to be 34.9×10^6 STB (123 bbl/acre-ft) as compared to a primary recovery of 109.6×10^6 STB (385 bbl/acre-ft). These numbers represent approximately 10 and 31% of the OOIP, respectively. Among the outstanding features of this project are (1) the use of triple completion injection wells with tubing and packer installations for control of the water that is injected into as many as 22 individual sands, (2) the plugging of 680 old wells and drilling of 149 new wells, and (3) the use of surveillance and selective injection programs to optimize oil recovery.

Langston *et al.*¹¹⁴ have reported on a large-scale water-injection project in the Jay/Little Escambia Creek field in Florida and Alabama. The project is a good example of a pressure- and rate-maintained project in a deep, undersaturated, carbonate reservoir. A summary of the production performance data for the field is presented in Table 44.16. The injection pattern is a 3:1 staggered line drive, as shown in Fig. 44.68. Reservoir pressure and

oil production rates, shown in Fig. 44.69, were maintained at constant levels for 6 years before they began to decline. Ultimate oil recovery is expected to be 346×10^6 STB, or 47.5% of the OOIP. This represents 222×10^6 STB more recovery than from primary operations—i.e., water-injection procedures will account for 64% of the total anticipated recovery. A great number of rock and fluid property data were acquired during the early development phase of the field. Use of these data provided the basis for decisions concerning unitization and the subsequent injection program.

Although water injection programs are being carried out in many offshore fields, primarily in the Persian Gulf area, in the North Sea, on the Louisiana-Texas gulf coast, and on the California coast, case histories have been reported on only a few. Jordan *et al.*¹¹⁵ reported on injection operations in the Bay Marchand field, offshore Louisiana, in April 1969.

Initial reservoir pressures in individual sands of the Bay Marchand field ranged from 4,600 to 5,291 psig. Reservoir temperatures varied from 182 to 197°F. Initial GOR's averaged 450 scf/STB and oil gravities were between 21 and 30° API. PVT properties varied with depth and the oil columns were undersaturated at their volumetric midpoints. Oil viscosities ranged from 1.1 to 1.9 cp, indicating favorable mobility ratios.

Porosities were rather uniform and averaged 29%. However, permeabilities exhibited wide variations; three reservoirs had geometric-mean air permeabilities of less than 100 md, while the remaining sands had values up to 2,000 md. Initial water saturations exhibited a corresponding variation, from 40 to 15%.

Pressure maintenance using seawater for injection began in 1963. According to McCune,¹¹⁶ who reported on operations in the Bay Marchand field in Oct. 1982, successful injection operations have been carried out over a 20-year period in six major sand reservoirs. A typical sand unit structure map and pressure-production history are illustrated in Figs. 44.70a and 44.70b, respectively.

The techniques used to test, treat, filter, and pump seawater are discussed in detail in the papers by Jordan *et al.*¹¹⁵ and McCune.¹¹⁶ The basic methods used in the Bay Marchand field, which include both coarse and fine filtration of solids, oxygen removal, and chemical treatment for control of corrosion and bacteria, have since been adopted in many other seawater injection projects.

Pilot Floods

A pilot waterflood is conducted to provide a means of evaluating the feasibility of a full-field implementation of the waterflood process. Both reservoir performance and operational procedures can be evaluated during the pilot flood. This experience is helpful in performing the engineering and economic studies that are necessary in deciding whether expanded waterflood operations should be carried out.

It is important to understand that a pilot flood should be designed to assure engineering success rather than economic success. Any small economic loss sustained by the pilot flood can be weighed directly against the much greater economic loss that would result from expanded waterflood operations that are undertaken without accurate pilot performance data. Such economic losses can result

Fig. 44.68—Jay/Little Escambia Creek waterflood well location map.

Fig. 44.69—Jay/Little Escambia Creek unit performance.

from the project capital investments or from a reduction in the ultimately recoverable oil reserves.

Caudle and Loncaric⁵⁰ has suggested several aspects of field pilot operations that need to be considered to achieve the greatest amount of useful data from the project. Fluid movement is most critical; one cannot isolate a segment (pilot area) of a reservoir and confine assessments of fluid movement to that segment.

A commonly used pilot flood pattern is the inverted five-spot, in which there is one injection well and four producing wells; all other nearby wells are shut in. The popularity of this pattern is mostly because only one injection well is required. The inherent problem with this pattern is that

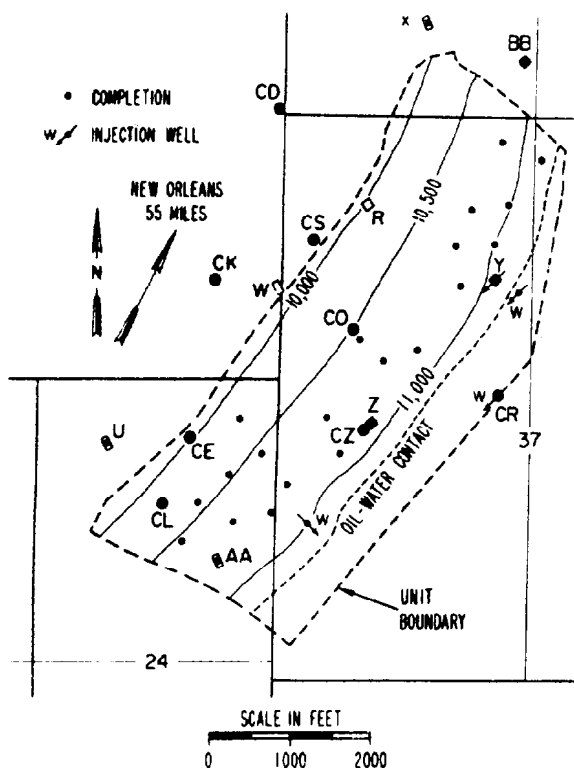

Fig. 44.70A—Typical unit structure map, Bay Marchand field.

Fig. 44.70B—Pressure production history vs. time. Typical unit reservoir, Bay Marchand field.

three-fourths of the produced fluid comes from outside the "pilot area" while, at the same time, fluid leaves the pilot area from the regions between the producing wells. The relative volumes are affected by the ratio of production rates to injection rates.

A "volumetric balance" can be maintained in the pilot area by allocating only one-fourth the rate of the injection well to each production well. Although the volumes are balanced, the production history will still reflect the fact that only one-fourth of the oil that is produced actually comes from inside the pilot area. Therefore, no reliable estimate of the amount of recoverable oil in the pilot area can be made. Computer model studies show that the production history for this pilot pattern is so greatly affected by conditions outside the pilot area that correction factors are probably inadequate to compensate for the errors. This is especially true if there is a gas saturation in the reservoir at the start of injection.

The considerations noted previously suggest that a reversal of that pattern, in which one producing well is surrounded by four injection wells, could be a more accurate mechanism for evaluating the performance of a pilot flood. This pattern would minimize the escape of the oil originally contained in the pilot area as well as the entry of outside oil into the pilot area. The conventional five-spot pattern, as it is known, is probably the most simple and useful pilot pattern. While it is true that three-fourths of the injected fluid will not enter the pilot area, the production from the center producer will be much more useful for predicting total fluid recoveries.

The purpose of the pilot flood is to facilitate an evaluation of the performance of a small section of the reservoir so that the resulting information can be used to estimate the behavior of a much more extensive operation. If the production history of the individual pilot well does not generate data that are representative of the entire area to be flooded, a correction factor can be used to adjust the actual production history in order that the potential production of a fully developed or "confined" pattern flood element can be estimated.

Such a pilot (or pilot production well) must operate as if it were in a confined area (i.e., in one that is surrounded by many similar areas). In reality, such a situation could occur only if the pilot area composed the entire proposed flood project. However, if a sufficient number of similar elements are operated around the pilot, results that would closely approximate those of the confined case could be achieved. The number of similar elements around the pilot area that are necessary to generate results that are usable without correction depends on the mobility ratio and initial gas saturation.

Model studies^{117,118} have shown that, in general, the single conventional five-spot pilot is adequate for mobility ratios below one. More complex pilot patterns are necessary at higher mobility ratios.

Certain considerations should be weighed in deciding the location of the pilot area. Knowledge of the reservoir's geometrical configuration, its structural data, and its stratigraphic data are necessary to make the selection. A partially confined or bounded area will increase the value

of the pilot in predicting the behavior of an expanded flood. The boundaries to be sought are as follows: (1) oil/water contacts with respect to monoclinical or anticlinal structures, (2) fault planes, (3) small fault blocks, (4) structural or permeability pinchouts, and (5) shale-outs to the side.

Reservoir and well conditions must be evaluated before initiation of the pilot flood. In selecting the portion of the reservoir in which the pilot flood is to begin, it is important to be informed concerning these elements: (1) the pattern and spacing of injection and producing wells with respect to the formation structure and the distribution of formation properties, (2) the type of well completions, completion intervals, and the repair and workovers that have occurred in the past, and (3) the productivity factors that have been measured for producing oil wells.

Reservoir conditions and other related data provide information that is necessary before, and at the initiation of, the pilot flood. Some characteristics and categories of data that are valuable in determining the magnitude and distribution of oil, water, and gas saturations before the start of the pilot flood are (1) the development and production history, (2) total oil recoveries during primary operations, (3) encroachment of water or gas, (4) reservoir pressures within and surrounding the selected pilot flood area, and (5) distribution of fluids through gravity drainage.

The behavior of the reservoir and the wells should be evaluated continually throughout the life of the pilot flood. The records of this monitoring should include information about the following matters: (1) water-injection history on each well, including the time the injection began; (2) cumulative volumes of water and the rate of injection, by well, for the flood; (3) injection pressures and the identities of the sections taking water; (4) fluid production history, by well, for the total area within the flood region and for wells in the surrounding area; included should be the rate of production and the cumulative volumes of oil, water, and gas; (5) WOR and GOR trends; (6) reservoir pressure distribution inside, and surrounding, the flood area; (7) the frontal advance and associated displacement efficiency of water, as evidenced by the time and location at which water appears in individual wells; (8) workover history of both injection and producing wells; and (9) any pertinent changes in the pilot flood program.

There are two efficiency factors that may be calculated and used in evaluating the effectiveness of the pilot flood. One involves a displacement efficiency, determined on the basis of the ratio of the volume of total fluids produced to the volume of water injected. This ratio will indicate whether the injected water is effectively moving fluids from the injection well to the producing well (or wells) within the pilot area. The second factor involves the sweep efficiency within the flood pattern and the fractional depletion of the oil zone, which determine the economic life of the reservoir as well as the ultimate oil recovery.

Production data in the form of production-decline curves may be used to evaluate the pilot flood performance. The usual procedure in presenting the history of oil production in pilot flood operations has been to plot the logarithm of oil production vs. time or the logarithm of time. The advantages of using production-decline curves are that

they indicate the time of fill-up and the current oil-production response with respect to the injection program. However, there are limitations in using production-decline curves to evaluate injection efficiencies and the future behavior of the pilot. Among these limitations is the fact that true decline conditions seldom exist because fluid production is controlled by water-injection rates. There is no basis for assuming any particular shape with regard to a production-decline curve because the oil rate does not necessarily vary with time; the oil production rate is directly dependent on the rate at which water is injected and on the physical characteristics of the reservoir rock and the fluids it contains.

During the development and operation of the pilot test, certain conclusions regarding the performance of an expanded waterflood may be drawn. For example, if the reservoir has a high water saturation, the water may be more mobile than the oil, which would soon result in a high WOR in the pilot area. Because of the permeability reductions around the wellbores of the input wells, the formation itself might not take a satisfactory injection rate without exceeding the maximum pressure. Again, excessive pressure would produce adverse conditions. Water-cut data, used in conjunction with the Stiles calculation¹⁹ or other similar conformance calculations, will indicate whether the pilot is performing as expected.

Surface-Active Agents in Waterflooding

Surface-active agents in waterflooding are used to improve oil recovery by (1) improving mobility, (2) reducing interfacial tension, and (3) altering the rock wettability.

Laboratory investigations and field tests in which various surface-active agents and other chemicals are used will be discussed in Chap. 45, "Miscible Displacement," and Chap. 47, "Chemical Flooding." The large number of technological advances that have taken place during the past decade and the voluminous publications on the use of surface-active agents allow only a brief reference to the subject in this chapter.

Mobility Improvement

Control of the mobility of the injected water, along with the use of surface-active agents and chemicals to alter the wettability characteristics of the reservoir rock, are among the techniques now being used in certain waterflood projects to improve oil displacement efficiencies. The addition of an acrylamide polymer or some similar chemical to increase the viscosity of water causes areal and vertical coverage in the reservoir to be increased as a result of a reduction in the mobility ratio between the displaced and displacing fluids. This addition of a polymer also reduces the volume of injected fluids required in the oil displacement process that lowers the saturation in the swept portion of the reservoir to its residual value. The first field studies involving the use of polymers for mobility control were reported by Sandiford in 1964.¹¹⁹

The injection of a high-molecular-weight polyacrylamide polymer to increase waterflood sweep efficiencies through improved mobility ratios was considered to be unprofitable in two reported case histories^{120,121} that are summarized below. In the Wilmington field, CA,¹²⁰ a large-scale injection program was initiated during 1969 in relatively unconsolidated sands that contained an

18° API gravity crude oil with a reservoir oil viscosity of 30.8 cp. The mobility ratio of brine/oil was 14.2, compared to a mobility ratio of 1.33 for a 250-ppm polymer/oil. After injection of 1,300,000 lbm of polymer over a period of 2.5 years at an average concentration of 213 ppm, the injection of polymer was discontinued because no increase in oil recovery could be attributed to the polymer injection. The poor response was believed to be caused by (1) a polymer concentration that was too low; (2) injection rates that decreased by an average of 25% (as a result of scale formation), accumulation of undissolved polymer on the face of the formation, and possible reduction in the reservoir permeability from adsorption of the polymer (85 lbm/acre-ft); and (3) a premature breakthrough of the polymer solution through highly permeable intervals.

A pilot project¹²¹ in the Pembina field of Alberta, Canada, was started in Nov. 1971 with two 160-acre, five-spot patterns composed of six injection wells and two producing wells. The producing interval consisted of a conglomerate zone underlain by a sandstone, and these zones had average permeabilities of 63.6 and 25.3 md, respectively.

The viscosity of the 37° API crude oil, at reservoir conditions, was 1.05 cp. A total of 217,400 lbm of polymer was injected, with the first 124,750 lbm being injected at a concentration of 1,000 ppm and the remaining 92,650 lbm being injected at decreasing concentrations from 1,000 to 100 ppm. The conclusions reached from the Pembina pilot project were as follows.

1. The overall performance of the producing wells in the pilot area showed no permanent improvement.
2. Early breakthrough of polymer through the conglomerate zone indicated that the polymer did not significantly reduce the effects of the highly permeable interval.
3. Water/rock interaction and formation water commingling reduced the effective viscosity level of the polymer solution to approximately 25% of the designed value.
4. There was a significant reduction in the injection rates of two injection wells during polymer injection.
5. Adsorption of the polyacrylamide polymer was about 2 mg/m² of surface area.

The injection of polymer solutions to improve oil recovery through mobility control has not yet been well established for general application. Laboratory displacement tests should be performed on reservoir rock samples, and the reservoir crude oil and formation water should be used as a guide in selecting the type of polymer and the concentrations necessary for scaling the formulation to field conditions. Of particular significance is the effect of the formation water's salinity on reducing both the viscosity of the polymer solution and its adsorption by the reservoir rock.

Published reports¹²²⁻¹²⁴ about various field applications of polymer solutions have indicated improvements in oil recovery efficiencies of 5 to 15% above recoveries from conventional waterfloods.

Reduction in Interfacial Tension

Early laboratory tests¹²⁵⁻¹²⁷ indicated that dilute solutions of surfactants would remove more oil from sandstone cores than would untreated water. The economic feasibility of using this process in a waterflood has been ques-

tioned because of the loss of the surfactant by adsorption at the rock/liquid interfaces. The adsorption is especially problematical with both anionic and cationic surfactants, and it occurs to a lesser degree with nonionic surfactants. In one field project, the results of which were published¹²⁸ in 1968, a nonionic surfactant was injected at concentrations of 25 to 250 ppm into a sandstone reservoir at an advanced stage of waterflooding; an additional oil recovery of approximately 9% was attributed to the use of the surfactant.

Alteration of Rock Wettability

Recognition of the use of alkaline salts to improve oil recovery was first disclosed by Squires¹²⁹ and patented by Atkinson¹³⁰ in 1927. Wagner and Leach,¹³¹ in 1959, presented laboratory results that showed improved oil recovery through the injection of water containing chemicals that altered the pH of the injected water. Acidic injection water resulted in an improvement in WOR and a corresponding increase in recovery; however, its use as an injection medium has not proved practical because of chemical reactions with most reservoir rocks. Subsequent laboratory tests¹³² established similarly improved oil recovery results with sodium hydroxide.

Laboratory tests have indicated that the injection of caustic solutions can result in improved oil recovery, primarily as a result of lowering the water relative permeability,¹³³ pH control,¹³⁴ and the oil/water interfacial tension.¹³⁵ These effects, though, are dependent on the water salinity,¹³⁴ the temperature,¹³⁶ and the type of crude oil.

In 1974, there was a report¹³⁴ of a field trial in which a solution containing 3.2 wt% sodium carbonate was injected into a previously waterflooded Miocene sand in southeast Texas. The test involved two wells located 36 ft apart. Some improvement in oil cuts was noted at the producing well before alkaline water breakthrough, suggesting the formation of a low-mobility water-in-oil emulsion bank. No economic evaluation of the test was reported.

The first field test of the caustic flooding process was mentioned by Nutting¹³⁷ in 1925. A report¹³² published in 1962 of a field trial in which sodium hydroxide was used in the Muddy "J" sand, Harrisburg field, West Harrisburg Unit, Banner County, NE. The injection of a 40,000-bbl slug of 2.0 wt% sodium hydroxide resulted in a recovery of approximately 8,700 bbl of oil from an area that previously had been flooded out by normal water injection operations. In another case, an 8% PV slug of 2.0 wt% sodium hydroxide was injected into a portion of the Singleton field, Banner County, NE. The test was in an area under waterflood that had not been completely watered out. Increased oil recovery, reported¹³⁸ in 1970, amounted to 17,600 bbl, or 2.34% PV.

The only description of a large-scale field trial of caustic flooding that has been published¹³⁹ involved a 63-acre area in the Whittier field, CA. The area had been under waterflood for 2.5 years before caustic was injected. A 0.2 wt% sodium hydroxide slug, equal in volume to 23% PV, was injected. The slug was followed by plain water. The increase in oil recovery beyond that by waterflooding was estimated to be from 350,000 to 470,000 bbl, or 5.03 to 6.75% PV.

Water Source and Requirements

During the planning stages of a waterflood program, these basic steps must be taken: (1) the water requirements should be determined as accurately as the data will permit; (2) all possible water sources should be surveyed with special attention given to satisfying the quantitative requirements; and (3) the selected source should be developed in the most economical manner permitted by good engineering practice.

Waterflood Requirements

Daily Water-Injection Rates. The largest daily demand for water from the water source occurs during the fill-up period when there is no return water available. During the early life of the reservoir's injection program, or during the fill-up period, it is usually advantageous to maintain a high rate of injection so as to accomplish an early fill-up (a rate between 1 and 2 B/D/acre-ft is desirable). One author¹⁴⁰ states that after fill-up has been achieved, the injection rate should be maintained at about 1 B/D and not less than ½ B/D/acre-ft. Flood pattern, well spacing, and injection pressures should be designed to meet these requirements.

Ultimate Water Requirements. The PV method has been found to give a good approximation of the ultimate water requirements for a waterflood. The volume of water required should range from 150 to 170% of the total pore space, and the measurement of such space should include the PV of any adjacent overlying gas sand or basal water sand. The ultimate water requirements, together with the average water-injection rate, will serve as a basis for estimating the total life of the waterflood.

Makeup Water. The volume of return water becomes an increasingly significant percentage of the required injection rate as a flood progresses; therefore, it is an economic necessity that produced water be injected unless the treating cost of the produced water is higher than that of the makeup water. If gas or water sands are not present, the produced water will compose 40 to 50% of the ultimate water requirements. If gas or water sands are present, less return water will be available—thus, the ultimate makeup water requirement will increase to as much as 60 to 70% of the total quantity of water that is injected. In recent years, federal and state agencies have enacted regulations that limit or prohibit disposal of oilfield waters in surface systems. Environmental regulations should be reviewed carefully when studies of the treatment and disposal of produced water are being made.

Water Sources

There are three principal freshwater sources and two sources of salt water that can be used for waterflooding purposes. Freshwater supplies include surface waters, municipal water, waters from alluvium beds, and some subsurface waters. Saltwater sources include some subsurface waters and the oceans. Where economically permitted, salt water usually is preferable to fresh water.

Fresh Water—Surface Sources. Surface waters, including ponds, lakes, streams, and rivers, have been used throughout the history of oilfield waterflooding projects,

and these are the sources for which competition from other industries and from municipalities is highest. There are a number of other factors that limit the availability of this resource. For example, there is a continuing growth in the demand for fresh water, and droughts have resulted in water shortages in some areas during recent years. In addition, some states have taken legislative action to control freshwater supplies. Therefore, when fresh water is to be used in a waterflood project, it may be necessary to obtain approval from the appropriate state agency before proceeding with development of such a source. If salt water is chosen as the injection medium, legal approval for the withdrawal of the water may not be necessary.

Small ponds and streams are very unreliable as a constant source of supply for all seasons of the year. Large lakes and rivers are preferable; however, these also may have limited capacity during drought periods. The principal disadvantages of surface sources are the unreliability of their quality and quantity, the high cost of treating equipment, and the cost of the chemicals that are necessary to obtain a satisfactory water.

Fresh Water—Alluvium Beds. A more favored method of using river or stream waters calls for the alluvium beds near the river to be tested with shallow wells. Use of this source in some of the world's largest waterfloods—the Salem unit in Illinois,¹⁴¹ the Burbank unit,¹⁴² and the Olympic pool in Oklahoma—indicates the high productivity that can be achieved from alluvium beds. If closed injection systems are used, chemical treatment (with the possible exception of a bactericide) normally is not required. Filtration usually is unnecessary because of the natural filtration of the alluvium beds.

Sulfate-reducing bacteria are anaerobic and thrive within a few feet of the surface, so waters from alluvium beds frequently can be highly contaminated with these bacteria. However, low-cost chemical treatment can control these organisms. Having noted this minor problem, it is safe to say that the quality of water from alluvium wells is more dependable than that from direct surface sources. Wells are not subject to extreme turbidity changes during rainy seasons or to the variable organic content of the surface waters.

The reliability of alluvium beds as a continuing source of water is slightly better than the reliability of an adjacent river or stream. The water table will drop steadily when a river dries up, but wells should go on supplying water for some time after the surface waters are depleted.

The principal advantages of alluvium-bed sources are their low development cost, low pumping cost, and the possibility that they will not need filtration. If bacteria are not a problem, corrosion rates should be low and chemical treatment unnecessary.

Fresh Water—Subsurface Formations. In certain areas, subsurface sand or carbonate formations may be tested for water production with good results. Good-quality water often is produced from certain formations whose depths range from close to the surface to 1,000 ft or more. As in the case of the alluvium wells, closed systems usually are used, thus eliminating chemical treatment and filtration requirements. When a well is completed in a freshwater subsurface formation, drawdown tests should

TABLE 44.17—RESERVOIR ENGINEERING

Dissolved Gas	Test	Effects	Remedial Treatment	pH Control	Tolerance Suggested
Hydrogen sulfide, H ₂ S	Odor or taste. If lab analysis desired, sample is preserved by addition of zinc acetate and sodium hydroxide.	Very corrosive in the presence of moisture, particularly if oxygen is present.	1. Open aeration (poor) 2. Synthetic or natural combustion exhaust gases flowing counter-current to water in packed towers. 3. Forced-draft aerators.	A decrease in pH will increase rate of corrosion, but the corrosion rate also depends on the composition of the contacted metal and the alkalinity of the solution.	50 ppm. ¹⁵⁷ Corrosion rate is rapid up to 15 ppm. High H ₂ S concentrations may act to inhibit corrosion.
Carbon dioxide, CO ₂	Determine the stability of the carbonate-bicarbonate balance, titrate for free CO ₂ at source point.	1. Corrosion increases with increasing percentages of CO ₂ . 2. Removal of CO ₂ may cause precipitation of metallic carbonates or bicarbonates.	1. Aeration by the three methods mentioned above. 2. Increase the alkalinity. 3. Chemical inhibitors.	An increase in pH also will decrease the free CO ₂ that is present. Free CO ₂ may not exist in water with pH values which are greater than 8.3.	Function of the carbonate and bicarbonate stability vs. corrosive activity is caused directly by the CO ₂ . Not as corrosive as equal portions of O ₂ or H ₂ S.
Oxygen	Determine if the Fe ⁺⁺ ion is being oxidized. Dissolved O ₂ meter and membrane probe is used when H ₂ S is absent.	1. It is largely responsible for corrosion of equipment. 2. Its reaction with metallic ions (Fe ⁺⁺ mostly) will cause plugging in the reservoir.	1. Use of closed systems will minimize oxygen use. 2. Open systems—vacuum aeration has been used. 3. Counterflow (in bubble tower) of natural gas with low oxygen content.	No effect is to be found in either acidic or alkaline water.	Limits of detection—i.e., 10 ppb (Note: iron bacteria can grow in waters containing 0.3 ppm. ¹⁵³ SRB can also live in aerobic conditions.) Soluble O ₂ is approximately four times as corrosive as equal mole volumes of CO ₂ .

be made to determine the initial productivity. The test should be conducted for a sufficient length of time to determine the static working fluid level, which will indicate the rate at which the well can be produced.

Optimal spacing in the water-supply wells may vary from 25 ft for sand points to as much as 1,320 ft for deep wells. The productivity will indicate how many wells are necessary to meet the daily water requirements. Where a number of deep wells are required to develop the fresh-water source, the economic viability of drilling the additional wells should be carefully considered.

Pumping equipment for water wells may include surface-driven or submersible, centrifugal (or rod) pumps. If a high-pressure gas source is available, gas-lifting methods should be considered also. Selection of the pumps should be governed by economic considerations, and these are influenced by the static fluid level, the drawdown, and the desired productivity. The advantages of freshwater wells in subsurface formations include low corrosion rates and the possible elimination of the need for chemical treating and filtration.

Salt Water—Subsurface. In most oil fields, either above or below the oil zones, there are saltwater formations that are potential sources of water supply.¹⁴³ The relatively shallow saltwater wells are similar in most respects to the shallow freshwater wells.^{144,145} The saltwater wells are completed in the same manner and have the same advantages of being adaptable to closed injection systems. Many producing areas have deep saltwater formations that have extensive areal coverage and a thickness of up to several hundred feet. These prolific saltwater-producing formations frequently have high working fluid levels. Such formations may contain waters with high mineral content, and have wellhead temperatures in the range of 100 to

173°F. Hydrogen sulfide may or may not be present. If the water contains significant amounts of hydrogen sulfide, open systems that incorporate aeration, sedimentation, and filtration capabilities should be used. Examples of prolific formations are the Arbuckle¹⁴⁶ and Mississippi limestones in Kansas and Oklahoma, the Ellenburger lime in Texas, the Tar Springs in Illinois, and the Madison lime in Wyoming. The drilling and completion costs of deep supply wells may range up to, and exceed, \$500,000; however, they frequently are the most economical source of large volumes of water because of small fluid-level drawdowns. The advantages of the deep saltwater wells include their adaptability to closed systems, their high and reliable productivity, the compatibility of salt water with the oil sand, and, where high hydrostatic fluid levels are found, the relatively low lifting costs.

Salt Water—Ocean. Use of ocean water for injection purposes is confined to coastal regions and offshore fields.^{116,147-149} Closed systems in which shallow wells on the shore are used as the source of supply are preferred. A moderately high corrosion rate should be expected, and ocean water probably will require a bactericide. The advantages of oceanwater supply include an inexhaustible source and low development and pumping costs.

Salt Water—Return Water. During the life of a flood, the return water may represent a total volume of from 30 to 60% of the injection requirements. The use of the return water for injection may improve the economic condition of the overall project. In open systems, return water generally is added to the makeup water and injected. The mixing of the waters in a pond or settling tank permits precipitation and sedimentation of the incompatible constituents. In recent years, however, it has been determined

TABLE 44.18—WATER-INJECTION PRESSURE MAINTENANCE

Organisms	Genus	Phylum	Environment	Agents Used for Treating	Effect of Agents in Reducing Growth	Purpose in Treating
Sulfate reducers	Desulfouibrio	—	Anaerobic (though they cannot grow in the presence of free oxygen, they can live; will not grow in highly saline waters.) Low-pH waters also stifle growth.	Chlorine* Quaternary ammonium compounds Other bactericides**	Partially effective Effective	1. To prevent corrosive activity as a result of H ₂ S formation. 2. To prevent plugging of sandface.
Organisms	Pseudomonas	—	Aerobic or facultative (usually require free oxygen for growth)	Chlorine* Quaternary ammonium compounds	Effective Effective. (Note: change bactericide if immunization occurs.)	1. To prevent plugging of equipment. 2. To prevent plugging of sandface.
Iron bacteria	Leptothrix Crenothrix Gallienella	—	Bacteria withdraw ferrous iron (Fe ⁺⁺) that is present in their aqueous habitat and deposit it in the form of Fe(OH).	Bactericides Chlorine*	Effective Effective. (Note: slug injection is usually sufficient.)	1. To prevent plugging of equipment. 2. To prevent plugging of sandface.
Algae	—	Thallophyta	Chlorophyll-containing plants (require presence of sunlight and moisture for growth).	Copper sulfate Sodium pendachlorphenate	Effective, depending on water alkalinity. Effective, depending on water alkalinity.	1. To prevent plugging of equipment. 2. To prevent plugging of sandface.
Fungi	—	Thallophyta	Oxygen (require presence of free oxygen).	Closed system Chlorine* Closed system	Effective Effective Effective	1. To prevent plugging of equipment. 2. To prevent plugging of sandface.

* Limited to iron-free waters.

** Mercuric and phenolic compounds; fatty and resin amines; formaldehyde.

that the mixing of the produced water and makeup water results in increased scale deposition and corrosion in the surface system and injection wells. Also, scale deposition in the perforations, and the transport of suspended solids (a product of corrosion) into the formation, reduce the well injectivity and necessitate frequent backwashing and acid treatments. Therefore, in many of the major waterfloods, the waters are isolated in the surface system and are injected separately into the reservoir.

In closed systems, the compatibility of the return and makeup waters is more critical than it is in an open system, but the two waters can be mixed satisfactorily in most cases. Complete analysis of the water should be made, with special attention being given to the detection of any combinations of ions that may precipitate on being mixed. The effect of the more common precipitates and the treatment of them is covered in this chapter under Water Treating.

Water Treating

During the early days of waterflooding, only the quantity, not the quality, of the water was given consideration. However, it was soon noted that when the quality was poor, higher injection pressures were required to maintain suitable injection rates and corrosion problems mounted. As a result, the operators of the early waterfloods began to realize that the quality of the water was equally as important as the quantity, and that poor water treating was proving disastrous to waterfloods that otherwise might have been successful. Water-treating practices have improved greatly as the waterflood industry has matured, a point that is substantiated in the literature by the many contributions on this subject.^{145,150-164} API has published recommendations for analysis of oilfield waters¹⁵⁰ and biological analysis of injection waters.¹⁵¹ Successful results normally can be achieved when these recommended

procedures are followed. Standardized procedures for membrane-filterability tests,¹⁵² a useful tool in water testing, also have been adopted by the industry.

After the water source is known, a water analysis is required to determine these matters: (1) compatibility of the injection water with the reservoir water (the test should include actual blends as well as theoretical combinations); (2) whether an open or closed injection facility would be the most suitable; and (3) what treatment is necessary to have an acceptable water for the reservoir and to minimize corrosion of the equipment.

Prudent operation of the waterflood requires that water analyses be conducted periodically to determine the presence of dissolved gases, certain minerals (discussed later), and microbiological growth—undesirable constituents of water. Samples of the injected water should be collected at several points in the system—for example, at any point in the system where a change in water quality could or should occur, and at the injection wells.

Sampling

The importance of good sampling practices cannot be overemphasized. An extremely accurate chemical analysis of a water sample followed by a brilliant assessment of the problems indicated by the analysis is worthless if the sample does not represent the water in the system.

Dissolved Gases

To eliminate the loss of dissolved gases through changes in temperature and pressure, testing of such gases should be carried out in the field soon after a water sample is taken. The three dissolved gases to be considered are hydrogen sulfide, CO₂, and oxygen. Table 44.17 lists the test, the effects of the gas when present, remedial treatment, pH control, and tolerance permitted in ppm.

Microbiological Growth

Static control of colonies of one-celled animals and plants is of much concern to operators attempting to maintain a suitable water for injection. Aerobic, anaerobic, fungal, and algal growths will cause reservoir and equipment plugging and corrosion. Table 44.18 lists the various organisms, their environment, the various treating agents that have been used, the results that may be expected, and the purpose of the treatment.

Special attention and control are required for sulfate-reducing bacteria (SRB). The presence of the sulfate ion is essential to the growth and reproduction of these particular bacteria. Sulfate, in turn, causes plugging. The reaction of the sulfate ion with the SRB forms the sulfide ion, which then reacts with iron. Iron sulfide is serious plugging agent and H_2S is an extremely corrosive agent.

Early studies of SRB involved the plate-count method,^{153,154} a clinical practice derived for the purpose of isolating and identifying bacteria. But this technique is of little value in assessing sulfate-reducing bacteria activity, which is what really counts.

The objective of studies of SRB in a water system is to determine whether practical problems exist, and to be able to execute effective countermeasures if such problems are found. The concept of bacterial activity was developed to meet this objective. The procedures for conducting these studies are presented in the API RP 38 publication.¹⁵¹

Many organic and inorganic bactericides are now available to control this problem.

Minerals

Appearance. A notation concerning the appearance of the water at the time it is sampled is important for future reference. Frequently, organic growths and precipitated material can be detected visually.

Temperature. The temperature of the water sample is important in estimating the solubilities of various materials. For example, calcium carbonate solubility decreases with increasing temperature, as does calcium sulfate and all sulfates.

Significance of pH. Simply put, pH is a measure of the acidity or caustic intensity of water. Two important points to remember are that calcium carbonate and iron solubilities both decrease with increasing pH value; therefore, the higher the pH the more difficult it is to hold iron in solution and to keep calcium scale from forming. However, if iron is being removed in the water-treating program, then a high pH may be beneficial. The pH value is very important when corrosion control is considered.

Turbidity. A turbidity test measures the suspended material in a water and it is based on the intensity of light scattered by the sample in comparison with light scattered by a known concentration of a standard solution. The higher the scattered light, the higher the turbidity. Standards are compared to Formazin polymer, which has gained acceptance as the turbidity reference standard suspension for water.

The generally accepted method of measurement is conducted with a nephelometer. Results are reported in nephelometric turbidity units (NTU), which correspond

with Formazin turbidity units (FTU) and Jackson candle units (JCU). Normal turbidity measurements are within the 0- to 50-NTU range.

Iron. Some form of iron is probably the most common plugging agent encountered in injection wells. Ferrous iron (Fe^{++}) is soluble to 100+ ppm, while ferric iron (Fe^{+++}) is insoluble except at low pH levels (3 ppm or less). Low iron contents are desirable in any water. The retention of soluble iron in solution is the prime objective in closed systems. In properly operated iron-removal plants, the iron content in the finished water should be less than 0.2 ppm. In many cases, it is possible to reduce the iron so that it is consistently less than 0.1 ppm. There should be no significant increase in iron content as the water travels from the pressure source to the injection wells.

Manganese. Soluble manganese in water reacts somewhat as iron does, except that it is more difficult to remove. In most waters, good manganese removal requires a pH level of 9.5 to 10 ppm. Manganese problems in the Appalachian oil fields have been very severe. Only in a few isolated cases has it been troublesome in the Illinois basin; it has been of little concern in most floods in that area, or farther west. Low to moderate manganese contents are found in many waters and can be tolerated as long as the pH values remain low enough to keep it in solution.

Alkalinity. The alkalinity of water is defined by the measure of its acid-neutralizing capacity. Since the occurrence of hydroxide is quite unusual in flood waters, alkalinity generally can be taken as a measure of carbonates and bicarbonates. Calcium carbonate solubility depends on alkalinity; however, other factors, such as pH, calcium content, temperature, and total dissolved solids, influence the reaction.

Sulfates. Sulfates are of most interest from a deposition standpoint. Three generalizations may be made with regard to this class of substances.

1. An abnormally low or zero sulfate value in a brine suggests the possibility of the presence of barium and strontium. It requires practice and experience to evaluate a low-sulfate-content water.
2. In general, high-sulfate water should not be mixed with water containing appreciable amounts of barium or strontium.
3. A high-sulfate brine indicates there is a possibility of exceeding the calcium sulfate solubility. The solubility of $SrSO_4$ or $CaSO_4$ is governed by the limiting factor of either SO_4 or Ca or Sr and the ionic strength or foreign salt concentration of the brine.

Chlorides. Chlorides are the primary indication of the salinity of a water, or the ionic strength of a brine, or the presence of a fresh water. Chloride tests can be useful in tracing the progress of a waterflood.

Hardness. The term hardness refers to a measure of the amounts of calcium and magnesium that are present in the water and is expressed in ppm of calcium carbonate. Since calcium is involved, the hardness of the water is of importance in relation to calcium carbonate stability.

Calcium and Magnesium. These two minerals are grouped together because they are the principal contributors to a water's hardness. The calcium salts are less soluble than magnesium under most practical conditions. Also, the presence of an appreciable quantity of calcium is necessary for calcium sulfate and calcium carbonate scale to form. It is important to note that other factors, beyond the calcium value, must be considered in assessing calcium carbonate formation.

Suspended Solids. Suspended solids are a mixture of fine, nonsettling particles, or precipitated material in the water. Unless suspended solids are removed, difficulties involving plugging of the injection or disposal wells can be expected.

Dissolved Solids. It is necessary to prevent precipitation of those soluble salts that are dissolved in the water, so that there will be no plugging of the sandface.

Total Solids. Technically, the term "total solids" means the combination of dissolved and suspended solids. Long experience in operating water injection systems has established that good water-quality control requires knowledge of not only the general content of the water but the constituents of the undissolved (suspended) material that exist under in-line conditions. It is this suspended material that may cause well and reservoir plugging. The suspended solids often are the result of the precipitation of constituents of the water, but the quantity and type of solids that actually are precipitating cannot be ascertained from the water analysis alone.

The Millipore™ filter test has been developed to provide a means of measuring suspended material under injection system conditions. This test is conducted with the MF-Millipore filter of mixed esters of cellulose and a uniform pore size of, generally, 0.45- μm opening. The filter diameter may be of several sizes; however, 90-mm-diameter filters are recommended because a greater volume of throughput water can be handled, thus giving a more representative test for the system being examined.

A small stream of water is taken, through suitable connections and the test apparatus, from the selected point in a system. The test apparatus that holds the filter will trap all the suspended material flowing through the sample line. The water effluent that passes through the filter is measured and recorded, for use in the later analysis, as volume throughput in milliliters of water. After sufficient water has passed through it and/or the initial pressure of about 10 psig has increased sufficiently to indicate plugging, the filter is removed and placed in a protective screwcap tube (preferably containing distilled water to prevent the drying out of the filter) and submitted to the laboratory for either comprehensive or selective analysis. As a safety precaution, it is highly recommended that duplicate samples be obtained through the use of a parallel-apparatus hookup.

Identification of the solids and particle size distribution (with Coulter counter) is useful for designing facilities to treat and to remove solids from the water.

Barium. Barium ions have been quite troublesome in many cases because of the extremely low solubility of the most common form of their deposition, barium sulfate.

It is generally undesirable to mix a water with appreciable amounts of barium with a water containing high sulfates or strontium.

Strontium. This is another alkaline earth metal that occurs in small quantities and is associated with calcium and barium minerals. It is found principally in the form of celestite (SrSO_4) and strontianite (SrCO_3) ores; its solubility in both forms is considerably greater than its barium counterpart but much less than CaSO_4 .

Sequestering and Chelating Agents. The use of sequestering and chelating agents in injection waters plays an important role in preventing the precipitation of salts of calcium, barium, strontium, iron, copper, nickel, manganese, etc.¹⁵⁵ The definition of each term is given as: (1) *sequester*: to set apart, to put aside, or to separate, and (2) *chelate*: pertaining to or designating a group or compound which, by means of two valences (principal or residual, or both), attaches itself to a central metallic atom so as to form a heterocyclic ring.

The sequestering agent will separate the metallic cation from the anion by chelation. This will prevent the metallic ion from reacting with the anions to form precipitates that will cause plugging of the reservoir. If precipitation of the metallic salt ions does occur, reverse flow of the injection well and acid treatments usually will correct the situation so that normal injection rates can be continued and maintained. The requirements for desirable sequestering agents are that they¹⁵⁵ (1) form chelates in the presence of other ions such as calcium, magnesium, strontium, barium, and others that are common to waters used for secondary recovery, (2) form stable water-soluble chelates or complexes with iron, (3) be compatible with other chemical compounds used for water treatment, (4) be economically feasible, and (5) be easy and safe to handle.

The most widely used sequestering agents are "Ver-sentates" (trademark for certain salts of ethylenediaminetetraacetic acid and related compounds), citric acid, gluconic acid, organic phosphonates, and the polyphosphates. Of these, the citric acid sequestrants have been most successful.

Corrosion Inhibitors. Corrosion inhibitors are chemicals that are used to control the corrosive activity between the metallic alloys and water. "The current interest in chemical inhibition is largely a result of the availability of organic treating compounds that possess both corrosion-inhibiting and biocidal properties. Field and laboratory tests made with organic inhibitors such as quaternary, rosin, and fatty amine compounds have indicated favorable results in minimizing corrosion caused by dissolved acidic gases."¹⁵⁶

Selection and Sizing of Waterflood Plants

The selection and the sizing of waterflood plant facilities normally are unique to each waterflood because of the many variable parameters. The primary parameters might be the volume and pressure, while secondary parameters might include the treating requirements and the economic position of the investor. A variation in any single one of these parameters might drastically modify or completely change the selection and sizing of a waterflood plant.

The volumes of injection water to be handled will, of course, be the most important basic item of information to learn for determining the size of the plant. Here, too, there are several parameters on which the calculation is based. Essentially, the water volume is a function of the gross size of the reservoir to be flooded, the porosity of the reservoir rock, the anticipated conformity or efficiency of the flood, and the ROS at both the initiation and completion of the flood. These data will be applied to the actual reservoir calculations, and only the final gross volume and the required daily injection rate must be known by the plant designer. As a general rule of thumb, 8 to 15 bbl of injected water per barrel of secondary oil, or $1\frac{1}{4}$ to 2 PV of injected water, will provide a reasonable estimate of the ultimate water-handling requirements. Daily injection rates may vary from 5 to 25 bbl/ft of pay. The producing-equipment capacity may be a limiting factor in determining the maximum injection rates. A relatively high ratio between the amount of fluid that is injected and the amount of fluid that is produced can be anticipated before fill-up.

There are certain other factors that should be considered in designing the proper capacity of the plant facilities. If the available quantity of supply water is relatively small, it is usually necessary to consider produced brine along with other supply waters so that an adequate injection volume is provided. Where the original source water is not compatible with the produced water, or where the produced water is best handled in a closed system and original source water is best handled in an open or semi-open system, flexibility in capacity design will be required. This flexibility is necessary to adjust or to balance capacities between two separate injection systems (one with a constantly increasing load, the other with a constantly diminishing load).

The pressure required to inject water into a formation is a function of formation depth, rock permeability, water quality, and the injection rate that is required. The basic reservoir data and secondary-recovery study will have defined the rock properties so that the anticipated surface pressures can be defined closely, if no adverse effects are anticipated as a result of poor-quality or incompatible water. Poor quality might be because the water contains a large quantity of solids as a result of poor filtration, inadequate settling, precipitation in an unstable water, or the growth of bacteria. Incompatibility might result from mixing injection water with formation water, from the swelling of clay particles, or from chemical reactions between the rock minerals and the injected water. In general, it has been found that the pressures than initially are encountered are less than might be anticipated when the only governing factors are depth and permeability; however, increasing pressures should be expected if there is no plan to reduce the injection rate as fill-up is approached. A final factor in predicting injection rates is the method of production. If the reservoir is to be produced by natural flow, the injection pressure must be sufficient to overcome dynamic hydraulic forces and to support a flowing rate of production. If, on the other hand, production is to be by mechanical means, with producing fluid levels at or near reservoir depth, a considerable reduction in injection-pressure requirements is possible. Consideration should be given to what the maximum allowable injection pressures should be. As a rule of thumb, pres-

sure at the surface should not exceed 0.5 psi for every foot of reservoir depth. The maximum wellhead injection pressure will limit the resulting pressure at the perforations, which is less than the parting or fracture pressure. This pressure can be determined by an injectivity test conducted before or during pilot flood operations. Breakdown pressures are often encountered below the 0.5-psi value, and in such circumstances the maximum pressure will be defined by the breakdown pressure. In older fields, or in reservoirs located at considerable depth, the mechanical strength of the injection-well casing may be the deciding factor concerning the pressure limit. This limitation can be overcome by installation of competent tubing set on a packer.

The source and the condition of the supply water will be the most important factors in determining a treating method. It is generally good practice to plan originally on using a closed system that requires little or no treating. Subsequently, the closed system may evolve into one in which the mixing of produced water will require custom-tailoring for conditions that are unique to the particular flood being considered. By starting with a basic treating system, the unit may be expanded into a complete version that may include aeration, chemical treating, flocculation, settling, corrosion inhibition, and bacteria control.

In developing the proper treating system for a particular plant, the economic factors that are unique to the situation should be given close attention. If the flood is to be of relatively short duration, it may be profitable to use a system that is less than adequate and to anticipate more than normal maintenance demands. In other circumstances, it might prove most profitable to install corrosion-resistant equipment and to reduce the use of corrosion-inhibiting treatment. Consideration should be given to installing fiberglass tubing or internally plastic-lined tubing in injection wells. Also, if new injection wells are to be drilled, a full or partial string of fiberglass casing should be considered to minimize corrosion and scale buildup, especially in the area across the producing formation. A paper published in 1980 discusses the use of fiberglass liners and injection tubing in a west Texas waterflood.¹⁶⁵

Possibly the last item to be considered by many design engineers, and yet the most important item in many companies, is the financial position of the investor. It is quite possible that a particular operator may have limited investment capital and would find it desirable to keep this sum to a minimum, at the expense of higher future operation costs or additional future investment. The capital investment situation might also affect the choice of injection rate. The operator might be in a financial position in which a low, long-term, constant income would be most advantageous; in other circumstances, a short-term, high-income situation might be most desirable. Under either of these conditions, the normal approach to determining injection rates and plant design would be modified to produce the most desirable income vis-à-vis investment conditions.

When the most desirable injection rate as well as the pressure and treating technique have been determined, the plant must be designed to fit the prescribed conditions. For a closed system, the plant design may be extremely simple and yet completely automatic. With in-line, high-

pressure filtration equipment and a relatively high-discharge head source well pump, it is possible to use the supply pump as the injection pump and to inject directly from the supply well to the injection well. In this plan, individual cartridge-type well filters may be used if the supply water is relatively free of solids.

The next stage in increasing the capacity of the injection plant would be to install a booster pump downstream from the filters, so that the supply pump and filters would not have to operate at injection pressures. The step after that would be to place a gas- or oil-blanketed water surge tank between the supply and filter system and the injection pumps. With this arrangement, low-pressure equipment can be used for supply and filtration; if the supply water and produced water are found compatible, produced water can be commingled in the surge tank. Where the systems are separated, it is also possible to use injection pumps with maximum pressure capacities. Further flexibility is also possible in that both source and injection rates can be varied independently, as long as the supply rate is at least as great as the injection rate. Corrosion frequently is minimized in the low-pressure side of this type of system by use of plastics, which also results in reduced fabrication costs.

If a supply water is naturally aerated, the operation of a closed system becomes pointless. Also, because of excessive amounts of dissolved acid gases and/or a high content of dissolved iron, it may be desirable to aerate the water as a treating technique. When an open treating system is being designed, consideration should be given to using natural elevation or substructures to obtain gravity flow through the system. Under these circumstances, open gravity filters are often the most economical and practical.

When a complete chemical-treating program is planned, the most common approach is to have the prefabricated mixing and sludge tank placed immediately ahead of the filters. In certain circumstances, it has been found desirable to deaerate the treated water before using it for injection. Chemical treatments can be used; however, chemicals are too costly except for the removal of very small quantities of oxygen. Counterflow, bubble-tray towers that use natural gas or a vacuum are sometimes used for oxygen removal. However, oxygen is not removed if it can be avoided, because of the relatively high cost of the process; the price must be weighed against the deleterious effects of the entrained oxygen.

Centrifugal pumps have proved most satisfactory for low-pressure supply water and for injection at low pressures. Among the advantages of this type of pump are the small number of its moving parts and its excellent adaptability to volume control; however, in cases in which an appreciable amount of power is to be used, the relatively low efficiencies of centrifugal pumps (particularly when they are operated at other than design conditions) may preclude their use. In selecting centrifugal pumps, the proper metals should be chosen carefully for both the case and the trim to ensure the best performance. The greatest economy may be achieved with a cheaper pump that is subject to some corrosion rather than with a much more expensive pump, even though it might not be susceptible to corrosion. The positive-displacement type of injection pump is the most common one in use. Some use has been made of multistage centrifugal pumps; however,

they have not yet been widely accepted because of some limitations in flexibility and efficiency.

The most generally accepted type of pump for medium- to high-pressure water injection is of either vertical or horizontal multicylinder design. These pumps are relatively simple to operate and to maintain, and they can be purchased with a variety of corrosion-resistant parts and accessories. The selection of the proper number of pumps and their capacity is contingent on the present and future requirements for the project. It is, of course, a good practice to provide a standby capacity that is sufficient to maintain continuous injection in case one pump has a mechanical failure. This can be accomplished by distributing the maximum design load over two or more units so that at least half the injection capacity can be maintained.

A considerable number of filtering techniques are now used in the oil field. These involve ceramic-, metallic-, paper-, and cloth-element pressure filters with sand, gravel, or coal media; and rapid sand pressure filters with sand, coal, or graphite media. The choice of filters is a function of the raw water quality and volume of water required for injection. If solids in the water must be reduced to submicrometer size, one of the element-type or diatomaceous-earth filters, or a combination of the two, is recommended. For less rigorous filtration, the gravity or rapid sand pressure filters are most widely used. In general, filtration rates are considered normal at about 2 gal/min-sq ft of filter area; however, this figure will vary considerably depending on the quality of the influent and the desired quality of the effluent. Decreased rates also may be desirable if very frequent backwashing is necessary. The rates and techniques for backwashing are prescribed by the manufacturers of the various types of filters; this function should be considered in plant design to ensure adequate clear-water storage for both backwashing and continuous injection. It may be desirable to install additional filter capacity so that filtration will not stop during backwashing. The addition of standby filtration facilities also offers a guarantee against a total shutdown in which a filter requires a complete change of the filter medium.

Refs. 116, 144, 145, 147, 148, and 149 discuss waterflood plant facilities. Also, Ref. 163 discusses waterflood plant facilities for a North Sea waterflood project.

For a more detailed discussion on plant design criteria, design calculations, etc., the reader is directed to Chap. 15, Surface Facilities for Waterflooding and Saltwater Disposal.

Nomenclature

- a = distance between wells in a row, ft
- A = cross-sectional area, sq ft
- B = FVF, RB/STB
- B_o = oil FVF, RB/STB
- B_{oi} = initial oil FVF, RB/STB
- B_{oR} = oil FVF at current reservoir conditions, RB/STB
- C_{ge} = correction for gas expansion
- d = distance between rows of wells, ft
- E_C = fractional coverage or conformance efficiency

- E_K = efficiency of permeability variation, fraction
 E_R = oil recovery efficiency, fraction
 f_{icw} = corner well producing water cut, fraction
 f_{isw} = side well producing water cut, fraction
 f_{o2} = fraction of oil flowing at the producing end of the system
 f_s = fraction of total flow coming from the swept portion of the pattern
 f_w = fractional flow of water
 F_C = Caudle and Witte conductance ratio
 F_F = ratio of viscous to gravity forces
 F_{og} = oil/gas saturation ratio
 F_P = corner-to-side-well producing-rate ratio
 F_{wo} = WOR
 g = acceleration caused by gravity, ft/sec²
 h = formation thickness, ft
 i_b = injection rate of fluid that has same mobility as the reservoir oil in a liquid-filled (base) pattern, as calculated from Eq. 20, RB/D
 i_w = water-injection rate, RB/D
 k_o = effective permeability to oil, md
 k_w = effective permeability to water, md
 k_x = permeability of x layer, or the layer that has just been flooded, md
 \bar{k} = mean permeability, md
 k_o = permeability value at 84.1% of cumulative sample, md
 L = distance, ft
 M = mobility ratio
 M_{wo} = water/oil mobility ratio multiplied by the FVF of the reservoir oil at the time of flooding
 n = number of layers
 n_{BT} = number of layers in which water has broken through (varies from 1 to n)
 N = initial oil in place, STB, or ratio of square root of production rates
 N_p = oil produced, STB
 N_{pu} = recovery to depletion (abandonment), fraction
 p_a = pressure at depletion (abandonment), psi
 p_{bp} = transient backpressure, psi
 p_e = effective reservoir pressure (external boundary pressure), psi
 p_i = initial pressure, psi
 Δp_{ic} = pressure differential between injection well and corner well, psi
 Δp_{is} = pressure differential between injection well and side well, psi
 P_c = capillary pressure, $p_o - p_w$, psi
 q_i = total flow rate ($q_w + q_o$), B/D
 r_e = pressure radius (external boundary radius), ft
 r_i = distance from well to the point of pressure equalization at p_{bp} , ft
 r_w = effective radius of a well, ft
 R_o = outer radius of oil bank, ft
 R_w = outer radius of waterflood front, ft
 S_F = position of center of unflooded area at moment of fill-up (correct drilling location), fraction of length of side or diagonal
 S_g = gas saturation at start of flood, fraction
 S_{gr} = residual gas saturation, fraction
 S_o = oil saturation at start of flood, fraction
 S_{or} = ROS, fraction
 S_w = water saturation, fraction
 S_{w2} = water saturation at the producing end of the system, fraction
 S_{wBT} = average water saturation at water breakthrough, % PV
 S_{wsc} = water saturation at upstream end of stabilized zone, % PV
 t = time, days
 V_d = displaceable PV's injected, fraction
 W_i = cumulative PV's of water injected, fraction
 θ = angle of formation dip referenced to horizontal
 μ_o = oil viscosity, cp
 μ_w = water viscosity, cp
 $\Delta\rho$ = density difference between water and oil, $\rho_w - \rho_o$, g/cm³
 ϕ = porosity

Key Equations in SI Metric Units

$$E_R = 0.2719 \log k + 0.25569 S_w - 0.1355 \log \mu_o - 1.5380 \phi - 0.0011444 h + 0.52478 \dots (14)$$

$$E_R = 93.5399 \left[\frac{\phi(1-S_w)}{B_{oi}} \right]^{0.0422} \left(\frac{k\mu_{wi}}{\mu_{oi}} \right)^{0.077} \times (S_w)^{-0.1903} \left(\frac{p_i}{p_a} \right)^{-0.2159} \dots (15)$$

$$\frac{3.4542 \times 10^{-4} k \Delta p t}{\mu_w \phi S_g r_w^2} = 1 + \left(\frac{1.0885 \times 10^{-3} k h \Delta p}{\mu_w i_w} - 1 \right) \times 10^{4.7297 \times 10^{-4} k h \Delta p / (\mu_w i_w)} \dots (19)$$

$$i_w = \frac{1.178966 \times 10^{-4} k_w h \Delta p}{\mu_w \left(\log \frac{d}{r_w} - 0.2688 \right)} \quad \dots \dots \dots (20)$$

$$i_w = \frac{1.572211 \times 10^{-4} k_w h \Delta p}{\mu_w \left(\log \frac{d}{r_w} - 0.2472 \right)} \quad \dots \dots \dots (23)$$

$$I = \frac{2.714382 \times 10^{-4} k_w h}{\mu_w \left(\ln \frac{d}{r_w} - 0.6190 \right)} \quad \dots \dots \dots (28)$$

where

B_{oi} is in m^3/m^3 ,
 d, h, r_e, r_w are in m,
 I is in m^3/d ,
 i_w is in m^3/d ,
 k, k_w are in μm^2 ,
 p_{iwf}, p_e are in kPa,
 S_g, S_w are in fraction,
 t is in days,
 μ_o, μ_w are in Pa·s, and
 ϕ is a fraction.

Chapter 45

Miscible Displacement

LeRoy W. Holm, Union Oil Co. of California*

Introduction

Through research efforts and pilot testing over the past 25 years, miscible-phase-displacement processes have been developed as a successful means of obtaining greater oil recovery in many reservoirs. To understand these processes, it is first necessary to provide a definition of miscibility, particularly as distinguished from solubility. "Solubility" is the ability of one substance (fluid) to mix with a fluid or fluids and form a single homogeneous phase. "Miscibility" is the ability of two or more fluid substances (gases or liquids) to form a single homogeneous phase when mixed in all proportions.

For petroleum reservoirs, miscibility is defined as that physical condition between two or more fluids that permits them to mix in all proportions without the existence of an interface. If two fluid phases form after some proportion of one fluid is added, the fluids are considered immiscible. Figs. 45.1, 45.2, and 45.3 illustrate the difference in immiscible and miscible relations between certain fluids.¹

Low-molecular-weight (MW) hydrocarbons such as ethane, propane, butane, or mixtures of liquefiable petroleum gas (LPG) are the injected fluids (solvents) that have been used for *first-contact miscible* flooding. These solvents in any amount will form a single phase with the oil in the reservoir, so are miscible upon first contact with the oil. Heavier hydrocarbons such as C_5 to C_{12} also are miscible with reservoir oils but have not been used as injectants because of their higher costs. However, since solvents like ethane and LPG are abundant in most reservoir oil, they can promote miscible displacement when nonoil-miscible fluids such as methane, natural gas, CO_2 , flue gas, or nitrogen are injected to vaporize or extract C_2 to C_{12} in situ from the

oil. This mechanism of in-situ transfer of light hydrocarbons from the reservoir oil to the injected fluid that forms a mixture miscible with reservoir oil is known as *dynamic miscibility* or *multiple-contact miscibility*.

There are, as a result of extensive research and development efforts by the petroleum industry and various universities (much of which was funded by the U.S. DOE during 1973–81), several forms of miscible displacement operations currently in use or under consideration. The processes include (1) miscible-slug drive for first-contact miscibility, (2) condensing-gas drive for dynamic miscibility, (3) vaporizing-gas drive for dynamic miscibility, and (4) extracting-liquid or critical-fluid drive for dynamic miscibility. A brief discussion of the theoretical aspects and limiting factors of each of these types of miscible displacement, in addition to an outline of engineering study basic requirements, are presented on the following pages. Engineering examples are presented in the Appendix in conjunction with a discussion of alternative procedures.

Theoretical Aspects of Miscible-Phase Displacement

Miscible-Slug Process

The simplest type of miscible drive is the "liquid slug" process.²⁻⁴ In this type of miscible drive, a slug of material such as propane or LPG (liquefied petroleum gases C_2 to C_4) is injected into the reservoir and followed by a dry gas.* The slug miscibly displaces oil from the contacted portion of the reservoir by virtue of a

*Originally, in 1962 edition, this chapter was a part of Chap. 40, Gas-Injection Pressure Maintenance and Miscible-Phase Displacement in Oil Reservoirs, written by James L. Moore and Richard F. Hinds.

*Other naphthohydrocarbon fluids, such as certain alcohols, can be miscible with reservoir oil.⁵ However, these alcohols tend to promote miscible displacement between oil and in-situ water so that complex phase and mobility relationships occur. Prohibitively large volumes of these alcohols are required to maintain a miscible displacement in the reservoir. As injected, soluble oils or oil external microemulsions also are miscible with the reservoir oil.^{6,7} Since complex phase relationships also occur between these fluids and both the oil and water in the reservoir, and because other chemicals are used in conjunction with them, discussion of this displacement process is found in Chap. 47—Chemical Flooding.

Fig. 45.1—Immiscibility of methane (gas) and oil (liquid) at reservoir conditions of temperature and pressure.

Fig. 45.2—Miscibility of methane (gas) and propane (or LPG) liquid at reservoir conditions of temperature and pressure. Here propane (or LPG) is a gas in presence of gas.

Fig. 45.3—Miscibility of propane (or LPG) liquid and oil liquid at reservoir conditions of temperature and pressure. Here propane (or LPG) is a liquid in the presence of a liquid.

solvent cleaning action. For the purposes of discussion, LPG will be used to denote the slug material. In practice, LPG solvents that are first-contact miscible with reservoir fluids are too expensive to inject continuously. Instead, the solvent is injected in a limited volume, or slug, that is small relative to the reservoir PV, and the slug, in turn, is miscibly displaced with a less expensive fluid such as methane, natural gas, or flue gas. Ideally with such a process scheme, solvent miscibly displaces reservoir oil while drive gas miscibly displaces the solvent, propelling the small solvent slug through the reservoir.

Pressure and Composition Requirements. The basic requirement for miscible displacement by the slug process is that the solvent slug be miscible with both the reservoir oil and the drive gas, which is mostly methane. Miscibility between the LPG slug and the displacing gas requires a certain minimum pressure,⁸ which can be estimated from published data on the cricondenbars of mixtures of pure components (Fig. 45.4). For example, this pressure may be as low as 1,100 psia at the reservoir temperature of 150°F.⁹ It is important to note that for temperatures between the critical temperature of LPG and methane, the critical pressure (miscible pressure) is usually much higher than the critical pressure of either fluid. Where additional data are required, these values should be determined in the laboratory.

Equilibrium phase diagrams, previously discussed in Chap. 20, are convenient representations of the ranges of temperature, pressure, and composition within which combinations of phases coexist.

Fig. 45.5 is a triangular phase diagram that illustrates the phase behavior requirement for first-contact miscibility.¹⁰ For the pressure and temperature at which this pseudoternary diagram was determined, all mixtures of LPG (C_2 to C_4) and oil (C_{5+}) lie entirely within the single-phase region. As indicated on the diagram, an LPG slug could be diluted with methane to Composition A and the resulting mixtures would remain first-contact miscible with Reservoir Oil B. Composition A is the intersection of the right side of the triangle (methane/LPG compositions) and the tangent to the phase boundary curve that passes through the oil composition.

As the concentration of methane in the injection fluid increases, the pressure (cricondenbar) increases and ultimately becomes impractically high for first-contact miscibility. When this happens, dynamic miscibility can be achieved by the condensing- or vaporizing-gas drive mechanisms.

Condensing-Gas Drive (or Enriched-Gas Drive)

A condensing-gas drive is that process of oil displacement by gas that makes use of an injected gas containing low-MW hydrocarbon (C_2 to C_6) components, which condense in the oil being displaced. To effect conditions of miscible displacement, sufficient quantities of low-MW components must be condensed into the oil to generate a critical mixture at the displacing front.

This process was brought to the attention of the industry in the late 1950's by laboratory investigations,^{11,12} which showed that the use of condensing gas drives would result in increased oil recovery from many reservoirs during either primary or secondary phases of

Fig. 45.4—Critical loci of binary n-paraffin systems.

production. Laboratory tests were conducted with a wide composition range of injection gases and reservoir fluids, at pressures greater than, equal to, or less than the saturation pressure (bubblepoint pressure) of the displaced fluid. One of the principal conclusions from these tests was that high oil recoveries could be obtained regardless of whether the oil was originally saturated or unsaturated with natural hydrocarbon gases at the displacement pressure.

The phase relations governing this process are illustrated by a triangular diagram in Fig. 45.6. Initially, a rich gas of Composition C is injected into Reservoir Oil A. As indicated by a line joining these two points, some mixture compositions fall in the two-phase region and thus these two components are not immediately miscible. However, after several consecutive steps of Gas C contacting the oil, the C_2 -to- C_6 components condensed out of the gas at each contact are absorbed by the oil until a critical Mixture B is obtained at the miscible front. It is noteworthy that, had Gas C initially fallen to the left of the immiscible-miscible (I-M) line, it would have been impossible to enrich the oil to B. There would not be sufficient amounts of the gas-enriching components in the injected gas to reach the Miscible Point B. The I-M line is referred to as the limiting tie line of the phase diagram.

Limiting Factors (Phase Behavior)

Control of Injection-Gas Composition. As indicated in the definition of miscible displacement by condensing-gas drive, the quantity of low MW components in the injection gas is critical.¹² Also, the actual dynamic or multiple-contact phase behavior may be more complicated than shown in the simple pseudoternary diagram

Fig. 45.5—Phase boundary curves for the system reservoir oil/LPG/tail gas; 180°F—volume percent basis.

of Fig. 45.6. Contiguous zones of miscible compositions of bubble- and dewpoint fluids can exist. The bubble-point curve represents the composition of a fluid where the last vapor disappears at a fixed pressure and temperature; the dewpoint curve represents the composition where the first liquid appears at these same conditions. Regions of liquid/liquid, liquid/liquid/vapor and liquid/vapor/solid (asphalt) equilibrium have been found in more recent studies. For this reason it is important that

Fig. 45.6—Illustration of miscible displacement (condensing-gas drive).

3. The reservoir fluid must be sufficiently undersaturated with respect to the injection pressure. This factor is very critical. The requirement that the oil composition lies to the right of the limiting tie line also implies that only oils that are undersaturated with respect to methane can be miscibly displaced by methane or natural gas. Thus, oil of Composition F on the bubblepoint curve of Fig. 45.7 could not develop vaporizing-gas drive miscibility with methane/natural gas. Inspection of Fig. 45.7 shows that as the concentration of low-MW hydrocarbons in the reservoir oil decreases, the oil Composition A moves toward the left side of the pseudoternary diagram and higher pressures are required to shrink the size of the two-phase region and to develop miscibility. Increasing pressure both decreases the size of the two-phase region and changes the slopes of tie lines by increasing the vaporization of low-MW hydrocarbons into the vapor phase.

4. The density of the reservoir fluid must be sufficiently low, as reflected in stock-tank gravities of approximately 40° API and greater.

Laboratory studies would provide quantification for these requirements.

Extracting-Liquid or Supercritical Fluid Drive

CO₂ Miscible Process. A fourth mechanism for achieving dynamic or multiple-contact miscibility involves the injection of a solvent gas (such as CO₂, ethane, N₂O, or H₂S), which is not first-contact miscible with reservoir oils but is highly soluble in them. Table 45.1 shows the critical temperatures and solubilities of some of these solvent gases for comparison with methane.

The critical temperatures of these gases are close to reservoir temperatures and the gases are very compressible at these conditions (Fig. 45.8).²³ CO₂, from the standpoint of availability, cost, and operational handling, is the most practical of these fluids. As a liquid, or as a dense, critical fluid solvent, CO₂ extracts from the oil hydrocarbons of higher MW than the predominantly C₂ to C₄ hydrocarbons that methane vaporizes.²⁴ In addition to the C₂ to C₄ hydrocarbons, these fluids include C₅ to C₁₂ hydrocarbons from the gasoline fraction of the crude and even C₁₃ to C₃₀ gas-oil fractions of the crude.

Fig. 45.8—Compressibility factors for CO₂.

TABLE 45.1—CRITICAL TEMPERATURES AND SOLUBILITIES OF SOLVENT GASES

	Critical Temperature		Solubility of Gas in a Crude Oil at 1,000 psi and 135°F (scf/bbl)
	(°F)	(°C)	
Carbon dioxide	88	31	634
Ethane	90	32	640
Hydrogen sulfide	213	100	522
Methane	-117	-82	209

In fact, the C₂ to C₄ hydrocarbons are not needed to achieve miscibility, so reservoir oils, which are depleted in methane and the low-MW hydrocarbons (dead oils), are still candidates for CO₂ miscible flooding.²⁵ This greatly increases the application potential for miscible displacement. After multiple contacts with the reservoir oil, the hydrocarbon-enriched-CO₂ phase miscibly displaces reservoir oil.^{26,27}

The phase behavior representation of this process is more complicated than the previous hydrocarbon injection processes. Fig. 45.9 indicates the enrichment in C₅ to C₃₀ hydrocarbons required to achieve the miscible displacement fronts.

Pressure-Composition Requirement. The reservoir pressures at which miscible displacement can occur are similar to those for the first-contact or enriched-gas processes (1,000 to 2,000 psi) because of the high solvency of the dense, supercritical CO₂ at these pressures and most reservoir temperatures (<200°F). Lower miscibility pressures are achieved at lower temperatures. Also, like the dependence of the vaporizing gas process on the C₂ to C₆ content of the in-situ oil, the CO₂ miscible process is dependent on the C₅ to C₃₀ content of the oil. At a given reservoir temperature, miscibility displacement with CO₂ is achieved at lower pressures where the C₅ to C₃₀ content is higher (Fig. 45.10).²⁸

Recent data indicate that the C₅ to C₁₂ content of the oil has the greatest effect on the miscibility pressure. The heavy portion (C₃₁+) of the oil also affects this

Fig. 45.9—Postulated phase diagram for fluids at displacement front after CO₂ has extracted hydrocarbons in-situ from reservoir oil, contacted at miscible pressure p_M .

Fig. 45.10—CO₂ density required for miscible displacement vs. C₅ to C₃₀ content of various crude oils. MMP's at 165°F for same crude oils.

miscibility pressure. Increased heavy oil components, usually accompanied by lesser amounts of C₅ to C₁₂ components, require higher pressure to compress the CO₂ to a more dense fluid and promote adequate enrichment at the displacement front. This means a greater mass of CO₂ would be required for miscible recovery of heavy oil with accompanying increased costs.

Process Considerations. To effect a true miscible displacement process, CO₂ should be injected continuously, or a CO₂ slug should be driven by a gas that is miscible with the CO₂. Methane, flue gas, or nitrogen can be used for this purpose. However, because of the improved mobility achieved, water is often used as the drive fluid. Although CO₂ is soluble in the water, it is not miscible with it, so that the water-driven CO₂ slug dissipates by leaving a residual phase. This residual is one of the factors controlling the CO₂ slug size required.

CO₂ often is available in mixtures with other gases. The effect of these impurities is either to raise or lower

the pressure required to achieve miscible displacement in a reservoir.^{14,29,30} Gases such as nitrogen and methane raise the minimum miscibility pressure (MMP); ethane, propane, or hydrogen sulfide tend to lower the pressure requirement.

Factors Affecting Displacement Efficiency

Under the conditions of miscible displacement, nearly all the oil in place within the pore channels contacted will be displaced by virtue of the elimination of interfacial forces between the gas and oil³¹ and by the absence of relative-permeability effects. As the enriched gas and oil approach their critical mixture, there is a marked reduction in their IFT. Even though miscibility (defined by zero IFT and no interface) has not been reached at this point, improved oil recovery over immiscible displacement has been observed in laboratory flooding using such two-phase fluids. Such displacement has been described as near-miscible (incorrectly as partial-miscible) displacement. The actual recovery from the reservoir by miscible and near-miscible floods will be considerably less than that obtained in laboratory floods because of factors affecting pattern and conformance efficiency and dispersion of the miscible slug in the reservoir. The following discussion of factors which affect displacement efficiency applies to all forms of miscible and near-miscible processes.

Dispersion

Mixing zones form between the reservoir oil and LPG slug (or multiple-contact miscible slug) and between the injected drive gas and the slug. Three mechanisms that contribute to this mixing are molecular diffusion, microscopic convective dispersion, and macroscopic convective dispersion.^{32,33,35} Microscopic dispersion is pore-size mixing in excess of that from the random motion of molecules and is caused by convection in the tortuous flow through porous media. Further mixing of fluids by macroscopic convective dispersion can be caused by permeability heterogeneities over a larger area of the porous rock³⁴ (Fig. 45.11).

In a relatively homogeneous reservoir, the length of these mixing zones determines the minimum slug size. The slug should not be diluted to such an extent that miscibility is lost before most of the reservoir area is contacted. On the other hand, viscosity and density differences between solvent and oil, which also affect the slug, may be moderated by diffusion and dispersion, with a decrease in fingering, gravity override, and resultant slug-stabilization tendencies.

Laboratory studies have indicated that in linear-flow systems the mixing zone grows rapidly at first, decreases in rate of growth as displacement continues, and eventually stabilizes in length. A survey of the literature shows that a difference of opinion exists about the stabilizing effect that diffusion and dispersion have on the mixing zone in the reservoir. It is generally agreed, however, that the length of the mixing zone varies proportionately with the viscosity of the driven fluid.^{4,36-39} As the viscosities of the injected gases and liquid, and even the vaporized or extracted hydrocarbon enriched slugs, are low (less than 1 cp), field applications generally have been restricted to reservoirs with oil viscosity of less than 5 cp.

Fig. 45.11—Mixing of solvent and oil by longitudinal and transverse dispersion.

Two correlations, based on laboratory data, have been presented in the literature as a means to estimate the minimum slug size required for miscible drive in a homogeneous reservoir. One correlation⁴ states that the mixing-zone length is related to the ratio of the viscosity difference to the viscosity ratio. The other correlation³ says that the slug size required for a given path length varies inversely as the square root of the path length. Laboratory tests^{3,4} have indicated that, under ideal conditions, a bank of solvent with a volume as low as a few percent of the hydrocarbon pore space is all that might be required to maintain miscibility. However, experience has shown that slug volumes required for practical field operation range from 10 to 30% HCPV in a pattern area to counter the effects of dispersion, gravity segregation, reservoir-rock heterogeneities, well-pattern arrangements, etc.^{8,21}

Mobility Ratio

Despite the fact that displacement of nearly 100% of the oil in the contacted area occurs, the overall efficiency of miscible displacement may be lowered by the effect of an unfavorable mobility ratio (defined here as the ratio of the displacing to the displaced mobilities). The sweep pattern in a miscible-slug operation is controlled by the ratio of the displacing gas to the displaced oil mobilities,⁴⁰ which in the swept area will reduce itself to the viscosity ratio of oil to gas⁴¹ (Fig. 45.12).

This ratio, of course, is unfavorable when compared with conventional waterflood operations. Laboratory tests have indicated that viscous fingering occurs at unfavorable mobility ratios (Fig. 45.13). This phenomenon has been described as dendritic fingers of solvent (or drive gas) forming and growing in length until they break through the penetrated LPG slug or oil bank. These viscous fingers result in earlier solvent breakthrough and poorer oil recovery after breakthrough for a given volume of solvent injected than would be the case if the displacing front remained stable. The breakthrough oil recovery of miscible floods will be governed principally by the mobility ratio of the injected fluids and reservoir oil, and by the reservoir geometry.

Conformance Efficiency

Assuming that miscible displacement can be achieved by one of the foregoing processes, the greatest single factor that controls maximum recovery of oil from a reservoir is conformance efficiency. For the purpose of this chapter, conformance efficiency is defined as the fraction of the total PV within the pattern area that is contacted by the displacing fluid. The dominating factors that control conformance are the gross sand heterogeneity and size distribution of the rock interstices, which usually are defined in terms of permeability variation or stratification.⁴² These factors become particularly critical when effecting the displacement of the higher-viscosity oils. The associated unfavorable mobility ratio, in conjunction with a wide variance in permeability, results in a low conformance. In addition, gravity segregation can take place in formations possessing vertical permeability.⁴³ This adverse effect occurs when the light injection gases or liquids rise to the top of the formation or

Fig. 45.12—Displacement behavior for developed five-spot, data from 0.0047-in. model.

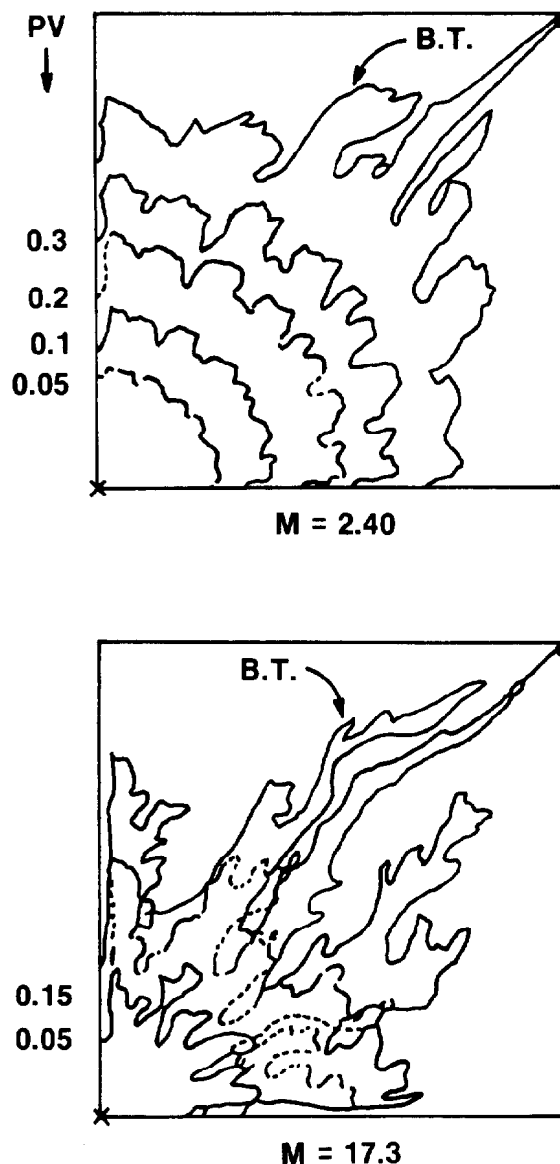

Fig. 45.13—Displacement fronts for different mobility ratios and injected PV until breakthrough, quarter of a five-spot.

Fig. 45.14—Combination water-drive/miscible-drive project in low-conformance reservoir provides high oil recovery by water in the nonconformance sections and by miscible displacement from the conformance sections.

permeable zone and override or bypass the denser reservoir oil. The combination of these factors in a miscible displacement operation can yield an overall recovery efficiency that is much lower than that of waterflood. This problem has been a principal deterrent to the use of miscible processes.

Improving Pattern and Volumetric Sweep Efficiencies With Water During Miscible Displacement

In 1957, a method for improving pattern and volumetric sweep (conformance) in miscible displacement operations was proposed.⁴⁰ The method consists of injecting LPG, followed by a bank of natural gas to displace the LPG miscibly, and then natural gas and water simultaneously. The injection of the water reduces the relative permeability to gas in the region swept by the LPG slug and increases the viscosity of part of the displacing phase. These two factors combine to lower total mobility of this system, resulting in improved sweep (Fig. 45.14). Further research and field pilot tests have extended this technique to both the slug and/or drive gas in all types of miscible displacement.⁴⁴ Water usually is injected alternately with the drive gas and/or the miscible slug (termed WAG). The injection of water with an LPG or CO₂ slug can trap a portion of the oil mobilized by the miscible gas, particularly in reservoirs having strong water-wetting characteristics. A low water-to-gas ratio (0.5:1) is recommended if WAG is required. Also, this type operation is limited to reservoirs in which sufficient injection capacity is available. A tight reservoir would require too many injection wells to inject the necessary volumes of gas and water to meet desirable oil production rates.

Two other potential problems with this technique are (1) segregation of the injected fluids into different strata and (2) trapping of oil by mobile water.⁴⁵ Fluid injection into selected strata and proportioning of the injected fluids within strata may be helpful in such cases. In laboratory studies it is important to use the actual reservoir fluids and rock to determine the effects of rock wettability on oil mobilization and trapping in the presence of water. Refined oils or single hydrocarbons such as decane do not wet rock to the degree that crude oil does

and, consequently, tend to be trapped to a greater extent by water.

Improving Recovery Efficiency by Gravity Stabilization

In reservoirs with dip, gravity segregation of fluids can be used advantageously to prevent viscous fingering or gravity override. This is achieved by injecting the solvent and/or gas updip and producing downdip at a rate low enough for gravity to keep the fluids segregated. Fingers of solvent or gas are suppressed and sweepout is improved. Field applications of this method have been successful.

Improving Recovery Efficiency with Foams or Emulsions

The mobility of solvents and gas in porous media can be decreased by foaming or emulsifying them with water containing surfactants.⁴⁶ Laboratory studies have shown that these foams form selectively in the highly permeable porous channels and thereby tend to reduce fluid channeling.^{47,48} Further field testing of this technique is in progress.

Engineering Study

Basic Requirements

A detailed engineering investigation is necessary to select and to design the miscible displacement operation properly and to ensure that it will be successful. The following information is generally necessary or desirable as a basis for selecting the operation that will be most economically feasible.

Detailed Geology. Core analyses from enough wells are needed to provide adequate areal and vertical distribution of rock properties, fluid saturations, capillary pressure, and waterflood susceptibility data.

Information regarding the reservoir structure, size, shape, and dip with particular emphasis on the definition of stratification or zoning conditions is needed also. If the latter is known to exist, an isometric fence diagram of the reservoir (Fig. 45.15) should be constructed that shows all the details of porosity development, shale conditions, etc., which can be obtained from well logs, core analysis, pressure transient tests, and individual well performance. This diagram aids in relating well performances and spacing with reservoir geometry.

Phase Behavior of Reservoir Fluids. Laboratory analysis of reservoir oil and gas should be conducted to determine such information as differential and flash vaporization data, liquid and gas viscosities, and hydrocarbon compositions over a wide range of pressures. In many instances, it is necessary to know the PVT relationships of the mixtures comprising the reservoir fluids as well as the possible materials that might be injected.

Laboratory displacement tests should be conducted in sandpacked columns (Berea or native cores) to determine: (1) the pressure required for miscible displacement [although correlations such as Fig. 45.10 and those in other references are available, laboratory tests (Fig. 45.16) are the most accurate method to find the MMP]⁴⁹; (2) the displacement efficiencies expected in

Fig. 45.15—Three-dimensional (fence) diagram illustrating general reservoir complexity.

the conforming areas for the LPG, condensing gas, high-pressure gas, etc; and (3) injection techniques at the desired operating pressure, temperatures, and for varying concentrations (or compositions) of injected materials.

Compatibility of injected materials with reservoir fluids should be determined. CO_2 , LPG products, or other light hydrocarbons will precipitate heavy paraffinic or asphaltic material in certain types of crude oil and may cause a reduction in permeability and a viscosity change in the oil.

Past Reservoir Behavior and Estimation of Primary and/or Conventional Secondary Recovery. The natural reservoir recovery mechanism should be evaluated to permit a reliable estimate of future primary recovery. Evaluation of any secondary recovery application in the reservoir is needed also.

Existing reservoir conditions should be determined. Past performance in connection with reservoir fluid and core analysis will provide an estimation of the state of the reservoir at the initiation of the miscible displacement project. This will include such essential items as reservoir pressure, fluid saturation distribution, and modeling or simulation of secondary-flooding history.

General Applicability of Miscible-Displacement Techniques. Knowledge of the previously mentioned factors, such as reservoir geometry and pressure conditions, can lead to the selection of the miscible process best suited to the reservoir.

Availability of injection materials and proximity of CO_2 , N_2 , or gasoline-plant facilities may dictate, in the final analysis, the selection of a specific miscible process.

Recovery by Miscible Displacement. Pattern efficiency is defined here as that areal coverage of the reservoir through which the displacing fluid moves from its source to the producing wells. This factor may be estimated from laboratory model studies or from the literature.^{50,51}

Fig. 45.16—Laboratory test results for fixed oil composition and fixed temperature in slim tubes.

It must be noted, however, that in the assumption of a pattern efficiency, the effect of unconformities and stratification must be considered.

Volumetric sweep efficiency, defined previously, is calculated from the knowledge of the stratification, vertical and areal variation of the rock properties, and mobility ratios of the displacing fluids to that of the displaced oil. There are several methods being used by engineers.⁵² One of these methods is illustrated in the example calculation (see Appendix) with reference to alternative procedures.

Displacement efficiency should be determined from laboratory studies. This factor represents the percent recovery from the conforming volume of the reservoir and may range from 80 to 100%. As mentioned previously, it is important to study the actual reservoir rock and fluids when possible to determine the rock wetting characteristics and their effect on displacement efficiency.

Total		419.7		

All the oil that is displaced in a miscible flood may not be produced. The ability of producing wells to capture the mobilized oil must be considered.

Total recovery factor, or percent recovery of oil from the entire reservoir, represents the product of the pattern, conformance, displacement, and capture efficiencies.

Injectivity and Productivity of Wells. These affect project life and have a significant effect on economics. Injectivity tests in the field or extensive relative permeability measurements may be necessary.

Mathematical Simulation. This may be used in projecting reservoir performance. Finite-difference,⁵³ modified black-oil,⁵⁴ finite-element and compositional simulators^{55,56} have been developed for predicting or history matching flood performance. Streamtube models^{57,58} and scaled physical models⁵⁹ also have been developed and may be informative.

Program Design. Design of production and injection facilities should be coordinated and used with current operations to the fullest advantage.

Economic Evaluation and Comparison. The miscible drive operation and other competitive methods^{60,61} should be evaluated and compared on an economic basis. This analysis generally governs the final decision.

Pilot Operation and Evaluation of Results. In many cases where waterflood operations appear very competitive with miscible drive, a pilot injection program is recommended if a suitable area in the field can be located. The selection of the ultimate program of operation may be delayed pending the results of the pilot, thus reducing the risks inherent in such operations.

Field Experience

Since the first miscible flooding projects of the early 1950's, there have been many applications throughout the world of all the miscible processes. Some of the best documented of each of these processes and their variations are listed under General References for Applications of Miscible Processes. More complete information on these is found in the publications listed under General References for Field Tests of Miscible Processes.

APPENDIX

Engineering Examples

As indicated in the previous sections, oil recovery and related performance in miscible drive operations will depend mainly on the degree of stratification and permeability distribution existing in the reservoir. Consequently, engineering calculations generally will be reduced to a function of estimating conformance efficiency.

In the following examples we have assumed a reservoir under an inverted nine-spot well pattern (see Fig. 45.17), with an average permeability profile and capacity distribution as indicated in Table 45.2. The procedure followed is a modification of a standard water-cut recovery calculation,⁶² which is based on the vertical distribution of productive capacity. The calculations for

these examples are carried out assuming (1) linear fluid flow with no crossflow, (2) distance of penetration of the miscible front being proportional to permeability, (3) constant pressure drop between the injection and producing wells, (4) S_{or} (residual oil saturation) behind front equals zero, (5) S_{gF} (free-gas saturation) equals zero, (6) k_{rg}/k_{ro} (relative-permeability ratio) equals one, thereby defining the mobility ratio as the viscosity ratio of reservoir oil to the displacing gas, and (7) abandonment at a GOR of 100,000/1.

High-Pressure Gas Injection and Condensing-Gas Drive

For comparison these two processes are calculated together using the basic reservoir data presented in Table 45.3. High-pressure gas injection is assumed to take place at the initial reservoir pressure, whereas the injection pressure for the condensing-gas-drive process is assumed to be at saturation pressure. The calculation of the recovery and producing GOR data are presented in Table 45.4. From this table the fraction of cumulative

Fig. 45.18—Permeability and capacity distribution vs. sand-thickness fraction.

thickness, h , is plotted as a function of dimensionless permeability, k_D , and fraction of total capacity, C . These data are illustrated in Fig. 45.18. The recovery and GOR data are shown in Fig. 45.19. Note that, at an assumed abandonment ratio of 100,000 scf/bbl. recovery by condensing-gas drive was indicated to be 74.2% of the oil existing in the pattern area. The corresponding recovery for high-pressure gas injection was found to be only 66.5%. The difference in recovery between these two methods is essentially a result of the difference in the compressibility factors of the displacing gas at the two pressures.

Time-Rate Performance. Time-rate performance was not calculated for all the examples presented since it would be a function of the well productivity. However, it must be pointed out that the excess pressure available in the high-pressure gas-injection process would yield higher well productivity and a shorter life, which could lead to more favorable economics.

Recovery of LPG Products. Recovery of LPG products contained initially in the injected gas under the condensing-gas-drive process was not illustrated. This item, however, would be a function of the following factors: (1) percent recovery from the reservoir (estimated

from GOR and oil-recovery data), (2) gasoline-plant recovery efficiency, and (3) plant ownership of recoverable liquids.

These factors, in addition to the high cost of LPG, become critical in an economic comparison of recovery processes.

Volume of Gas Injected. The volume of gas injected is estimated on a reservoir volume in/reservoir volume produced basis. The volume of rich gas injected in condensing-gas-drive operations will depend on an evaluation of performance as related to the zones of stratification. To achieve the maximum effect from miscible displacement it is necessary to inject sufficient rich gas to establish a miscible front in the least permeable zone.

Miscible-Slug Injection

To illustrate the miscible-slug process the reservoir in the previous examples was assumed to have been depleted to 1,500 psig. Table 45.5 presents a list of the pertinent reservoir data that existed for this condition.

The recovery and GOR performance was calculated using the capacity distribution data (Cols. 1 through 11) in Table 45.4 and the A factor, as calculated from the fluid data. These results are summarized in Table 45.6 and illustrated in Fig. 45.20. It is noted that the recovery at a GOR of 100,000/1 was found to be 58.2% of the oil existing in the pattern area. This is a somewhat lower value than those indicated for high-pressure gas injection and condensing-gas drive. The difference is attributed to the more unfavorable mobility ratio at the lower pressure.

In this example, the GOR has decreased to approximately solution ratio as breakthrough was approached. It was assumed that all the free-gas saturation was produced during this interval.

The size of the LPG slug injected was assumed to be 5% of the HCPV in the pattern area. This volume is within the range (2 to 10%) dictated by economics but does not include a substantial safety factor. The volume of LPG slug produced was not calculated for this exam-

ple, but it can be estimated by multiplying the conformance efficiency at abandonment by the volume of slug injected. The net recoverable LPG, similar to that of condensing-gas-drive operations, would be reduced by the gasoline-plant recovery efficiency and plant-ownership percentage.

The volume of dry gas injected is estimated on a reservoir volume in/reservoir volume out basis.

Alternative Calculation Procedures

Alternative procedures for predicting performance of miscible drive operations are found in the literature. Several investigators have presented solutions to the permeability-stratification problem in the analysis of waterflooding which may be modified to fit miscible-drive processes.⁶³⁻⁶⁸ Other authors have presented their treatments with respect to gas cycling, which in itself is an example of miscible displacement.⁶⁹⁻⁷² For direct application to miscible drive operations, theoretical analyses and equations for linear displacement have been presented that offer a direct means for describing performance.^{68,73}

An excellent example that compares the results of calculated and actual performance of a pilot LPG flood has been published.²¹ In this example the reservoir was divided into several zones of varying permeability with radial-flow forms of Darcy's law used to calculate performance.

Mathematical simulators commonly are used today for designing and predicting reservoir performance of miscible floods. Two examples are (1) a vaporizing gas drive in a moderately stratified reservoir by use of a compositional simulator^{74,75} and (2) a condensing gas drive in a downward displacement in a reef by use of a black-oil simulator.⁷⁶

Nomenclature

C = capacity, fraction of total capacity

C_{cum} = cumulative capacity, fraction of total capacity

CF = equivalent gas production

Fig. 45.20—Oil recovery vs. producing GOR for LPG slug injection.

$$F = k_{rg}/k_{ro} \times \mu_o/\mu_g \times B_o/B_g$$

h = cumulative thickness, fraction of total thickness

\bar{h} = average cumulative thickness, fraction of total thickness

k = permeability, millidarcies

$k_D = \Delta C/\Delta h$ = dimensionless permeability

$N_p = [k_D h + (1 - C)]/k_D$ = fraction of total oil recovery

p_M = miscible pressure, psia

$R_p = CA/(1 - C) + R_s$ = producing gas-oil ratio, Mcf/STB

R_s = solution GOR

$1 - C$ = equivalent oil production

Chapter 46

Thermal Recovery

Chieh Chu, Getty Oil Co.*

Introduction

Thermal recovery generally refers to processes for recovering oil from underground formations by use of heat. The heat may be supplied externally by injecting a hot fluid such as steam or hot water into the formations, or it may be generated internally by combustion. In combustion, the fuel is supplied by the oil in place and the oxidant is injected into the formations in the form of air or other oxygen-containing fluids. The most commonly used thermal recovery processes are steam injection processes and in-situ combustion.

Two Forms of Steam Injection Processes

In principle, any hot fluid can be injected into the formations to supply the heat. The fluids used most extensively are steam or hot water because of the general availability and abundance of water. Hot water injection has been found to be less efficient than steam injection and will not be discussed here. A schematic view of the steam injection process is shown in Fig. 46.1, together with an approximate temperature distribution inside the formation.¹

There are two variations of steam injection processes—steam stimulation and steam displacement.

Steam Stimulation

This method has been known as the huff 'n' puff method, since steam is injected intermittently and the reservoir is allowed to produce after each injection. In this process the main driving force for oil displacement is provided by reservoir pressure, gravitational force, rock and fluid expansion, and, possibly, formation compaction. In the steam stimulation process only the part of the reservoir adjacent to the wellbore is affected. After a number of cycles of injection and production, the near-wellbore region in reservoirs having little or no dip becomes so depleted of oil that further injection of steam is futile. In this case, wells must be drilled at very close spacing to obtain a high oil recovery.

Steam Displacement

This process, usually referred to as steamflood or steam-drive, has a much higher oil recovery than steam stimulation alone. Whereas steam stimulation is a one-well operation, steamflood requires at least two wells, one serving as the injector and the other serving as the producer. The majority of steamflood projects use pattern floods. In many cases, steam stimulation is required at the producers when the oil is too viscous to flow before the heat from the injector arrives. Because of the high oil recovery achievable through steamflooding, many reservoirs that were produced by steam stimulation previously now are being steamflooded.

Three Forms of In-Situ Combustion

In-situ combustion usually is referred to as fireflood. There are three forms of in-situ combustion processes—dry forward combustion, reverse combustion, and wet combustion.

Dry Forward Combustion

In the earlier days, this was the most commonly used form of the combustion processes. It is dry because no water is injected along with air. It is forward because combustion starts at the injector and the combustion front moves in the direction of the air flow.

Fig. 46.2 gives a schematic view of the dry forward combustion process.² The upper part of the figure shows a typical temperature distribution along a cross section leading from the injector at the left to the producer at the right. Two things need to be pointed out. First, the region near the producer is cold, at the original temperature of the reservoir. If the unheated oil is highly viscous, it cannot be pushed forward by the heated oil at its back that has been made mobile by the high temperature of the combustion zone. This phenomenon is called "liquid blocking." Second, the temperature of the region in the back of the combustion zone is high, indicating a great amount of heat being stored in the region, not used efficiently.

*Now with Texaco Inc.

Fig. 46.1—Steam injection processes.

Fig. 46.2—Dry forward combustion.

Fig. 46.3—Reverse combustion.

The lower part of Fig. 46.2 shows the fluid saturation distributions inside the formation under the combustion process. One should note the clean sand in the burned-out region. Being able to burn the undesirable fraction of the oil (the heavier portion) is one advantage of the forward combustion process over the reverse combustion process.

Reverse Combustion

Strictly speaking, it should be called dry reverse combustion, because normally only air is injected, no water. A simple example will help to explain how reverse combustion works. In ordinary cigarette smoking, one ignites the tip of the cigarette and inhales. The burning front will travel from the tip of the cigarette toward one's mouth, along with the air. This is forward combustion. The cigarette also can be burned if one exhales. This way, the burning front still moves from the tip of the cigarette toward one's mouth, but the air flow is in the opposite direction. This is, then, reverse combustion.

Fig. 46.3 shows the various zones inside the formation, with the cold zone near the injector at the left and the hot zone near the producer.³ Since the region around the producer is hot, the problem of liquid blocking mentioned earlier in connection with the dry forward process has been eliminated.

In principle, there is no upper limit for oil viscosity for the application of the reverse combustion process. However, this process is not as efficient as the dry forward combustion because a desirable fraction of the oil (the lighter portion) is burned and an undesirable fraction of the oil (the heavier portion) remains in the region behind the combustion front. Besides, spontaneous ignition could occur at the injector.⁴ If this happens, the oxygen will be used up near the injector and will not support combustion near the producer. The process then reverts to forward combustion.

No reverse combustion project has ever reached commercial status. Nevertheless, this process should not be written off because, in spite of the difficulties facing this process, it could offer some hope of recovering extremely viscous oil or tar.

Wet Combustion

The term "wet combustion" actually refers to wet forward combustion. This process was developed to use the heat contained behind the combustion zone. In this process, water is injected either alternately or simultaneously with air. Because of its high heat capacity and latent heat of vaporization, water is capable of moving the heat behind the combustion front forward, and helping to displace the oil in front of the combustion zone.

Fig. 46.4 shows the temperature distributions of the wet combustion process as the water/air ratio (WAR) increases.⁵ The curve for WAR=0 refers to dry combustion. With an increase in WAR, the high-temperature zone behind the combustion zone shortens (WAR=moderate). With a further increase in WAR, the combustion will be partially quenched as shown by the curve for WAR=large.

The wet combustion process also is known as the COFCAW process, which is an acronym for "combination of forward combustion and waterflood." This process also can be construed as steamflood with in-situ steam

generation. It should be noted that this method cannot prevent liquid blocking and its application is limited by oil viscosity, as is the dry forward combustion.

Historical Development

The following lists chronologically some of the major events that occurred in the development of the thermal recovery methods.

- 1931 A steamflood was conducted in Woodson, TX.⁶
- 1949 A dry forward combustion project was started in Delaware-Childers field, OK.⁷
- 1952 A dry forward combustion project was conducted in southern Oklahoma.⁸
- 1955 A reverse combustion project was initiated in Belamy, MO.⁹
- 1958 The steam stimulation process was accidentally discovered in Mene Grande Tar Sands, Venezuela.¹⁰
- 1960 Steam stimulation was started in Yorba Linda, CA.¹¹
- 1962 Wet combustion phase of a fireflood project was started in Schoonebeek, The Netherlands.¹²

Current Status

U.S. Oil Production by Enhanced Recovery Methods

The significance of the thermal recovery processes can be seen from the April 1982 survey of the *Oil and Gas J.*¹³ As shown in Table 46.1, of the daily U.S. oil production with EOR processes, 76.9% comes from steam injection and 2.7% comes from in-situ combustion, totaling 79.6% obtained by thermal recovery processes. The combustion process, although dwarfed by the steam injection processes, accounts for more than double the production of all the chemical floods combined, which amounts to 1.2%.

Geographical Distribution of Thermal Recovery Projects

Table 46.2, based largely on the 1982 survey,¹³ shows the geographical distribution of the steam injection projects in the world. Of the daily oil production from steam injection processes, 71.7% comes from the U.S., 15.4%

Fig. 46.4—Wet combustion.

from Indonesia, 7.0% from Venezuela, and 3.0% from Canada. In the U.S., California accounts for nearly all the production, with small percentages coming from Louisiana, Arkansas, Texas, Oklahoma, and Wyoming.

The daily oil production by in-situ combustion is shown in Table 46.3. Here, the U.S. accounts for 40.0% of the total production, followed by Romania (26.0%), Canada (22.1%), and Venezuela (10.8%). Of the U.S. production, nearly one-half comes from California, one-third from Louisiana, with the rest from Mississippi, Texas, and Illinois.

Major Thermal Recovery Projects

The major thermal recovery projects, again based largely on the 1982 survey,¹³ are listed in Table 46.4.

Reservoirs Amenable to Thermal Recovery

Table 46.5 shows the ranges of reservoir properties in which the technical feasibility of steamflood and fireflood has been proven.¹⁴

Potential for Incremental Recovery

According to Johnson *et al.*,¹⁵ vast energy resources exist in the tar sands in Venezuela and Colombia (1,000 to 1,800 billion bbl), Canada (900 billion bbl), and the U.S. (30 billion bbl). These tar sands should be a major target

OOIP at start, bbl/acre-ft	370 to 2,230	430 to 2,550

for development of thermal recovery methods, since the results will be most rewarding if a percentage of these resources can be tapped economically.

Based on an assumed oil price of \$22.00/bbl, Lewin and Assocs. Inc.¹⁶ estimated that the ultimate recovery in the U.S. by thermal recovery methods will amount to 5.6 to 7.9 billion bbl. This includes 4.0 to 6.0 billion bbl by steamfloods and 1.6 to 1.9 billion bbl by firefloods.

Production Mechanisms

The production mechanisms in steam injection processes have been identified by Willman *et al.*¹⁷ as (1) hot water-flood, including viscosity reduction and swelling, (2) gas drive, (3) steam distillation, and (4) solvent extraction effect. The relative importance of these mechanisms on light and heavy oil, represented by 37.0 and 12.2 °API, respectively, is given in Table 46.6.

In firefloods, the above mechanisms are also important. In addition, the breaking up of heavy oil fractions into light oil fractions through cracking should have at least two effects: increase in volume and more drastic reduction in viscosity. The gas drive effect also should be increased because of the large amount of air injected and combustion gas produced.

Theoretical Considerations

Surface Line and Wellbore Heat Losses

In current field practice, downhole steam generators are still in the developmental stage. Surface steam generators are being used in almost all of the steam injection projects. Steam from a generator normally is sent to the injector wellhead through a surface line. Some heat will be lost to the surrounding atmosphere by convection and radiation. As steam travels from the wellhead through the wellbore to the sandface at the pay zone, heat will be lost to the overburden, mainly by conduction. The method of calculating surface line and wellbore heat losses is discussed below.

Surface Line Heat Losses

The steam lines in most of the steam injection projects are insulated. The heat loss from such a line, Btu/hr, is:

$$Q_{rl} = 2\pi r_{in} U_{ti} (T_s - T_{at}) \Delta L, \dots \dots \dots (1)$$

where

r_{in} = outside radius of the insulation surface, ft,

T_s = steam temperature, °F,

T_{at} = atmospheric temperature, °F, and

ΔL = pipe length, ft.

In the above, U_{ti} is the overall heat transfer coefficient (based on inside radius of the pipe or tubing), Btu/hr-ft-°F, and can be calculated as follows.

$$U_{ti} = \left[\frac{r_{in} \ln \left(\frac{r_{in}}{r_{to}} \right)}{k_{hin}} + \frac{1}{h+I} \right]^{-1}, \dots \dots \dots (2)$$

where r_{to} is the outside radius of pipe, ft, and k_{hin} is the thermal conductivity of insulation material, Btu/hr-sq ft-°F.

The convection heat transfer coefficient, h , Btu/hr-sq ft-°F, can be calculated thus¹⁸:

$$h = 0.75 v_w^{0.6} / r_{in}^{0.4}, \dots\dots\dots (3)$$

where v_w is the wind velocity, mi/hr. The radiation heat transfer coefficient, I , normally can be neglected.

If the pipe is bare, that is, uninsulated, then $r_{io} = r_{in}$ and

$$U_{ii} = h. \dots\dots\dots (4)$$

If the steam is superheated, T_s will vary along the line as heat is being lost to the atmosphere. When the pipe is long, it needs to be broken up into segments and the heat loss calculated segment by segment. In each segment,

$$T_{s2} = T_{s1} - Q_{rl} / w_s C_s, \dots\dots\dots (5)$$

where

T_{s1}, T_{s2} = steam temperatures at the beginning and the end of the segment, °F,

Q_{rl} = heat loss along the segment, Btu/hr,

w_s = mass rate of steam, lbm/hr, and

C_s = heat capacity of steam, Btu/lbm-°F.

If the steam is saturated, the heat loss will cause reduction in steam quality.

$$f_{s2} = f_{s1} - Q_{rl} / w_s L_s, \dots\dots\dots (6)$$

where f_{s1} and f_{s2} equal the steam quality at the beginning and the end of the pipe segment, fraction, and L_s is the latent heat of steam, Btu/lbm.

Wellbore Heat Losses

In most of the steam injection projects, saturated steam at a certain quality is injected into the formation. Here, we assume a more general case in which the steam first enters the wellbore as superheated steam, becomes saturated with a gradually diminishing quality, and is further cooled after its complete condensation into hot water.

Superheated Steam. Assume that when the depth D is 0, the temperature of the steam is T_s and varies with time. Also assume that a linear geothermal gradient exists so that

$$T_f = g_G D + T_{su}, \dots\dots\dots (7)$$

where T_f is the temperature of the formation. Suppose one starts with the temperature of the steam at a depth D_1 , and desires to calculate the temperature at depth D_2 with the length of the depth interval $\Delta D = D_2 - D_1$. Since the formation temperature at D is $g_G D_1 + T_{su}$, Ramey's equation for the gas case¹⁹ becomes

$$\begin{aligned} T(D_2, t) = & g_G D_2 + T_{su} - g_G A - AB \\ & + [T(D_1, t) - g_G D_1 - T_{su} + g_G A + AB] e^{-\Delta D/A}. \end{aligned} \dots\dots\dots (8)$$

A is defined as

$$A = \frac{w_s C_s [k_{hf} + r_{ii} U_{ii} f(t)]}{2\pi r_{ii} U_{ii} k_{hf}} \dots\dots\dots (9)$$

and

$$B = \frac{1}{778 C_s}, \dots\dots\dots (10)$$

where

k_{hf} = thermal conductivity of the formation, Btu/D-ft-°F,

r_{ii} = inside radius of the tubing, ft,

U_{ii} = overall heat transfer coefficient for the annular space between inside of the tubing and outside of the casing based on r_{ii} , Btu/D-ft-°F,

$f(t)$ = transient heat conduction time function for earth, dimensionless, shown in Fig. 46.5,

C_s = heat capacity of steam, Btu/lbm-°F,

g_G = geothermal gradient, °F/ft, and

T_{su} = surface temperature, °F.

For $t > 7$ days,

$$f(t) = \ln \frac{2\sqrt{\alpha t}}{r_{co}} - 0.29, \dots\dots\dots (11)$$

where α is the thermal diffusivity, sq ft/D, and r_{co} is the outside radius of casing, ft.

Saturated Steam. When the steam is saturated, the wellbore heat loss will cause changes in the steam quality whereas the steam temperature, T_s , is kept constant. If

TABLE 46.6—MECHANISMS CONTRIBUTING TO STEAM RECOVERY

	Recovery (% Initial Oil in Place)			
	Torpedo Sandstone Core 37°API Crude		Torpedo Sandstone Core 12.2°API Crude	
	800 (520°F)	84 (327°F)	800 (520°F)	84 (327°F)
	71.0	68.7	68.7	66.0
Steam injection pressure, psig				
Hot waterflood recovery (includes viscosity reduction and swelling)	3.0	3.0	3.0	3.0
Recovery from gas drive	18.9	15.6	9.3	4.9
Extra recovery from steam distillation	4.7	4.6	3.0	3.7
Recovery improvements from solvent/extraction effects				
Total recovery by steam	97.6	91.9	84.0	77.6

Fig. 46.5—Transient heat conduction in an infinite radial system.

the steam quality at D is $f_s = f_s(D_1, t)$, the steam quality at D_2 can be calculated by Satter's equation²⁰:

$$f_s(D_2, t) = f_s(D_1, t) + \frac{A'B' + aD_1 + b - T_s}{A'} \Delta D + \frac{a(\Delta D)^2}{2A'} \quad (12)$$

In Eq. 12,

$$A' = \frac{w_s L_s [k_{hf} + r_{ii} U_{ii} f(t)]}{2\pi r_{ii} U_{ii} k_{hf}} \quad (13)$$

and

$$B' = \frac{1}{778 L_s} \quad (14)$$

Hot Water. For cooling of the hot water, Ramey's equation for the liquid phase¹⁹ applies. To advance from depth D_1 to D_2 ,

$$T(D_2, t) = g_G D_2 + T_{su} - g_G A + [T(D_1, t) - g_G D_1 + T_{su} + g_G A] e^{-\Delta D/A} \quad (15)$$

Overall Heat Transfer Coefficient. The temperature distribution in an annular completion is shown in Fig. 46.6.²¹ To evaluate the overall heat transfer coefficient, U_{to} , based on the outside tubing surface, the following procedure developed by Willhite²¹ can be used.

1. Select U_{to} based on outside tubing surface.
2. Calculate $f(t)$, as defined previously.
3. Calculate T_{cf} at cement/formation interface.

$$T_{cf} = \frac{T_{fl} f(t) + \frac{k_{hf}}{r_{io} U_{to}} T_f}{f(t) + \frac{k_{hf}}{r_{io} U_{to}}} \quad (16)$$

Fig. 46.6—Temperature distribution in an annular completion.

where T_{fl} = temperature of fluid, °F.

4. Calculate T_{ci} at casing inside surface.

$$T_{ci} = T_{cf} + \left(\frac{\ln \frac{r_{cf}}{r_{co}}}{k_{hce}} + \frac{\ln \frac{r_{co}}{r_{ci}}}{k_{hca}} \right) r_{to} U_{to} (T_{fl} - T_{cf}) \quad (17)$$

where

r_{cf} = radius to cement/formation interface, ft,

r_{ci} = inside radius of casing, ft,

k_{hce} = thermal conductivity of the cement, Btu/hr-ft-°F, and

k_{hca} = thermal conductivity of the casing material, Btu/hr-ft-°F.

5. Estimate I for radiation and h for natural convection.

6. Calculate U_{to} .

$$U_{to} = \left(\frac{1}{h + I} + \frac{r_{to} \ln \frac{r_{cf}}{r_{co}}}{k_{hce}} \right)^{-1} \quad (18)$$

With commercial insulation of thickness Δr ,

$$U_{to} = \left[\frac{r_{to} \ln \frac{r_{in}}{r_{to}}}{k_{hin}} + \frac{r_{to}}{r_{in}(h' + I')} + \frac{r_{to} \ln \frac{r_{cf}}{r_{co}}}{k_{hce}} \right]^{-1} \quad (19)$$

where h' and I' are based on insulation outside surface.

Calculations Including Pressure Changes. A more sophisticated calculation procedure proposed by Earlougher²² includes the effect of pressure changes inside the wellbore. The wellbore is divided into a sequence

of depth intervals. The conditions at the bottom of each interval are calculated, on the basis of the conditions at the top of that interval. The procedure is as follows.

1. Calculate the pressure at the bottom of the interval, p_2 .

$$p_2 = p_1 + 1.687 \times 10^{-12} (v_{t1} - v_{t2}) \frac{w_s^2}{r_{ti}^4} + 6.944 \times 10^{-3} \frac{\Delta D}{v_{t1}} - \Delta p, \dots (20)$$

where

v_t = specific volume of the total fluid, cu ft/lbm (condition 1 is top of interval and 2 is bottom),

ΔD = length of depth interval, ft, and

Δp = frictional pressure drop over interval, psi.

The Beggs and Brill correlation²³ for two-phase flow can be used to calculate the Δp in the above equation.

2. Calculate the heat loss over the interval.

$$Q_l = \frac{2\pi k_{hf} r_{co} U_{co} \Delta D}{k_{hf} + r_{co} U_{co} f(t)} \times [0.5(T_{s1} + T_{s2}) - 0.5(T_{f1} + T_{f2})], \dots (21)$$

where U_{co} is the overall heat transfer coefficient based on outside casing surface, Btu/hr-sq ft-°F.

3. Calculate the steam quality at the bottom of the interval.

$$f_{s2} = \frac{f_{s1} L_{v1} + H_{w1} - H_{w2} - Q_l / w_s}{L_{v2}}, \dots (22)$$

where H_{w1} and H_{w2} are the enthalpy of liquid water at top and bottom of the interval, Btu/lbm, and L_{v1} and L_{v2} are the latent heat of vaporization at top and bottom of the interval, Btu/lbm.

More Recent Developments. A new model has been developed by Farouq Ali²⁴ that treats wellbore heat losses rigorously by using a grid system to represent the surrounding formation. In addition, the pressure calculation accounts for slip and the prevailing flow regime, based on well-accepted correlations.

Analytical Models for Steam Injection

For predicting reservoir performance under steam injection processes, the usual practice is to use three-dimensional (3D), three-phase numerical simulators. Where the simulators are unavailable or a quick estimate of the performance is needed, one can resort to simple analytical methods. Usually these methods take into account the thermal aspects of the process only, without regard to the fluid flow aspects.

Front Displacement Models

Marx-Langenheim Method.²⁵ Consider that heat is injected into a pay zone bounded by two neighboring for-

Fig. 46.7—Temperature distribution in Marx-Langenheim model.

mations. The heat-carrying fluid is supposed to advance with a sharp front perpendicular to the boundaries of the formation (Fig. 46.7). The heat balance gives: heat injected into the pay zone equals heat loss to the overburden and underlying stratum plus heat contained in the pay zone.

The heated area at any time t can be calculated

$$A = \frac{Q_{ri} M h \alpha_o}{4 k_{ho}^2 \Delta T} \left(e^{t_D} \operatorname{erfc} \sqrt{t_D} + 2 \sqrt{\frac{t_D}{\pi}} - 1 \right), \dots (23)$$

where

A = heated area at time t , sq ft,

t = time since injection, hr,

Q_{ri} = heat injection rate, Btu/hr,

M = volumetric heat capacity of the solid matrix containing oil and water, Btu/cu ft-°F

$$= (1 - \phi) \rho_r C_r + S_{wi} \phi \rho_w C_w + S_{oi} \phi \rho_o C_o,$$

$$\dots (24)$$

ϕ = porosity, fraction,

ρ_r, ρ_o, ρ_w = density of rock grain, oil, water, lbm/cu ft,

C_r, C_o, C_w = heat capacity of rock, oil, water, Btu/lbm-°F,

S_{oi}, S_{wi} = initial saturation of oil, water, fraction,

h = pay thickness, ft,

α_o = overburden thermal diffusivity, sq ft/hr,

k_{ho} = overburden thermal conductivity, Btu/hr-ft-°F,

$\Delta T = T_{inj} - T_{fi}$, °F,

T_{inj} = injection temperature, °F,

T_{fi} = initial formation temperature, °F,

t_D = dimensionless time

$$= \left(\frac{4 k_{ho}^2}{M^2 h^2 \alpha_o} \right) t, \dots (25)$$

and

$$\sqrt{t_D} = \left(\frac{2k_{ho}}{Mh\sqrt{\alpha_o}} \right) t^{1/2} \quad (26)$$

The complementary error function is:

$$\operatorname{erfc} x = 1 - \operatorname{erf} x = 1 - \frac{2}{\pi} \int_0^x e^{-\beta^2} d\beta, \quad (27)$$

where β is a dummy variable.

To evaluate $e^{t_D} \operatorname{erfc} \sqrt{t_D}$, one can use the following approximation,²⁶

$$\text{Let } y = \frac{1}{1 + 0.3275911\sqrt{t_D}}, \quad (28)$$

$$\begin{aligned} e^{t_D} \operatorname{erfc} \sqrt{t_D} &= 0.254829592y - 0.284496736y^2 \\ &+ 1.42143741y^3 - 1.453152027y^4 + 1.061405429y^5 \\ &\dots \dots \dots (29) \end{aligned}$$

Assume that all the movable oil is displaced in the heated area. If we assume that all the displaced oil is produced, we can calculate the cumulative steam/oil ratio (SOR):

$$F_{so}^* = \frac{i_s t}{4.275 A h \phi (S_{oi} - S_{io})}, \quad (30)$$

where

i_s = steam injection rate, B/D, cold water equivalent,

S_{oi} = initial oil saturation, and

S_{io} = irreducible oil saturation.

Differentiation of the expression for A with t gives the rate of expansion of the heated area. The oil displacement rate, q_{od} , in B/D, is

$$q_{od} = 4.275 \left[\frac{Q_{ri} \phi (S_{oi} - S_{or})}{M \Delta T} \right] e^{t_D} \operatorname{erfc} \sqrt{t_D} \quad (31)$$

From this one can calculate the instantaneous SOR:

$$F_{so} = \frac{i_s}{q_{od}} \quad (32)$$

The thermal (heat) efficiency, E_h , is defined as

$$E_h = \frac{Q_{hz}}{Q_{it}} \quad (33)$$

where

Q_{hz} = heat remaining in the heated zone, Btu,

Q_{it} = total heat injection, Btu, and

$$E_h = \frac{A h M \Delta T}{Q_{ri} T} \quad (34)$$

It can easily be shown that

$$E_h = \frac{1}{t_D} \left(e^{t_D} \operatorname{erfc} \sqrt{t_D} + 2 \sqrt{\frac{t_D}{\pi}} - 1 \right) \quad (35)$$

Ramey's Generalization of the Marx-Langenheim Method.²⁷ The Marx-Langenheim method can be extended to the case where a series of constant injection rates is maintained over various time periods. If the heat injection rate is $(Q_{ri})_i$ over the period $0 < t < t_1$, and $(Q_{ri})_n$ over the period $t_{n-1} < t < t_n$,

$$\begin{aligned} A &= \frac{M h \alpha_o}{4 k_{ho}^2 \Delta T} \left\{ (Q_{ri})_n F(t_{Dn}) \right. \\ &+ \sum_{i=1}^{i=n-1} [(Q_{ri})_i - (Q_{ri})_{i+1}] F(t_{Di}) \left. \right\}, \quad (36) \end{aligned}$$

where

$$F(t_{Di}) = e^{t_{Di}} \operatorname{erfc} \sqrt{t_{Di}} + 2 \sqrt{\frac{t_{Di}}{\pi}} - 1 \quad (37)$$

and $F(t_{Dn}) = F(t_{Di})$ with $i = n$. The oil displacement rate at t_i depends on the heat injection rate at that time, independent of the previous heat injection rates.

Mandl-Volek's Refinement of the Marx-Langenheim Method.²⁸ Mandl and Volek observed that the heated area measured in laboratory experiments tends to be lower than that predicted by the Marx-Langenheim method after a certain critical time, t_c . For $t \geq t_c$,

$$\begin{aligned} A &= \frac{Q_{ri} M h \alpha_o}{4 k_{ho}^2 \Delta T} \left[e^{t_D} \operatorname{erfc} \sqrt{t_D} + 2 \sqrt{\frac{t_D}{\pi}} - 1 - \sqrt{\frac{t_D - t_{cD}}{\pi}} \right. \\ &\times \left(\frac{1}{1 + \frac{L_s f_s}{C_w \Delta T}} + \frac{t_D - t_{cD}^{-3}}{3} e^{t_D} \operatorname{erfc} \sqrt{t_D} \right. \\ &\left. \left. - \frac{t_D - t_{cD}}{3 \sqrt{\pi t_D}} \right) \right] \quad (38) \end{aligned}$$

t_c is determined by this equation:

$$e^{t_{cD}} \operatorname{erfc} \sqrt{t_{cD}} = \frac{1}{1 + \frac{L_s f_s}{C_w \Delta T}} \quad (39)$$

The relationship between t_c and t_{cD} is again

$$t_{cD} = \left(\frac{4 k_{ho}^2}{M^2 h^2 \alpha_o} \right) t_c \quad (40)$$

Myhill and Stegemeier²⁹ used a slightly different version of the Mandl-Volek model and calculated oil/steam ratio (OSR) for 11 field projects. They found that the actual OSR's range from 70 to 100% of the calculated ratios.

Steam Chest Models

In contrast to the front displacement models discussed previously, Neuman³⁰ visualized that steam rises to the top and grows both horizontally outward and vertically downward. Doscher and Ghassemi³¹ took a view even more drastic than Neuman's. They theorized that steam rises to the top instantly and the only direction of the steam zone movement is vertically downward. Vogel³² followed the same reasoning and developed the following simple equation for thermal efficiency:

$$E_h = \frac{1}{1 + \sqrt{\frac{4}{\pi} t_D}} \quad (41)$$

Table 46.7 compares the thermal efficiencies calculated by the Marx-Langenheim method and the Vogel method. This table shows that the Vogel method predicts a thermal efficiency that lies between 80 and 100% of that calculated by the Marx-Langenheim method.

Steam Stimulation

Steam stimulation usually is carried out in a number of cycles. Each cycle consists of three stages: steam injection, soaking, and production. The basic concept of this process follows.

Without stimulation, the oil production rate is

$$q_{oc} = \frac{0.00708kk_{ro}h}{\mu_{oc} \ln \frac{r_e}{r_w}} (p_e - p_w), \quad (42)$$

where

- q_{oc} = cold oil production rate, B/D,
- k = absolute permeability, md,
- k_{ro} = relative permeability to oil, fraction,
- μ_{oc} = cold oil viscosity, cp,
- p_e = static formation pressure at external radius r_e , psia, and
- p_w = bottomhole pressure, psia.

After steam injection, the oil inside the heated region, $r_w < r < r_h$, will have a lower viscosity, μ_{oh} . The hot oil production, q_{oh} , is:

$$q_{oh} = \frac{0.00708kk_{ro}h}{\mu_{oh} \ln \frac{r_h}{r_w} + \mu_{oc} \ln \frac{r_e}{r_h}} (p_e - p_w), \quad (43)$$

TABLE 46.7—COMPARISON BETWEEN MARX-LANGENHEIM AND VOGEL METHODS

t_D	Thermal Efficiency		Ratio Vogel/ML
	Marx-Langenheim	Vogel	
0.01	0.930	0.900	0.967
0.1	0.804	0.737	0.917
1.0	0.556	0.470	0.845
10.0	0.274	0.219	0.799
100.0	0.103	0.081	0.787

where r_h equals the radius of the heated region, ft. The ratio between q_{oh} and q_{oc} is

$$\frac{q_{oh}}{q_{oc}} = \frac{1}{\frac{\mu_{oh}}{\mu_{oc}} \frac{\ln \frac{r_h}{r_w}}{\ln \frac{r_e}{r_h}} + \frac{\ln \frac{r_e}{r_h}}{\ln \frac{r_e}{r_w}}} \quad (44)$$

As the reservoir fluids are produced, energy associated with the fluids are removed from the reservoir. This causes a reduction in r_h and a reduction in temperature, which increases μ_{oh} .

Several methods have been developed for calculating reservoir performance under steam stimulation. One of the methods, which has enjoyed wide acceptance, is the Boberg and Lantz method.³³ This method assumes a constant r_h , with a changing \bar{T} inside the heated zone. The method consists of the following steps.

1. Calculate the size of the heated region using the Marx-Langenheim method.
2. Calculate the average temperature in this region.
3. Calculate the oil production rate, taking into account the reduced oil viscosity in this region.
4. Repeat Steps 1 through 3 for succeeding cycles, by including the residual heat left from preceding cycles.

The average temperature of the heated region is calculated by

$$\bar{T} = T_R + (T_s - T_R)[\bar{V}_r \bar{V}_z (1 - \delta) - \delta], \quad (45)$$

where

- \bar{T} = average temperature of the heated region, $r_w < r < r_h$, at any time t , °F,
- T_R = original reservoir temperature, °F,
- T_s = steam temperature at sandface injection pressure, °F,
- \bar{V}_r, \bar{V}_z = average values of V_r, V_z for $0 < r < r_h$ and all h_j ,*
- V_r, V_z = unit solution for the component conduction problems in the r and z directions, and
- δ = energy removed with the produced fluids, dimensionless.

The quantities \bar{V}_r and \bar{V}_z can be obtained from Fig. 46.8 as functions of dimensionless time, t_D . For \bar{V}_r ,

$$t_D = \frac{\alpha_o(t - t_i)}{r_h^2}, \quad (46)$$

*These symbols have no physical connotation. They are simply mathematical symbols.

Fig. 46.8—Solutions for V_r and V_s , single sand.

where

- α_o = overburden thermal diffusivity, sq ft/D,
 t = time since start of injection for the current cycle, D,
 t_i = time of injection for the current cycle, D,
 and
 r_h = radius of region originally heated, ft.

For \bar{V}_z ,

$$t_D = \frac{\alpha_o(t-t_i)}{\bar{H}_1^2}, \quad (47)$$

where

$$\bar{H}_1 = \frac{m_{sit}(f_s L_s + H_{ws} - H_{wR})}{\pi(r_h^2 M)(T_s - T_R)N_s}, \quad (48)$$

and

- m_{sit} = total mass of steam injected, lbm,
 N_s = number of sands,
 H_{ws}, H_{wR} = enthalpy, Btu/lbm, of water at steam and reservoir temperatures, °F, and
 M = volumetric heat capacity, Btu/cu ft-°F.

The energy removed with produced fluids, δ , can be calculated thus:

$$\delta = \frac{1}{2} \int_{t_i}^t \frac{Q_{rt} dt}{h_t \pi r_h^2 M (T_s - T_R)}, \quad (49)$$

where

- h_t = total thickness of all sands, ft,
 Q_{rt} = heat removal rate at time t , Btu/D,

$$Q_{rt} = q_{oh}(H_{og} + H_w), \quad (50)$$

$$H_{og} = (5.6146M_o + R_t C_g)(\bar{T} - T_R), \quad (51)$$

and

$$H_w = 5.6146\rho_w[F_{wot}(h_f - H_{wR}) + R_t L_s], \quad (52)$$

where h_f is the enthalpy of liquid water at T above 32°F (see steam tables), Btu/lbm, H_{og} is the enthalpy of oil and gas based on a STB of oil, Btu/STB oil, and H_w is

the enthalpy of water carried by oil based on a STB of oil, Btu/STB oil. Also, L_s is h_{fg} in the steam tables.

If $p_w > p_s$ and $F_{so} < F_{wot}$

$$F_{so} = 0.0001356 \left(\frac{p_s}{p_w - p_s} \right) R_t, \quad (53)$$

bbl liquid water at 60°F/STB oil.

If F_{so} (calculated) $> F_{wot}$,

$$F_{so} = F_{wot}. \quad (54)$$

In the above,

- R_t = total produced GOR, scf/STB,
 F_{wot} = total produced WOR, STB/STB,
 F_{so} = steam/oil ratio, STB/STB,
 p_w = producing bottomhole pressure, psia, and
 p_s = saturated vapor pressure of water at \bar{T} , psia.

The rate of hot oil production can be calculated thus:

$$q_{oh} = F_J J_c \Delta p, \quad (55)$$

where F_J is the ratio of stimulated to unstimulated productivity indexes, dimensionless,

$$F_J = \frac{1}{\frac{\mu_{oh}}{\mu_{oc}} C_1 + C_2}, \quad (56)$$

and J_c is the unstimulated (cold) productivity index, STB/D/psi,

$$J_c = \frac{0.000708 k k_{ro} h}{\mu_{oc} \ln \frac{r_e}{r_w}}. \quad (57)$$

If p_e is constant,

$$C_1 = \frac{\ln \frac{r_h}{r_w}}{\ln \frac{r_e}{r_w}} \quad (58)$$

and

$$C_2 = \frac{\ln \frac{r_e}{r_h}}{\ln \frac{r_e}{r_w}}. \quad (59)$$

Thus Eq. 55 is identical with Eq. 43 in this case. If p_e is declining,

$$C_1 = \frac{\ln \frac{r_h}{r_w} - \frac{r_h^2}{2r_e^2}}{\ln \frac{r_e}{r_w} - \frac{1}{2}} \quad (60)$$

Fig. 46.9—Correlation of steam stimulation results.

and

$$C_2 = \frac{\ln \frac{r_e}{r_h} - \frac{1}{2} + \frac{r_h^2}{2r_e^2}}{\ln \frac{r_e}{r_w} - \frac{1}{2}} \quad \dots \dots \dots (61)$$

This method of calculating oil production rate is probably the weakest part of the Boberg-Lantz method.

1. It assumes a monotone decline between p_e and p_w . Actually, because the injected steam is at a high pressure, there could be a high pressure p_s near r_h and the pressure declines toward both p_w and p_e .

2. Only the change in μ_o is accounted for in changing from cold oil productivity to hot oil productivity. Left unaccounted for is the change in k_{ro} , which should change with changing S_o .

Based on the Boberg-Lantz method, a correlation was developed by Boberg and West³⁴ that allows one to estimate incremental OSR with known reservoir properties (Fig. 46.9).

Numerical Simulation

The analytical models for thermal recovery processes usually are concerned with the thermal aspects of the processes only. The fluid flow aspects are neglected. To account adequately for the fluid flow inside porous media under a thermal recovery process, numerical simulators will be needed. In these simulators, the reservoir is divided into a number of blocks arranged in one, two, or three dimensions. A detailed study is made of the reservoir by applying fundamental equations for flow in porous media to each one of the blocks.

Numerical reservoir simulators are no substitute for field pilots. They have several advantages, however, over field pilots. Field conditions are irreversible. It took millions of years for the field to develop to the present state. Once disturbed, it cannot revert to the original conditions and start over again. Furthermore, it takes a long time, in terms of months or even years, before the pilot results

can be evaluated. The cost for pilots is, of course, enormous. In comparison, a simulated reservoir can be produced many times, each time starting at the existing state. This can be done within a short period of time, in terms of seconds, once the reservoir model is properly set up. The cost for reservoir simulation is much less than that of a pilot. However, simulated reservoirs may never duplicate field performance. Modern practice is to use reservoir simulation to help design a pilot before launching a large-scale field development.

Numerical models and physical models are complementary to each other. As will be detailed later, physical models can be classified into two types: elemental models and partially scaled models. In an elemental model, experiments are conducted with actual reservoir rock and fluids. The results can help explain various fluid flow and heat transfer mechanisms as well as chemical reaction kinetics. In a partially scaled model, reservoir dimensions, fluid properties, and rock properties are scaled for the laboratory model so that the ratios of various forces in the reservoir and the physical model are nearly the same. One can only build partially scaled models because fully scaled models are difficult or impossible to construct. One of the advantages of a numerical model over a physical model is that there is no scaling problem in numerical simulation. However, in many cases, a numerical model needs physical models to validate the formulation or to provide necessary input data for the simulation.

Steam Injection Model

Numerical simulation models for steam injection processes have been developed by Coats *et al.*³⁵ and Coats.^{36,37} A steam injection model consists of a number of conservation equations.

1. *Mass balance of H_2O .* Both water and steam are included.

2. *Mass balances of hydrocarbons.* Only one equation will be necessary for nonvolatile oil. For volatile oil, two or more pseudocomponents will be needed to describe the vaporization/condensation phenomenon of the oil and two or more equations will be needed.

3. **Energy balance.** The energy balance accounts for heat conduction, convection, vaporization/condensation phenomenon, and heat loss from the pay zone to its adjacent formations. The need to include an energy balance in the model sets the thermal recovery processes apart from isothermal processes for oil recovery.

In addition to the conservation equations, the model needs to include the following auxiliary equations.

1. If both water and steam coexist, temperature is the saturated steam temperature for a given pressure. An equation is needed to describe this relationship between temperature and pressure.

2. The sum of saturations for the oil, water, and gas phases equals unity.

3. The mol fractions of hydrocarbon components in the liquid and gas phases are related through equilibrium vaporization constants (K -values).

4. The sum of gas-phase mol fractions equals unity. This includes steam and any volatile components of hydrocarbons.

5. The sum of liquid-phase mol fractions for hydrocarbons equals unity.

In-Situ Combustion Model

Numerical simulation models have been developed by Crookston *et al.*,³⁸ Youngren,³⁹ Coats,⁴⁰ and Grabowski *et al.*⁴¹ The in-situ combustion model is more complicated than the model for steam injection. The conservation equations are as follows.

1. **Mass balance of H_2O .** This equation includes the water produced from combustion.

2. **Mass balances of hydrocarbons.** This includes consumption of certain hydrocarbons through cracking and combustion. It also may include the production of certain other components through cracking.

3. **Mass balance of oxygen.** This accounts for the consumption of oxygen by combustion.

4. **Mass balance of inert gas.** If air is used, the conservation of nitrogen should be accounted for. CO_2 produced from combustion may be included in the equation for the inert gas or be treated separately.

5. **Mass balance of coke.** This includes the formation and burning of coke.

6. **Energy balance.** This equation now includes the heat of reaction for the reactions involved in the in-situ combustion process. These reactions may include low-temperature oxidation of hydrocarbons, high-temperature oxidation or burning of hydrocarbons, thermal cracking (which produces coke and other products), and combustion of coke.

This model also needs a number of auxiliary equations, which include (1) steam/water equilibrium, (2) vaporization equilibrium of hydrocarbons, (3) phase saturation constraints, (4) mol fraction constraints, and (5) chemical stoichiometry. An example is:

This says that one mol of oil reacts with a mols of oxygen to form b mols of CO_2 and c mols of H_2O .

This model also requires a chemical reaction kinetics equation. For each reaction involved in the process, an equation can be written to denote that the reaction rate varies as a function of temperature and concentrations of

the various reactants. One possible form of the reaction rate equation is the following Arrhenius equation:

$$w = k'(C_o)^m (C_{O_2})^n \exp\left(-\frac{E}{RT}\right) \dots \dots \dots (62)$$

This equation says that the reaction rate, w , is proportional to the concentration of oil, C_o , raised to the m th power times the concentration of oxygen, C_{O_2} , raised to the n th power. The temperature dependence of the reaction rate is in the given exponential form, where E is the activation energy, the energy barrier the reactants need to overcome before being converted to the products, R is the gas constant, and T is the absolute temperature. The proportionality constant, k' , usually is called the pre-exponential factor.

The models developed so far are believed to be adequate as far as the formulation of the process mechanisms is concerned. However, problems abound.

1. Artificial breakdown of the crude oil into two components may not be sufficient to describe faithfully the vaporization/condensation phenomena and the chemical reactions involved in the combustion process. More components mean more equations to be solved and hence higher computer costs.

2. The grid size problem could be severe. A grid size large enough for economic computation could greatly distort the temperature distributions in the simulated reservoir. This would lead to erroneous predictions of the chemical reaction rates and thus of reservoir performance under combustion.

Laboratory Experimentation

The thermal numerical models have been used widely for screening thermal prospects, designing field projects, and formulating production strategies. Still, we cannot completely dispense with laboratory experiments for several reasons. First, the numerical models need data that can be measured only experimentally. These data include relative permeabilities, chemical kinetics, adsorption of chemicals on rocks, etc. Second, the numerical models are valid only when all the pertinent mechanisms are accounted for. The currently available models cannot handle adequately situations such as injection of chemicals along with steam, swelling of clays, which reduces the permeability, etc.

As previously mentioned, physical models for thermal recovery processes may be classified into two types, namely, elemental models and partially scaled models. The elemental models are used to study the physico-chemical changes inside a rock-fluid system under certain sets of operating conditions and are normally zero-dimensional (0D) or one-dimensional (1D). The partially scaled models are used to simulate the performance of a reservoir under thermal recovery operations and are normally 3D. Although the intent is to scale every physico-chemical change that takes place in the processes, the models usually are partially scaled because of the extreme difficulty in achieving full scaling.

Elemental Models

Elemental models used for steamflooding can be exemplified by those used by Willman *et al.*¹⁷ In their classic work, they used glass bead packs and natural cores

of different lengths to study the recovery of oil under hot waterflood and steamflood at different temperatures. The oils used included crudes of different gravities and oil fractions.

Fireflood pots and combustion tubes are also elemental models. In another classic work, Alexander *et al.*⁴² used fireflood pots (0D) to study fuel laydown and air requirement, as affected by crude oil characteristics, porous medium type, oil saturation, air flux, and time-temperature relationships. The combustion tube (1D) used by Showalter⁴³ enabled him to delineate the temperature profiles at various times, thus giving the combustion front velocity. More recently, combustion tubes were used to study the use of water along with air⁴⁴⁻⁴⁶ and the use of oxygen-enriched air in combustion.⁴⁷

Partially Scaled Models

Partially scaled models have been used to simulate steamfloods in $\frac{1}{8}$ of a five-spot pattern, $\frac{1}{4}$ of a five-spot pattern, etc.⁴⁸⁻⁵³ Similar attempts have also been made for firefloods.⁵⁴ However, it is certainly much more difficult to include chemical kinetics along with the fluid flow and heat transfer aspects of the combustion process.

Partially scaled models for steamfloods fall into two types, namely, high-pressure models and vacuum or low-pressure models.

High-Pressure Models. All experimental studies on steamflooding had used high-pressure models until vacuum models came along and offered an alternative approach. The scaling laws of Pujol and Boberg⁵⁵ normally were followed in the design. If the dimensions are scaled down by a factor of F in the model, the steam injection rate will be scaled down by the same factor and so will the pressure drop between the injector and the producer. The permeability will be scaled up by a factor of F , and the model time will be scaled down by a factor of F^2 . Because of the necessity of increasing the permeability in the model to a great extent, reservoir rock material cannot be used. Nevertheless, the experiments will be conducted with the actual crude. Also, the steam pressure and steam quality to be employed in the field will be used in the model.

Vacuum Models. In a small-scale physical model, the thickness is reduced greatly as compared with that in the field. To obtain the same gravitational effects as in the field, the pressure drop from the injector to the producer also must be reduced greatly. The vaporization/condensation phenomenon of water and hydrocarbons is governed by the Clausius-Clapeyron equation, which involves $d \ln p$, or dp/p . Thus, a decrease in the pressure drop (dp) necessitates a corresponding decrease in the pressure (p) itself. This is the rationale behind the vacuum-model approach developed by the Shell group as reported by Stegemeier *et al.*⁵⁶

To see the differences between a high-pressure model and the vacuum model, Table 46.8 has been prepared for using both models to simulate a hypothetical field element with a hypothetical oil. The entries for the high-pressure models were based on the scaling laws of Pujol and Boberg⁵⁵ and the entries for the vacuum model were based on the work of Stegemeier *et al.*⁵⁶

TABLE 46.8—COMPARISON OF HIGH-PRESSURE AND VACUUM MODELS FOR STEAMFLOODS

	Field	High-Pressure Model	Vacuum Model
Length, ft	229	1	1
Permeability, darcies	2	458	1,527
Time	5 yrs	50 min	120 min
Steam rate	300 B/D	144.7 cm ³ /min	263.1 cm ³ /min
Pressure 1, psia	400	400	2.70
Steam quality	0.80	0.80	0.082
Oil viscosity, cp	3.0	3.0	23.6
Temperature, °F	445	445	137.5
Pressure 2, psia	100	100	1.24
Steam quality	0.80	0.80	0.108
Oil viscosity, cp	6.3	6.3	38.2
Temperature, °F	328	328	108.9

The following observations can be made on the high-pressure and vacuum models.

1. Neither the high-pressure model nor the vacuum model can accurately simulate the capillary forces and the relative permeability curves of the actual rock/fluid system because, to obtain a very high permeability, actual rock material is not being used.

2. The high-pressure model does not observe the Clausius-Clapeyron equation, whereas the vacuum model follows it to a large extent but not exactly.

3. To use the vacuum model, an oil has to be reconstituted to obtain the required oil viscosity/temperature relationship. This is completely different from the actual crude in many physicochemical aspects, including its vaporization/condensation behavior and chemical kinetics. In contrast, a high-pressure model normally uses actual crudes.

Field Projects

Screening Guides

In dealing with oil prospects, the first step is to find out whether the field in question can be produced by certain recovery methods. Screening guides are useful for this purpose. Screening guides for steamflood and fireflood processes have been proposed by various authors including Farouq Ali,⁵⁷ Geffen,⁵⁸ Lewin *et al.*,⁵⁹ Iyoho,⁶⁰ Chu,⁶¹⁻⁶³ and Poettmann.⁶⁴ These screening guides are listed in Table 46.9.

A perusal of the various screening guides listed in Table 46.9 shows that some of the earlier screening guides were quite restrictive in selecting oil prospects. Such a guide tends to minimize the error of the second kind, that is, the risk of excluding some undesirable prospects. In so doing, it tends to increase the error of the first kind, that is, the risk of missing some desirable prospects. Recent changes in the price structure of the crude oil and improved technology helped to widen the range of applicability for the steamflood and fireflood processes. This is reflected in the less restrictive screening guides developed in more recent years. However, in minimizing the error of the first kind (erroneous rejection), the newer guides may possibly increase the error of the second kind (erroneous acceptance). This should be borne in mind when applying these guides to oil prospects.

Reservoir Performance

Performance Indicators Common to Both Steamfloods and Firefloods. Sweep Efficiency. The areal and vertical sweep of the steam front or burning front has pronounced influence on the economics of the steamflood or fireflood projects. Some reported sweep efficiencies of the steamflood and fireflood projects are given in Table 46.10.⁶⁵⁻⁸¹ Whereas the volumetric sweep of steamfloods varies from 24 to 99%, that of firefloods appears to be lower, ranging from 14 to 60%.

TABLE 46.10—SWEEP EFFICIENCY OF STEAMFLOOD AND FIREFLOOD PROJECTS

Oil Recovery. Table 46.11 lists some of the reported oil recoveries of steamflood and fireflood projects.⁸²⁻¹²¹

For the estimation of the oil recovery obtainable in a steam injection project, the analytical methods discussed previously can be used. As steam injection continues, the thermal efficiency will gradually diminish and the instantaneous SOR will increase gradually. When this ratio reaches a certain limit, further injection of steam will become uneconomical and needs to be stopped. The cumulative oil production at that time divided by the original oil in place (OOIP) will give the oil recovery.

The oil recovery from a fireflood project can be calculated with the recognition that oil production comes from both the burned and unburned regions (Nelson and McNeil¹²²). Let E_{vb} equal the volumetric sweep efficiency of the burning front and E_{Ru} equal the recovery efficiency in the unburned region. The overall oil recovery is:

$$E_R = \left(1 - \frac{C_m}{62.4\phi S_o}\right) E_{vb} + (1 - E_{vb}) E_{Ru}, \dots (63)$$

where C_m is the fuel content, lbm/cu ft. In this equation, the fuel consumed is taken to be a 10° API oil with a density of 62.4 lbm/cu ft.

The equation developed by Satman *et al.*¹²³ can be used to calculate the oil recovery from a dry combustion project.

$$Y = 47.0 \left[0.427S_o - 0.00135h - 2.196 \left(\frac{1}{\mu_o} \right)^{0.25} \right] X, \dots (64)$$

where

$$Y = \frac{\Delta N_p + V_{fh}}{N} \times 100 \dots (65)$$

and

$$X = \frac{i_{at} E_{O_2}}{[N_{sp}/(\phi S_o)](1 - \phi)} \dots (66)$$

* Anticipated.

In the above equation,

ΔN_p = cumulative incremental oil production, bbl,

V_{fb} = fuel burned, bbl,

N = OOIP, bbl,

i_{at} = cumulative air injection, 10^3 scf,

E_{O_2} = oxygen utilization efficiency, fraction, and

N_{sp} = oil in place at start of project, bbl.

Gates and Ramey¹²⁴ developed a correlation between oil recovery and PV burned at various initial gas saturation, on the basis of field data taken from the South Belridge fireflood project⁷⁶ and laboratory combustion-tube data. This correlation, shown in Fig. 46.10, should be useful in predicting current oil recovery as the fireflood proceeds.

Changes in Oil Property. At the temperatures and pressures prevailing in steamfloods, no changes in the oil property are expected to occur because of any chemical reactions. However, the properties of the recovered oil could have been changed as a result of steam distillation. In firefloods, of course, oil properties change considerably because of thermal cracking and combustion, as well as steam distillation. Changes in oil property in some of the reported steamfloods and firefloods are shown in Table 46.12.¹²⁵⁻¹³⁰

Performance Indicator Pertaining to Steamfloods Only. Steam Oil Ratio (SOR). The SOR, F_{so} , is the most important factor characterizing the success or failure of a steamflood project. Its reciprocal, the OSR, F_{os} , also is used commonly. In projects where oil is used as fuel

**Fig. 46.10—Estimated oil recovery vs. volume burned.**

for steam generation, 1 bbl of oil normally can generate 13 to 14 bbl (cold-water equivalent) of steam. Thus, the highest SOR that is tolerable without burning more oil than that produced is 13 to 14. For steamflood operation, there are other costs than fuel alone. Because of this, steam injection is normally terminated when the instantaneous SOR reaches the level of eight or so. Ideally the overall SOR should be around four. This corresponds to 3 to 4 bbl of oil produced per barrel of oil burned.¹³¹ This ideal case is, unfortunately, not normally achievable. The SOR of the majority of the steamflood field projects falls into the range of 5 to 7.

The following set of regression equations developed by Chu⁶² can be used to estimate the SOR with known reservoir and crude properties.

1. For $F_{so} > 5.0$ ($F_{os} < 0.20$),

$$F_{so} = 1 / (-0.011253 + 0.00002779D + 0.0001579h - 0.001357\theta + 0.000007232\mu_o + 0.00001043kh/\mu_o + 0.5120\phi S_o) \quad (67)$$

2. For $F_{so} \leq 5.0$ ($F_{os} \geq 0.20$),

$$F_{so} = 18.744 + 0.001453D - 0.05088h - 0.0008864k - 0.0005915\mu_o - 14.79S_o - 0.0002938kh/\mu_o, \dots (68)$$

where

D = depth, ft,

h = reservoir thickness, ft,

θ = dip angle, degrees,

μ_o = oil viscosity, cp,

k = permeability, md, and

S_o = oil saturation at start, fraction.

Another method of estimating F_{so} has been given by Myhill and Stegemeier,²⁹ based on the Mandl-Volek model.

Performance Indicators Pertaining to Firefloods Only.

Fuel Content. Fuel content (lbm/cu ft of burned volume) is the amount of coke available for combustion that is deposited on the rock as a result of distillation and thermal cracking. It is the most important factor influencing the success of a fireflood project. If the fuel content is too low, combustion cannot be self-sustained. A high fuel content, however, means high air requirement and power cost. Besides, oil production also may suffer.

Fuel content can be determined by laboratory tube runs. Gates and Ramey¹²⁴ presented a comparison of the estimated fuel content by use of various methods including laboratory experiments and field project data from the South Belridge project.⁷⁶ Their comparison shows that fuel content determined from the tube runs can provide reasonably good estimation of the fuel content obtainable in the field.

In the absence of experimental data, the correlation of Showalter⁴³ relating the fuel content to API gravity can be used. Fig. 46.11 shows a comparison of the Showalter data and field project data.⁶³ In addition, the following regression equation developed by Chu⁶² based on data from 17 field projects can be used to calculate the fuel content:

$$C_m = -0.12 + 0.00262h + 0.000114k + 2.23S_o \\ + 0.000242kh/\mu_o - 0.000189D - 0.0000652\mu_o, \quad (69)$$

where C_m is the fuel content, lbm/cu ft.

Both laboratory experiments and field projects indicate that, for a specific reservoir, fuel content decreases as WAR increases. However, no statistically significant correlation was found to exist between fuel content and WAR in the presence of widely varying reservoir properties.⁶³

Air Requirement. As pointed out by Benham and Poettmann,¹³² air requirement, a , in 10⁶ scf/acre-ft of burned volume, can be calculated on the basis of stoichiometric considerations:

$$a = \frac{\left(\frac{2F_{cc} + 1}{F_{cc} + 1} + \frac{F_{HC}}{2} \right) C_m}{0.001109(12 + F_{HC})E_{O_2}} \times 0.04356, \quad (70)$$

where F_{cc} is the CO₂/CO ratio in produced gas and F_{HC} is the atomic H/C ratio. In the absence of necessary data for Eq. 70, the Showalter correlation⁴³ relating air requirement to API gravity can be used. A comparison of the Showalter data and field project data is given in Fig. 46.12.⁶³ It can be seen that all the field points fall on the upper side of the Showalter curve. Air requirement in the fields can exceed laboratory values because of air channeling and migration. In addition, the following regression equation developed by Chu⁶³ can be used:

$$a = 4.72 + 0.03656h + 9.996S_o + 0.000691k, \quad (71)$$

Fig. 46.11—Effect of oil gravity on fuel content.

Fig. 46.12—Effect of oil gravity on air requirement.

Air-Oil Ratio (AOR). This important ratio relates air injection to oil production and usually is expressed in terms of 10^3 scf/bbl. Oil recovery comes from both the burned and unburned regions. The AOR can be calculated thus¹²²:

$$F_{ao} =$$

$$\frac{a}{\left[\left(\frac{\phi S_o}{5.6146} - \frac{C_m}{350} \right) E_{vb} + \frac{\phi S_o}{5.6146} (1 - E_{vb}) E_{Ru} \right]} 43.56 \quad (72)$$

In the absence of E_{vb} and E_{Ru} , the following regression equation developed by Chu⁶² based on 17 field projects can be used.

$$F_{ao} = 21.45 + 0.0222h + 0.001065k + 0.002645\mu_o - 76.76\phi S_o \quad (73)$$

Besides, the correlation between oil recovery and PV burned developed by Gates and Ramey¹²⁴ can be used for estimating the current AOR as the fireflood proceeds.

Both laboratory experiments and field projects indicate that, for a specific reservoir, AOR decreases as WAR increases. No statistically significant correlation, however, has been found between AOR and WAR in the presence of widely varying reservoir properties.⁶³

Project Design

Design Features Common to Both Steamfloods and Firefloods

Pattern Selection. For any oil recovery process with fluid injection, a cardinal rule of pattern selection is that, to achieve a balance between fluid injection and production,

the ratio of the number of producers to the number of injectors should be equal to the ratio of well injectivity to well productivity (Caudle *et al.*¹³³). Because of the high mobility of air or steam compared to that of the oil, the injectivity/productivity ratio is high, favoring a high producer/injector ratio. This rule generally has been followed by the various reported steamflood and fireflood projects. The use of inverted 13-spot, 9-spot, 7-spot, and 6-spot patterns, unconfined five-spot patterns, down-the-center line of injectors, and single well injection has been reported.

Aside from the injectivity/productivity ratios, other factors also should enter into consideration in pattern selection. These factors include: heat loss considerations, utilization of existing wells, reservoir dip, difficulty in producing hot wells, etc. Based on these and other considerations, repeated five-spot patterns, updip and crest injections and line drive also were used. The choice of pattern or nonpattern floods in the various steamflood and fireflood projects is shown in Table 46.13.¹³⁴⁻¹³⁸

Completion Intervals. In most of the steamflood and fireflood projects, the producers usually are completed for the entire sand interval to maximize production. The injectors usually are completed at the lower third or lower half of the interval, to minimize the override of the steam or air. In wet combustion projects, it is advisable to complete the lower part for air injection and upper part for water injection. This is to minimize the underflow of water as well.

Producer Bottomhole Pressure (BHP). In their study for a steamflood, Gomaa *et al.*¹³⁹ found that decreasing the producer BHP lowers the average reservoir pressure, increases steam volume, and increases predicted oil recovery. It is, therefore, important to keep the producers pumped off all the time. Without any reason to believe otherwise, keeping the producers pumped off should benefit a fireflood as well as a steamflood.

TABLE 46.13—PATTERN TYPES OF STEAMFLOODS AND FIREFLOODS

Pattern Types	Steamfloods	Firefloods
Inverted 13-spot	Slocum, TX ^{89,90} (Shell)	
Inverted 9-spot	San Ardo, CA ⁸⁸ (Texaco) Yorba Linda, CA ¹¹ (Shell)	Bellevue, LA ^{107,108} (Cities Service) Bellevue, LA ¹⁰⁹⁻¹¹² (Getty)
Inverted 7-spot	Kern River, CA ⁸⁴ (Chevron) Slocum, TX ^{89,90} (Shell) Tia Juana, Venezuela ¹³⁵ (Shell)	Silverdale, Alta. ¹³⁴ (General Crude)
Unconfined inverted 5-spot		West Newport, CA ^{126,127} (General Crude)

Design Features Pertaining to Steamfloods Only

Steam Injection Rate. According to Chu and Trimble,¹⁴⁰ the optimal choice of a constant steam injection rate is relatively independent of sand thickness. As sand thickness decreases, the total oil content in the reservoir decreases. This calls for a lower steam rate. At the same time, a higher steam rate is needed to compensate for the increased percentage heat loss with a decrease in thickness. These two counteracting factors result in only a small variation in the optimal steam rate as thickness is changed from 90 to 30 ft.

The same study with five-spot patterns shows that the optimal choice of a constant steam rate is proportional to the pattern size. Furthermore, varying steam rates appear to be preferable to constant steam rates. An optimal steam rate schedule calls for a high steam rate in the initial stage and a decrease in the steam rate with time.

Steam Quality. Steam quality refers to the mass fraction of water existing in vapor form. Gomaa *et al.*¹³⁹ reported that increasing steam quality increases oil recovery vs. time but had little effect on recovery vs. Btu's injected. This indicates that heat injection is the important parameter in determining steamflood performance.

Just as with steam injection rates, the optimal choice of steam quality should be studied. High-quality steam could cause excessive steam override. This may be remedied by using lower-quality steam at one stage of a steamflood.

Design Features Pertaining to Fireflood Only

Dry vs. Wet Combustion. The choice between dry combustion and wet combustion is an important decision to be made in conducting a field project. Laboratory experiments indicated that the use of water either simultaneously

or alternately with air does reduce the AOR, although the oil recovery may not be improved significantly. As was mentioned previously, a correlation between AOR and WAR, based on data from 21 field projects, was found to be statistically insignificant in the presence of widely varying reservoir properties.⁶³

Cities Service conducted a field comparison test of dry and wet combustion in the Bellevue field, LA,¹⁴¹ in which possible interference by variations in reservoir properties was essentially circumvented by using two contiguous patterns, one with dry combustion and another with wet combustion. This test found that, with wet combustion, the volumetric sweep was improved to a great extent. This indirectly implies an increase in oil recovery. Furthermore, the air requirement for a specific volume of reservoir was reduced. This reduced the operating cost and improved the economics. Because of these encouraging results, the possible advantages of using wet combustion should be explored.

Air Injection Rate. According to Nelson and McNeil,¹²² the air injection rate depends on the desired rate of advance of the burning front. A satisfactory burning rate was stated to be 0.125 to 0.5 ft/D. In the design method proposed by these authors, a maximum air rate is first determined, based on the minimum burning rate of 0.125 ft/D. They recommended a time schedule such that the air rate would be increased gradually to the maximum rate, held at this rate for a definite period, and then reduced gradually to zero. The Midway Sunset, CA, project of Chanslor-Western⁹⁹ used a burning rate of 1 in./D (0.08 ft/D). Gates and Ramey¹²⁴ found that the air rate should provide a minimum rate of burning front advance of 0.15 ft/D or an air flux of at least 2.15 scf/hr-sq ft at the burning front.

WAR. The reported WAR in various field projects ranged from 0 (for dry combustion) to 2.8 bbl/10³ scf. The choice of WAR depends on water availability, quality of the water available, well injectivity, and economic considerations. Combustion tube experiments, properly designed and executed, should be helpful.

Well Completion

Special well completions are needed for injectors and producers to withstand the high temperatures in steamfloods, and to withstand the corrosive environment as well in firefloods.

According to Gates and Holmes,¹⁴² wells used in steam operations should be completed with due consideration of heat loss with thermal stresses. In deep wells, tubular goods with high qualities, such as the normalized and tempered P-105 tubing and P-110 casing, should be used if the tubing and casing are not free to expand. Thermal stress can be minimized by the proper use of expansion joints. Thermal packers should be used on steam injection wells and deep wells undergoing cyclic steaming. The cement should include a thermal strength stabilizing agent, an insulating additive and a bounding additive.

For firefloods, Gates and Holmes¹⁴² felt that steel casing and tubing such as J-55 is suitable for injectors. These wells can be completed with normal Portland ce-

ment, with high-temperature cement placed opposite and about 100 ft above the pay zone. The high-temperature cement recommended for the injectors is calcium aluminate cement (with or without silica flour), pozzolan cement, or API Class G cement (with 30% silica flour). If spontaneous ignition occurs, the use of cemented and perforated liners is required to prevent well damage resulting from burnback into the borehole. The producers should be completed to withstand relatively high temperatures and severe corrosion and abrasion. These authors recommended the use of gravel-flow pack, and stainless steel 316 for both liner and tubing opposite the pay zone.

The well completion methods for injectors and producers in the various steamflood and fireflood projects, detailed by Chu^{61,63} previously, are given in Table 46.14.

Field Facilities

Steamflood Facilities

Steam Generation and Injection. Most of the steam injection projects use surface steam generators. The major difference between oilfield steam generators and industrial multitube boilers is the ability to produce steam from saline feedwater with minimum treatment. Other features include unattended operation, portability, weatherproof construction, and ready accessibility for repairs. The ability to use a wide variety of fuels including lease crude is also an important requirement. The capacity of steam generators used in steamflood projects usually ranges from 12 to 50×10⁶ Btu/hr, with 50×10⁶ Btu/hr becoming the industry standard in California.

With surface steam generators, the steam goes from the generators to the injection wells through surface lines. Most surface steam lines are insulated with a standard insulation with aluminum housings. The steam is split into individual injectors through a header system using chokes to reach critical flow. This procedure requires that the steam achieve sonic velocity, which, under one field condition,⁶⁸ calls for a pressure drop of about 55% across the choke. The chokes are sized to each other to give the desired flow rate into each injector. As long as the pressure drop is greater than 55%, the flow rate will be independent of the actual wellhead injection pressure.

A recent development is the use of downhole steam generators to eliminate wellbore heat losses in deep wells. There are two basic designs, which differ on the method of transferring heat from the hot combustion gases to produce steam.¹⁴³ In one design, the combustion gas mixes directly with feed water and the resulting gas/steam mixture is injected into the reservoir. Because of this, the combustion process takes place at the injection pressure. In another design, there is no direct contact between the combustion gas and water, just as in the surface generators. The combustion gas returns to the surface to be released after giving up much of the heat to generate steam. A lower pressure than injection pressure can be used in this case.

Still another new development is cogeneration of steam and electricity.¹⁴⁴ The effluent gas from a combustor is used in a gas turbine, which drives an electrical generator. The exhaust gas from the turbine is then used in steam generators to produce steam for thermal recovery purposes.

TABLE 46.14—WELL COMPLETION FOR STEAMFLOODS AND FIREFLOODS

Injectors	Steamfloods	Firefloods
Casing	Grades: J-55, K-55, and N-80 Sizes: 4½, 5½, 6¾, 7, and 9¾ in. Tensile prestressing of casing in deep wells	Grades: J-55 and K-55 Sizes: 4½, 5½, 7, and 8½ in. across the pay zone
Openhole or perforated completions	Both openhole completions with slotted liners and solid-string completion with jet perforations have been reported. Liner sizes: 4½, 5½, or 7 in. Perforations: ¼ or ½ in., one or two per foot, or one-half per foot Some with stainless steel wire-wrapped screens.	Perforated completion more prevalent than openhole completion with or without liners. Liner sizes: 3½ or 5½ in. Perforations: ¼ or ½ in. (two or four per foot)
Cement	Class A, G, and H cement with silica flour (30 to 60% of dry cement).	Use of high-temperature cement prevalent.
Gravel packing	Use not prevalent.	Use not prevalent.
Tubing	Tubing insulations used in deep wells: asbestos with calcium silicate, plus aluminum radiation shield; or jacketed tubing with calcium silicate.	Tubing used for air injection or as a thermowell. In wet combustion, various ways have been used for injection of air and water.
Producers		
Casing	Grade: K-55 Sizes: 4½, 5½, 6¾, 7, and 8¾ in. Tensile prestressing of casing in deep wells	Grades: H-40, J-55, and K-55 Sizes: 5½, 7, 8¾, and 9¾ in.
Openhole or perforated completions	Both openhole completion with slotted liners and solid-string completion with jet perforations have been reported. Liner sizes: 4½, 4¾, or 6¾ in. Slot sizes: 40, 60, or 60/180 mesh Perforations: ½ in., four per foot Some with stainless steel wire-wrapped screens.	Openhole completion with or without slotted liners and perforated completion are equally prevalent. Liner sizes: 4¾, 5½, or 6¾ in. Slot sizes: 60-mesh, 0.05, 0.07, or 0.08 in. Perforations: ½ in. (two or four per foot)
Cement	Class G and H cement with silica flour (30 to 60% of dry cement).	Use of high-temperature cement was reported.
Gravel packing	Use more prevalent than in injectors. Gravel size: 6/9 mesh flow-packed.	Use more prevalent than in injectors. Gravel sizes: 20/40 or 6/9 mesh, flow- or pressure-packed.
Tubing	Tubing for rod pump.	Tubing for rod pump, to serve as a thermowell, or for cooling water injection.

Water Treatment. The feedwater treatment for steam generation consists mainly of softening, usually through zeolite ion exchange. Some feedwaters may require filtration and deaeration to remove iron. Still others may need to use KCl for control of clay swelling and chlorine to combat bacteria. Facilities for oil removal also will be needed if the produced water is to be reused as feedwater for steam generation.

Fireflood Facilities

Ignition Devices. In many fields, the reservoir temperature is so high that spontaneous ignition would occur only a few days after starting air injection. In some projects, steam, reactive crude, or other fuels will be added to help ignition.

Many other fields need artificial ignition devices, which include electrical heaters, gas burners, and catalytic ignition systems. The various ignition methods, including equipment and operational data, have been discussed by Strange.¹⁴⁵

Air Compressors. The air compressors can be gas engine or electrical motor driven. Depending on the total

injection rate the compressor needs to supply and the output pressure needed, the capacity of the compressors can range from 1.0 to 20.0×10^6 scf/D, and the power rating can range from 300 to 3,500 hp.

Monitoring and Coring Programs

Monitoring Programs

A thermal recovery project could be a complete failure economically and still be considered a success if it could provide useful information on the reservoir performance under steamflood or fireflood. A properly designed monitoring program carried out during the project and coring programs during and after the project are important in providing the information necessary for evaluating steamflood or fireflood performance.

The Sample, Control, and Alarm Network (SCAN) automation system installed by Getty in the Kern River field¹⁴⁶ illustrates how a large steam injection operation can be monitored. This system consists of a devoted central computer that monitors 96 field sites. At these sites, the production rates of more than 2,600 producers and the operating rates of 129 steam generators are gathered. The SCAN performs several functions.

1. It automatically schedules and controls well production tests at each site.
2. It monitors results of well production tests, steam generator operating rates, flow status, and injection status of producers, valve positions during well tests, and various status contact checks.
3. It sounds the alarm upon any malfunctioning at a field site or a steam generator.
4. It reports necessary operating information routinely on a daily, weekly, or monthly basis, and other special reports on demand from the operator.

The Silverdale, Alta., fireflood project of General Crude¹³⁴ also uses an automatic data collection system. Differential pressure transducers, thermocouple-amplifier transducers, pressure transducers, and motor load transducers are used to measure and record data at each well. These data are transmitted to a central system, which can be interrogated and can indicate any alarm situation when pressures, temperatures, or flow rates fall outside certain specified ranges.

Not all thermal projects call for elaborate automatic monitoring programs. The following program used in the Bodcau, LA, fireflood project of Cities Service-DOE¹⁴⁷ typifies one needed for a small-scale pilot.

1. Gas production rates, useful for mass balance calculations, were measured monthly. Monthly analysis of the produced gas gave data for the calculation of the oxygen utilization efficiency.
2. Oil and water production rates were measured at least twice each month.
3. Flow line temperatures were measured daily. These temperatures, in conjunction with the gas production rates, were useful in determining the amount of quench water needed at the producers.
4. Downhole temperature profiles were taken monthly at the observation wells. These profiles helped to delineate the development of the burned volume.

Coring Program

Drilling core holes could be very expensive, depending on the depths of the pay zones. However, a judiciously designed and properly executed coring program, either during a thermal project or afterward, could provide valuable information on the project performance. Such a program can give the following information: (1) residual oil saturation (ROS) after steamflood or fireflood, (2) vertical sweep of the injected steam or burned volume, (3) areal sweep of the steam front or burning front, (4) maximum temperature distribution, both areally and vertically, and (5) effective permeability of the rock, and whether any deposits formed during the process could have reduced the flow capacity.

A typical coring program, used for postmortem evaluation in the Sloss, NE, fireflood project,⁷⁹ is summarized next.

Core Analyses. Porosity, permeability, and oil saturations were measured on each foot of the recovered cores. Oil saturations were determined by the routine Dean-Stark extraction and weight loss method, and the infrared absorption method.

Log Analyses. Compensated formation density and dual-induction laterolog logs were run in the core holes to determine porosity and oil saturation.

Photographs and Visual Examination. Whereas black-and-white photographs were found to be rather useless, ultraviolet photographs gave an excellent picture as to where the oil was removed by the burning process. The absence of oil also could be seen by visual examination. In some intervals, the reddish color of the core indicated that the core had been subjected to a temperature high enough for iron oxidation.

Mineral Analyses of the Cores. Various minerals, including glauconite, illite, chlorite, and kaolinite, underwent permanent changes with the temperature increase. The maximum temperature to which the core samples had been exposed could be determined from the form and color of these minerals.

Microscopic Studies. The scanning electron microscope was used to study anhydrite formation and clay alteration in the core samples, which had been subjected to high temperatures.

Tracers

The use of tracers helped to monitor fluid movement and interpret areal coverage in individual steamflood patterns. According to Wagner,¹⁴⁸ preferred aqueous-phase or gaseous-phase tracers include radioisotopes, salts with detectable cations and anions, fluorescent dyes, and water-soluble alcohols. Radioactive tracers include tritium, tritiated water, and krypton-85. Other tracers include ammonia, air, sodium nitrite, sodium bromide, and sodium chloride.

Operational Problems and Remedies

Operational problems plaguing steamflood and fireflood projects and their remedies, previously detailed by Chu,^{61,63} are summarized next.

Problems Common to Steamfloods and Firefloods

Well Productivity. Production of the highly viscous crude may be extremely low before the arrival of the steam front or burning front. The production rate can be improved by injecting light oil as a diluent, hot oil treatment, cyclic steam injection, or burning at the producers.

When producer temperature exceeds 250°F, pump efficiency decreases to a great extent because of hot produced fluids flashing to steam or direct breakthrough of the injected steam or flue gas. The best remedy is to plug off the hot zone and redirect the steam or flue gas to the oil section before entering the wellbore.

Sanding. Sanding can be severe even in steamflood projects. The remedies include the HypercleanTM technique, foamed-in tight-hole slotted liners, a sodium aluminate sand consolidation technique, and the use of phenolic-resin gravel packing.

In firefloods, sanding is particularly severe if the sand is extremely unconsolidated. The erosion can be aggravated further by coke particles and high gas rates. Sandblasting could require frequent pulling of wells and replacement of pumps.

Emulsions. In steamfloods, emulsions sometimes can be broken easily by chemical treatment. The problem could

Fig. 46.13—Production history of cyclic steam stimulation, TM sand, Huntington Beach offshore field, CA.

become severe if the emulsion is complicated with the solids produced and with the continuously changing nature of the produced fluids.

Emulsions found in fireflood projects are formed of heavy oil, cracked light ends, quench and formation water, solids, and possibly, corrosion products. They can become a continual and major problem in some projects, and require expensive emulsion breakers.

Problems Plaguing Steamfloods Only

Steam Placement. The lack of control of steam placement during steam stimulation is a major problem in producers with liner completions. The use of solid string completions will help reduce the problem.

Steam Splitting. The uneven splitting of steam in a two-phase regime can cause significant differences in steam quality into different injectors. This can be corrected by modifying the layout of the steam line branching system.

Oil viscosity at 125°F, cp	682
Oil saturation at start, %	75

Problems Plaguing Firefloods Only

Poor Injectivity. Various substances can cause losses in injectivity for the air injectors. If identifiable, these problems can be remedied by appropriate means. Injector plugging by iron oxide can be reduced by injecting air into the casing and bleeding it through the tubing. Asphaltene buildup can be reduced by squeeze washing with asphaltene solvent. Emulsion formed in situ can be reduced by emulsion breakers. Scale formation caused by barium and strontium sulfate can be reduced by an organic phosphate. The injection of NuTri™ (trichloromethylene) and acidizing are useful in improving the injectivity.

Corrosion. Corrosion can be mild or serious and is caused by simultaneous injection of air and water, production of acids, sulfur, oxygen, and CO₂. Corrosion inhibitors are needed regularly.

Exploration Hazards. To minimize explosion hazards in the air injection system, an explosion-proof lubricant should be used. Flushing of the interstage piping with a nitrox solution is necessary.

Case Histories

Many thermal recovery projects have been reported in the literature. The following describes a number of selected projects and gives the reasons for their selection.

Steam Stimulation Operations

Huntington Beach, CA (Signal)¹⁴⁹—Typical Operation. The steam stimulation project was conducted in the TM sand, in the Huntington Beach offshore field, Orange County, CA. This project typifies the behavior of a heavy-oil reservoir under cyclic steam stimulation. The reservoir properties are given in Table 46.15.

Steam injection was started in nine producers in Sept. 1964, resulting in a large increase in oil production. This early success prompted the expansion of the project by drilling wells on 5-acre spacing. The number of wells increased from 9 in 1964 to 35 in 1969. The performance of the steam stimulation project during the 1964–70 period is shown in Fig. 46.13. With steam stimulation and with the almost quadrupling of the number of wells, the oil rate increased more than 10-fold, from 125 B/D oil in 1964 to about 1,500 B/D oil in 1970.

The performance of steam stimulation normally deteriorates as the number of cycles increases. As shown in Table 46.16, the OSR changed from the range of 3 to 3.8 bbl/bbl for the first two cycles to the range of 2.4 to 2.5 bbl/bbl for the third and fourth cycles.

Fig. 46.14 shows how oil production in one well decreases during a cycle and how it varies from one cycle to another.

Paris Valley, CA (Husky)¹⁵⁰—Co-Injection of Gas and Steam. A wet combustion project was initiated at Paris Valley, which is located in Monterey County, CA. Before the arrival of the heat front, the producers were stimulated with steam. A special feature that made this project interesting was the co-injection of air and steam in three of the stimulation cycles. The reservoir properties are given in Table 46.17.

Fig. 46.14—Oil production rate, Well J-128, Huntington Beach offshore field.

In Table 46.18, Cycles 3 and 5 of Well 20 and Cycle 7 of Well 3 used air-steam injection. For Well 20, oil production in Cycle 3 was 4,701 bbl while that in Cycle 2 was 2,449 bbl. Thus, with air-steam injection, oil production increased by 92%. A similar increase was noticeable for Cycle 5 of Well 20 and Cycle 7 of Well 3 when compared with their respective preceding cycles, which used steam only.

Steamflood Projects

Kern River, CA (Getty)⁶⁸⁻⁷⁰—Largest Steamflood. The Kern River field is located northeast of Bakersfield, CA, in the southeastern part of the San Joaquin Valley. Getty Oil Co.'s steam displacement operation in this field is the largest in the world, based on a 1982 survey.¹³ According to this survey, the thermal oil production rate was 83,000 B/D in an area of 5,070 acres.

The Kern River formation consists of a sequence of alternating sand and shale members. The reservoir properties are given in Table 46.19.

The Kern River field was discovered in the late 1890's. In the mid-1950's, bottomhole heaters were used to improve the oil productivity. In Aug. 1962, a 2.5-acre normal five-spot hot waterflood was started. Results showed that this process was technically feasible but economically unattractive. In June 1964, the hot waterflood pilot was converted to a steam displacement test and the number of injectors was increased from the original 4 wells to 47 wells. Continued expansion through the years has increased the number of injectors to 1,788 wells, with 2,556 producers by 1982. The original Kern project and some later expansions are shown in Fig. 46.15. The steam displacement operation was in general conducted in 2.5-acre five-spot patterns.

Getty Oil Co.'s steam displacement operation includes many projects. For illustration purposes, the Kern project is presented here with a map showing the well patterns (Fig. 46.16) and a figure showing the injection and

production history of the four-pattern pilot (Fig. 46.17). In this project, the cumulative SOR was 3.8 bbl/bbl and the production rate reached 100 B/D of oil per pattern. Core hole data before and after the steamflood showed an oil recovery of 72% and also a very high areal sweep efficiency.

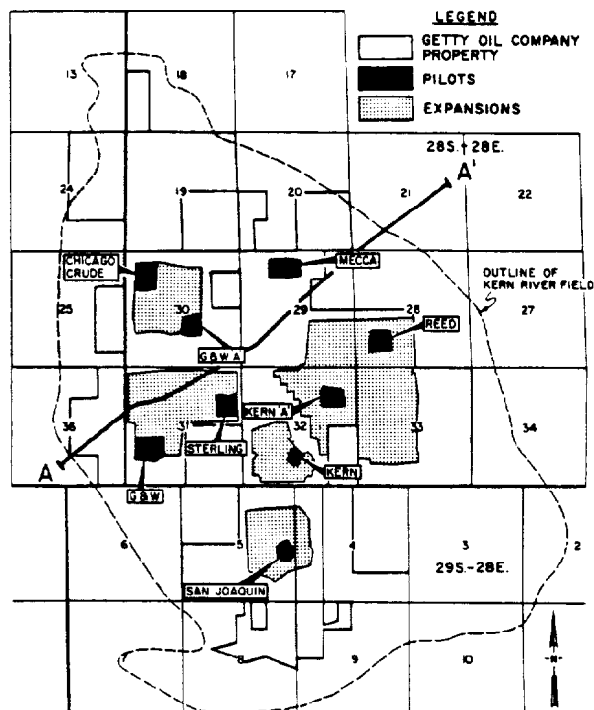

Brea, CA (Shell)¹²⁵—Steam Distillation Drive, Deep Reservoir, Steeply Dipping. A steam distillation drive was initiated in 1964 in the Brea field, which is located about 25 miles east of Los Angeles. This project is interesting because the oil is relatively light with low viscosity, and the reservoir is steeply dipping at a great depth. The reservoir properties are summarized in Table 46.20.

The dipping reservoir is seen clearly in Fig. 46.18. The injectors are located updip, as shown in Fig. 46.19. Because of the depth, insulated tubing was used for the injectors. This figure also shows the area of temperature response and production response. The injection and production rates are given in Table 46.20. As of Dec. 1971, the steam rate was 1,010 B/D water and the oil rate was 230 B/D, giving an estimated SOR of 4.4 bbl/bbl.

Smackover, AR (Phillips)^{82,83}—Reservoir With Gas Cap. The Smackover field is located in Ouachita County, AR. The steamflood pilot, conducted in the Nacatoch sand, is worth mentioning because the reservoir has a gas cap thicker than the oil sand itself. This gas cap can be seen readily in the log and coregraph of Sidum Well W-35 (Fig. 46.21). The reservoir properties are given in Table 46.21.

Fig. 46.20—Injection and production history, Brea steam distillation pilot.

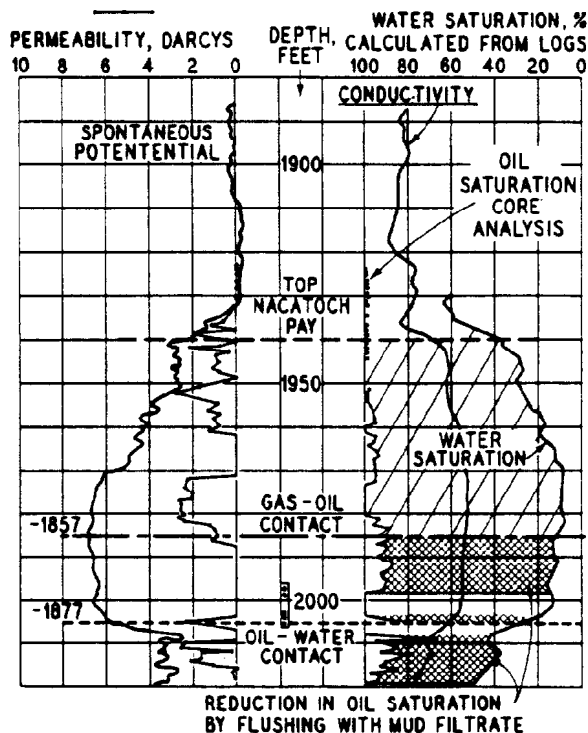

Fig. 46.21—Log and coregraph, Sidum Well W-35, Smackover field, AR.

Fig. 46.22 is a map of the 10-acre five-spot pilot, which was later expanded to a 22-acre nine-spot pattern by adding four more producers. As shown in Fig. 46.23, steam injection started in Nov. 1964 and stopped in Oct. 1965. The oil production continued long after steam injection stopped. As of Aug. 1970, the additional oil produced by steamflood was 207,000 bbl. With total steam injection of 860,000 bbl, the cumulative SOR was 4.14 bbl/bbl.

The temperature log in Fig. 46.24 shows that steam goes to the gas cap. It can be concluded that the increase in oil production was not caused by frontal displacement. Rather, the oil zone temperature increased because of conduction and convection from the gas cap, thus reducing the oil viscosity and increasing the oil production.

Slocum, TX (Shell)^{89,90}—Reservoir With Water Sand. The Slocum field is located in southern Anderson County in northeast Texas. The steamflood project interests us since it is conducted in an oil reservoir underlain by a water sand, as shown in the type log (Fig. 46.25). The reservoir properties are given in Table 46.22.

The field was discovered in 1955. Only about 1% of OOIP was produced by primary operation. A small steamflood pilot using a $\frac{1}{4}$ -acre normal five-spot pattern showed encouraging results. A full-scale seven-pattern project was initiated in 1966–67, with 5.65-acre, 13-spot patterns (Fig. 46.26).

Both injectors and producers were completed a few feet into the water sand. Steam moves horizontally through the water layer, rises vertically into the oil layer, and displaces oil that had been heated and mobilized. The oil then falls down and subsequently is swept toward the producers. The injection and production history is shown in Fig. 46.27.

Street Ranch, TX (Conoco)¹⁵¹—Extremely Viscous Tar, Fracture-Assisted Steamflood. The Street Ranch pilot was conducted in the San Miguel-4 tar sand reservoir located in Maverick County, TX. This pilot proved the technical feasibility of the fracture-assisted steamflood technology (FAST) in recovering extremely viscous heavy oils and tars. The reservoir properties are given in Table 46.23. The pilot used a 5-acre inverted five-spot pattern. The four producers were fractured horizontally with cold water, steam stimulated, perforated, and resteamed. The injector then was fractured horizontally to establish communication with the producers. The pilot consisted of three

phases: (1) fracture preheat, (2) matrix steam injection, and (3) heat scavenging with water injection. The tar production and steam/tar ratio during the 31-month history are shown in Figs. 46.28 and 46.29, respectively. The average tar production rate was 185 B/D and the cumulative steam/tar ratio was 10.9 bbl/bbl. Postpilot core holes showed residual tar saturations as low as 8% and an average recovery efficiency of 66%.

Lacq Supérieur, France (Elf Aquitaine)¹⁵²—Carbonate Reservoir. The Lacq Supérieur field is on the north side of the Pyrenees Mts. in southwest France. The steam-flood pilot is unique because it was conducted in a carbonated, dolomitized, and highly fractured reservoir. The reservoir properties are given in Table 46.24.

The pilot was located in the central part of the fractured limestone zone, near the top of an anticline. The pattern area is 35 acres, defined by six old producers, as shown in Fig. 46.30. The injector was the only one drilled for the pilot. Steam injection started in Oct. 1977. Oil production started to increase, only 3 months after steam injection began. The production history is shown in Fig. 46.31. By June 1980, incremental oil production amounted to 176,000 bbl with a cumulative steam injection of 926,000 bbl. The cumulative SOR is 5.26 bbl/bbl. This

pilot showed that a strongly fissured reservoir can be exploited efficiently by the steamflood process, as if it were a homogeneous reservoir. The dissociation of the carbonate rocks by steam apparently produced no unfavorable effects. Rather, the CO_2 evolved might have some positive effect on the process efficiency.

Fireflood Projects

Suplacu de Barcau, Romania (IFP-ICPP)¹²⁰—Largest Fireflood. The Suplacu de Barcau field lies in northwestern Romania. This is reportedly the largest fireflood project in the world, producing nearly 6,563 B/D of 15.9°API oil. The reservoir properties are given in Table 46.25.

The project started with a pilot in 1964 using a 1.24-acre inverted five-spot pattern that was later expanded into a 4.94-acre inverted nine-spot pattern. This was followed by a semicommercial operation in the period 1967–71 with eight 9.88-acre inverted nine-spot patterns. This operation further expanded into full commercial operation, first retaining the nine-spot patterns with the same spacing, and later changing to linedrive operation. The original pilot and later expansions are shown in Fig. 46.32. Injection wells numbered 38 in 1979 with 20 using alternate air and water injection and the balance using straight air. The production history is given in Fig. 46.33. The WAR was 0.089 to 0.178 bbl/ 10^3 scf. As of 1979, the air injection rate was $63,600 \times 10^3$ scf/D. With an oil rate of 6,563 B/D, the AOR was estimated to be 9.7×10^3 scf/bbl.

West Heidelberg, MS (Gulf)^{114,115}—Deepest Fireflood. The West Heidelberg field is located in Jasper County in eastern Mississippi. With a depth exceeding 2 miles, it is the deepest fireflood project, or the deepest thermal project, for that matter. The Cotton Valley formation has eight sands. The fireflood was conducted in Sand No. 5. The reservoir properties are given in Table 46.26.

As shown in the structure map of Sand No. 5 (Fig. 46.34), only one injector was used, near the top of the structure, with seven producers located downdip. The injection and production history is given in Fig. 46.35. It can be estimated from this figure that, during the period 1973–76, the average air injection rate was about 900×10^3 scf/D whereas the average oil production rate was about 400 B/D. This gives an AOR of only 2.25×10^3 scf/bbl.

Gloriana, TX (Sun)^{116,118}—Thinnest Reservoir Produced by a Fireflood. The Gloriana field is in Wilson County, TX. The fireflood took place in the Poth "A" Sand. It is possibly the thinnest reservoir that has ever been produced by a fireflood. The reservoir properties are given in Table 46.27.

The field originally was developed on 40-acre spacing. A new well, Well 2-8, was ignited in May 1969. Well 2-5, a producer, burned out and was converted to air injection in May 1971. These wells, along with other wells,

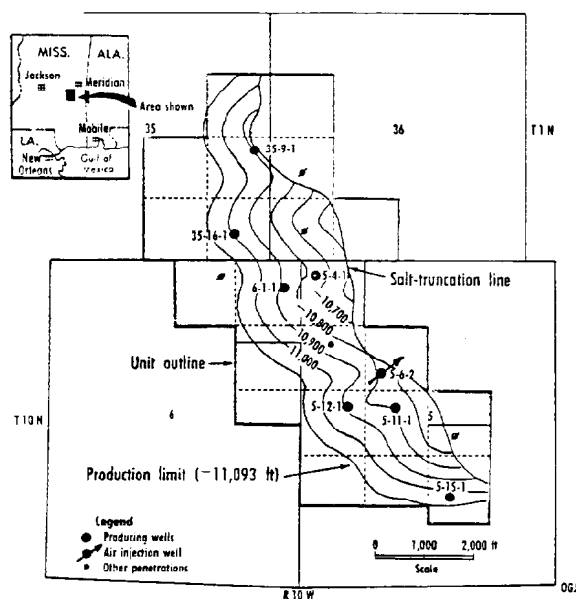

Fig. 46.34—Structure map of Sand No. 5, West Heidelberg field, MS.

are shown in the isopachous map in Fig. 46.36. The injection and production histories are given in Figs. 46.37 and 46.38, respectively. Air injection stopped in Dec. 1974 when the oil production rate declined to the economic limit.

Sloss, NE (Amoco) 77-79—Wet Combustion, Tertiary Recovery. The Sloss field is located in Kimball County, NE. The pilot used a wet combustion process in a previously waterflooded reservoir. Here, the pay is thin and deep, the oil is light, the viscosity is low, and the oil satu-

ration at the start of the flood was low. The reservoir properties are given in Table 46.28.

The fireflood started in 1967 with six 80-acre five-spots. Additional wells were included so that it covered 960 acres in its final stage. The pilot area is shown in Fig. 46.39. The injection and production data in the 4½-year period of its operation are given in Figs. 46.40 and 46.41, respectively. Between Feb. 1967 and July 1971, total air injected was $13,754 \times 10^6$ scf and water injected was $10,818 \times 10^3$ bbl, giving a WAR of 0.79 bbl/ 10^3 scf. The total oil production was 646,776 bbl. This gives an AOR of 21.3×10^3 scf/bbl. The areal sweep by the greater-than-350°F zone was 50%. Combining with a vertical sweep of 28%, the volumetric sweep was only 14%.

Asphalt Ridge, UT (DOE) 130—Extremely Viscous Tar, Combination Reverse/Forward Combustion. The Northwest Asphalt Ridge deposit is located in northeast Utah, near the city of Vernal. The fireflood conducted

Fig. 46.35—Injection and production history, West Heidelberg field.

Fig. 46.36—Isopachous map, net oil, Poth "A" sand, Gloriana field, TX.

in this deposit is interesting because it attempted to use a combination of reverse and forward combustion for the recovery of oil from tar sands. The reservoir properties are given in Table 46.29.

The U.S. DOE conducted two fireflood tests in the Asphalt Ridge area. The first, conducted in 1975, demonstrated the feasibility of using reverse combustion to recover oil in the tar sand. The second tested a combination of reverse combustion and forward combustion during the period from Aug. 1977 to Feb. 1978. The location of the test sites and well arrangements are shown in Fig. 46.42. In both tests, the line drive was on a small area of 120×40 ft, covering only 0.11 acres. In the second test, several echoings of reverse and forward combustion phases were noticed in the northwest area, as seen from the temperature variations at observation Well 203 (Fig. 46.43). The reverse combustion phase had an areal sweep of 95% and vertical sweep of 91%, giving a volumetric sweep of 86%. The echoing forward combustion phase had an areal sweep of 75% and vertical sweep of 44%, giving a volumetric sweep of only 33%. The produced oil was of better quality than the original bitumen, with the pour point reduced from 140 to 25°F and the amount of residue lowered from 62 to 35 wt%.

Forest Hill, TX (Air Products-Greenwich)¹⁵³—**Oxygen-Enriched Air.** The Forest Hill field is located in Wood County, TX. The significance of the field test lies in the use of oxygen-enriched air for the fireflood. The reservoir properties are given in Table 46.30.

The field was on primary production in 1964. Air injection started in 1976. One of the air injectors was switched to oxygen-enriched air in 1980. The test site is shown in Fig. 46.44. As seen in Fig. 46.45, during a 2-year period, the oxygen concentration in the injected gas ranged from 21 to 90%. The test showed that essentially pure oxygen can be handled and injected safely in a typical oilfield environment. Short of any definitive comparison, the test only hinted that using enriched air might produce oil faster than using air only.

Thermal Properties

Only some selected thermal properties of the rock/fluid systems encountered in the thermal recovery projects will be presented briefly. A more complete compilation of tables and figures has been included in Appendix B of Ref. 154.

Oil Viscosities

The viscosity-temperature relationships for representative heavy-oil deposits are shown in Fig. 46.46. Oil viscosities should be measured experimentally. In the absence of experimental data, the viscosities can be estimated by charts (Fig. 46.47 to 46.49)¹⁵⁵⁻¹⁵⁷ and equations.¹⁵⁸

Beggs and Robinson¹⁵⁸ suggested the following equations for estimating viscosities of live oils. Dead-oil viscosity is first calculated:

$$\mu_{od} = 10^X - 1, \dots\dots\dots (74)$$

where μ_{od} equals the viscosity of dead oil (gas-free oil) at T , cp.

$$X = YT^{-1.163}, \dots\dots\dots (75)$$

$$Y = 10^Z, \dots\dots\dots (76)$$

and

$$Z = 3.0324 - 0.02023 \gamma_o, \dots\dots\dots (77)$$

where γ_o equals the oil gravity, °API, and T is the temperature, °F. Live-oil viscosity is calculated next.

$$\mu = A\mu_{od}B, \dots\dots\dots (78)$$

where

$$A = 10.715(R_s + 100)^{-0.515}, \quad (79)$$

$$B = 5.44(R_s + 150)^{-0.338}, \quad (80)$$

and R_s is the solution gas/oil ratio, scf/STB.

Relative Permeability Curves

Relative permeability data should be determined experimentally. In the absence of experimental data, the following equations may be used for rough estimation. According to Brooks and Corey,¹⁵⁹

$$k_{rw} = (S_w^*)^5, \quad (81)$$

$$k_{ro} = (1 - S_w^*)^2 (1 - S_w^{*2}), \quad (82)$$

and

$$S_w^* = \frac{S_w - S_{iw}}{1 - S_{iw}}, \quad (83)$$

where S_{iw} is the irreducible water saturation, percent.

Fig. 46.47—Dead oil viscosity.

Fig. 46.48—Universal temperature/viscosity chart.

Fig. 46.49—Live oil viscosity.

According to Somerton,¹⁶⁰ for unconsolidated sand,

$$S_{iw} = 0.211 + 2.0 \times 10^{-4} T + 1.1 \times 10^{-6} T^2, \dots (84)$$

where T is the temperature, °F.

The effect of temperature on irreducible water saturation and relative permeability of unconsolidated sands has been studied by Poston *et al.*¹⁶¹ Some of their results are given in Figs. 46.50 through 46.52. The effect of temperature on relative and absolute permeabilities of consolidated sandstones has been studied by Weinbrandt *et al.*¹⁶² Some of their results are given in Figs. 46.53 through 46.56.

PV Compressibility

The compressibility of unconsolidated, Arkosic sands was measured by Sawabini *et al.*¹⁶³ Fig. 46.57 shows that the effective PV compressibility lies in the range between 10^{-4} and 10^{-3} psi⁻¹, about 2 to 3 orders of magnitude higher than the normally accepted figure of 10^{-6} psi⁻¹ for consolidated sandstones. In Fig. 46.57, p_{to} is the total overburden pressure, psi, and p_p is the pore pressure, psi.

Thermal Conductivity

Thermal behavior of unconsolidated oil sands was studied by Somerton *et al.*¹⁶⁴ Fig. 46.58 shows how thermal conductivity of Kern River oil sands varies with brine saturation.

Vaporization Equilibrium

Vaporization equilibrium of an oil fraction is described by the equilibrium vaporization constant, K , which is defined as

$$K = \frac{y}{x}, \dots (85)$$

where y is the mol fraction in vapor phase and x is the mol fraction in liquid phase.

Poettmann and Mayland¹⁶⁵ in 1949 published a series of charts on equilibrium constants of various oil fractions with normal boiling points of 300°F, 400°F, etc., up to 1,000°F. To illustrate how K values vary with temperature and pressure, the figure for normal boiling point=500°F is shown in Fig. 46.59.

More recently, Lee *et al.*¹⁶⁶ presented equilibrium constants of oil fractions with 100°F boiling ranges. For example, Fraction 1 has the boiling range up to 300°F, Fraction 2 boiling between 300 and 400°F, and Fraction 6 boiling above 700°F. Figs. 46.60 and 46.61 show the effects of pressure and temperature, respectively, on the K values for these oil fractions as well as N₂, CH₄, and CO₂.

Chemical Kinetics

Chemical reactions taking place in an in-situ combustion process are considered to fall into three types: (1) low-temperature oxidation, (2) fuel deposition or coke formation, and (3) combustion. The kinetic data of these three types of reactions reported by various authors have been summarized in the paper by Fassihi *et al.*¹⁶⁷ and will not be reproduced here.

Steam Properties

An abbreviated steam table¹⁶⁸ is given in Table 46.31.

Nomenclature

a = air requirement, 10^6 , scf/acre-ft
 A = heated area at time t , sq ft, or
quantities defined by Eqs. 9 and 79
 A' = quantity defined by Eq. 13
 B = quantities defined by Eqs. 10 and 80
 B' = quantity defined by Eq. 14
 C_m = fuel content, lbm/cu ft
 C_o = heat capacity of oil, Btu/lbm-°F, or
concentration of oil, lbm mol/cu ft
 C_r = heat capacity of rock, Btu/lbm-°F
 C_s = heat capacity of steam, Btu/lbm-°F
 C_w = heat capacity of water, Btu/lbm-°F
 C_{O_2} = concentration of oxygen, lbm mol/cu ft
 C_1 = quantity defined by Eqs. 58 and 60
 C_2 = quantity defined by Eqs. 59 and 61
 D = depth, ft
 E = activation energy, Btu/lbm mol
 E_h = thermal (heat) efficiency, fraction
 E_{O_2} = oxygen utilization efficiency, fraction
 E_r = overall oil recovery
 E_{Ru} = recovery efficiency in the unburned
region, fraction
 E_{vb} = volumetric sweep efficiency of the
burning front, fraction
 f_{s1} = steam quality at the beginning of the
pipe segment, fraction

f_{s2} = steam quality at the end of the pipe
segment, fraction
 $f(t)$ = transient heat conduction time function
for earth, dimensionless
 F_{ao} = AOR
 F_{cc} = CO₂/CO ratio in produced gas
 F_{HC} = atomic H/C ratio
 F_J = ratio of stimulated to unstimulated
productivity indices, dimensionless
 F_{so} = steam/oil ratio, STB/STB
 F_{wor} = total produced WOR, STB/STB
 h = pay thickness, ft, or convection heat
transfer coefficient, Btu/hr-sq ft-°F
 h' = convection heat transfer coefficient
based on insulation outside surface,
Btu/hr-sq ft-°F
 h_f = enthalpy of liquid water at T above
32°F, Btu/lbm
 h_t = total thickness of all sands, ft
 H_{og} = enthalpy of oil and gas Btu/lbm
 H_w = enthalpy of water carried by oil based
on a STB of oil, Btu/STB oil
 H_{wR} = enthalpy of water at reservoir tempera-
ture, Btu/lbm
 H_{ws} = enthalpy of water at steam tempera-
ture, Btu/lbm
 i_{at} = cumulative air injection, 10^3 scf
 i_s = steam injection rate, B/D
 I = radiation heat transfer coefficient,
Btu/hr-sq ft-°F

I' = radiation heat transfer coefficient based on insulation outside surface, Btu/hr-sq ft-°F	r_{to} = outside radius of pipe, ft
J_c = unstimulated (cold) productivity index, STB/D-psi	r_w = well radius, ft
k = absolute permeability, md	R = gas constant
k' = pre-exponential factor	R_s = solution GOR, scf/STB
k_{hca} = thermal conductivity of the casing material, Btu/hr-sq ft-°F	R_t = total produced GOR, scf/STB
k_{hce} = thermal conductivity of the cement, Btu/hr-ft-°F	S_g = gas saturation, fraction
k_{hcf} = thermal conductivity of the formation, Btu/D-ft-°F	S_{io} = irreducible oil saturation, fraction
k_{hin} = thermal conductivity of insulation material, Btu/hr-ft-°F	S_{iw} = irreducible water saturation, percent
k_{ho} = overburden thermal conductivity, Btu/hr-ft-°F	S_o = oil saturation at start, fraction
k_{ro} = relative permeability to oil, fraction	S_{oi} = initial oil saturation, fraction
k_{rw} = relative permeability to water, fraction	S_{wi} = initial water saturation, fraction
K = equilibrium vaporization constant	S_w^* = normalized water saturation, fraction
L = pipe length, ft	t = time since injection, hours
L_s = latent heat of steam, Btu/lbm	t_c = critical time, hours
L_{v1} = latent heat of vaporization at top of interval, Btu/lbm	t_D = dimensionless time
L_{v2} = latent heat of vaporization at bottom of interval, Btu/lbm	t_i = time of injection for the current cycle, days
m_{sit} = total mass of steam injected, lbm	\bar{T} = average temperature of the heated region, $r_w < r < r_h$, at any time t , °F
M = volumetric heat capacity, Btu/cu ft-°F	T_{at} = atmospheric temperature, °F
N = OOIP, bbl	T_{cf} = temperature at cement/formation interface, °F
N_s = number of sands	T_{ci} = temperature at casing inside surface, °F
N_{sp} = oil in place at start of project, bbl	T_{fi} = initial formation temperature, °F
ΔN_{sp} = cumulative incremental oil production, bbl	T_{ff} = temperature of fluid, °F
p_e = static formation pressure at external radius, psia	T_{inj} = injection temperature, °F
p_p = pore pressure, psi	T_R = original reservoir temperature, °F
p_s = saturated vapor pressure of water at \bar{T} , psia	T_s = steam temperature, °F
p_{to} = total overburden pressure, psi	T_{su} = formation temperature at ground surface, °F
p_w = bottomhole pressure, psia	U_{co} = overall heat transfer coefficient based on outside casing surface, Btu/hr-sq ft-°F
p_1 = pressure at top of interval, psia	U_{ti} = overall heat transfer coefficient based on inside radius of pipe or tubing, Btu/hr-sq ft-°F
p_2 = pressure at bottom of interval, psia	U_{to} = overall heat transfer coefficient based on outside tubing surface, Btu/D-sq ft-°F
Δp = frictional pressure drop over interval, psia	v_t = specific volume of total fluid, cu ft/lbm
q_o = oil displacement rate, B/D	v_w = wind velocity, mile/hr
q_{oc} = cold oil production rate, B/D	V_{fb} = fuel burned, bbl
q_{oh} = hot oil production rate, B/D	V_r, V_z = unit solution for component conduction problems in the r and z directions*
Q_{hz} = heat remaining in heated zone, Btu	\bar{V}_r, \bar{V}_z = average values of V_r and V_z for $0 < r < r_h$
Q_{it} = total heat injection, Btu	w = Arrhenius reaction rate
Q_{ri} = heat injection rate, Btu/hr	w_s = mass rate of steam, lbm/hr
Q_{rt} = heat loss along the segment, Btu/hr	x = mole fraction in liquid phase
Q_{rt} = heat removal rate at time t , Btu/D	X = quantity defined by Eq. 66
r_{cf} = radius to cement/formation interface, ft	y = mole fraction in vapor phase
r_{ci} = inside radius of casing, ft	Y = quantity defined by Eq. 65
r_{co} = outside radius of casing, ft	α = thermal diffusivity, sq ft/D
r_e = external radius, ft	α_o = overburden thermal diffusivity, sq ft/D
r_h = radius of region originally heated, ft	
r_{in} = outside radius of insulation surface, ft	
r_{ti} = inside radius of tubing, ft	

*These symbols have no physical connotation. They are simply mathematical symbols.

β = dummy variable in Eq. 27
 δ = energy removed with the produced fluids, dimensionless
 Θ = dip angle, degrees
 μ_o = oil viscosity, cp
 μ_{oc} = cold oil viscosity, cp
 μ_{od} = viscosity of dead oil (gas-free oil) at T , cp
 μ_{oh} = hot oil viscosity, cp
 ρ_o, ρ_r, ρ_w = density of oil, rock grain, and water, lbm/cu ft
 ϕ = porosity, fraction

Key Equations in SI Units

$$h = 7.165 v_w^{0.6} / r_{in}^{0.4} \quad (3)$$

$$p_2 = p_1 + 7.816 \times 10^{-12} (v_{t1} - v_{t2}) \frac{w_s^2}{r_{ti}^4} + 9.806 \times 10^{-3} \frac{\Delta D}{v_{t1}} - \Delta p \quad (20)$$

$$F_{so}^* = \frac{Q_s t}{Ah\phi(S_{oi} - S_{io})} \quad (30)$$

$$q_{oc} = \frac{0.0005427 k k_{ro} h}{\mu_{oc} \ln \frac{r_e}{r_w}} (p_e - p_w) \quad (42)$$

$$Y = 0.2639 \left[0.427 S_o - 0.004429 h - 0.3905 \left(\frac{1}{\mu_o} \right)^{0.25} \right] X \quad (64)$$

where

$$X = \frac{i_{at} E_{O_2}}{[N_{sp}/(\phi S_o)](1 - \phi)}$$

$$F_{so} \text{ (in m}^3/\text{m}^3\text{)} = 1 / \left(-0.011253 + 0.00009117D + 0.0005180h - 0.07775\Theta + 0.007232\mu_o + 0.00003467 \frac{kh}{\mu_o} + 0.5120\phi S_o \right) \quad (67)$$

$$F_{so} \text{ (in m}^3/\text{m}^3\text{)} = 18.744 + 0.004767D - 0.16693h - 0.89814k - 0.5915\mu_o - 14.79S_o - 0.0009767 \frac{kh}{\mu_o} \quad (68)$$

$$C_m \text{ (in kg/m}^3\text{)} = -1.9222 + 0.137695h + 1.85029k + 35.72S_o + 0.012887 \frac{kh}{\mu_o} - 0.00993D - 1.0444\mu_o \quad (69)$$

$$a = \frac{\left(\frac{2F_{cc} + 1}{F_{cc} + 1} + \frac{F_{HC}}{2} \right) C_m}{0.01776(12 + F_{HC})E_{O_2}} \quad (70)$$

$$a \text{ (in std m}^3/\text{m}^3\text{)} = 108.356 + 2.75367h + 229.477S_o + 16.073k \quad (71)$$

$$F_{ao} = \frac{a}{\left[\left(\phi S_o - \frac{C_m}{1,000} \right) E_{vb} + \phi S_o (1 - E_{vb}) E_{Ru} \right]} \quad (72)$$

$$F_{ao} \text{ (in std m}^3/\text{m}^3\text{)} = 3820.4 + 12.97h + 192.20k + 471.1\mu_o - 13671.5\phi S_o \quad (73)$$

where

a is in std m³/m³,
 A is in m²,
 C_m is in kg/m³,
 D is in m,
 F_{ao} is in std m³/m³,
 F_{so} is in m³/m³,
 F_{so}^* is in m³/m³,
 h is in kJ/m² · h · K (Eqs. 2 through 4),
 h is in m,
 i_{at} is in std m³,
 k is in μm²,
 N_{sp} is in m³,
 ρ 's are in kPa,
 q_{oc} is in m³/d,
 Q_s is in m³/h,
 r_{in} is in m,
 r_{ti} is in m,
 t is in h,
 v_t is in m³/kg,
 v_w is in kg/h,
 w_s is in kg/h,
 μ_o is in Pa · s, and
 μ_{oc} is in Pa · s.

Chapter 47

Chemical Flooding

Larry W. Lake, U. of Texas

Introduction

Chemical flooding is any isothermal EOR process whose primary goals are to recover oil by (1) reducing the mobility of the displacing agent (mobility control process), and/or (2) lowering the oil/water interfacial tension (low-IFT process).

These classifications do not exclude processes where both effects are important, such as micellar/polymer (MP) flooding, nor do they imply that other effects, such as wettability alteration, extraction, or oil swelling, are not present.

Mobility control processes inject a low-mobility displacing agent to increase volumetric and displacement sweep efficiency. The two main techniques are (1) polymer flooding, whereby a small amount of polymer is added to thicken brine and (2) foam flooding, through which low mobilities are attained by injecting a stabilized dispersion of gas in water. Polymer or mobility buffer "drives" also are used to displace micellar and high-pH slugs. Foams have been used or proposed as driving agents for micellar, solvent, and steam slugs also. For these reasons foam flooding could be discussed easily in the chapters on solvent and thermal EOR processes; however, foam stabilization requires surfactants, whose discussion belongs in this chapter.

Low-IFT methods rely on injecting or forming in-situ a surface-active agent (surfactant) which lowers oil/water IFT and, ultimately, residual oil saturation (ROS). Processes that inject the surfactant are called "MP" floods because of the tendency for surfactants to form micelles in aqueous solutions and the inevitable need to drive the micellar solution with polymer. High-pH or alkaline processes produce a surfactant in situ, since these processes rely on reactions with acidic components of the crude to generate the surfactant.

This chapter is divided into sections corresponding to mobility control and low-IFT processes. Each section begins with a general discussion of how the particular mechanism recovers oil, followed by material on the individual

processes, and concludes with typical oil displacement results. The chapter concludes by giving comparative screening parameters for each chemical flooding process.

Mobility Control Processes

Effect of Low Mobility on Oil Recovery

Mobility control processes are most applicable to reservoirs that have substantial movable oil [oil in place (OIP) minus ROS] since they displace oil only in excess of ROS. The mobility ratio concept illustrates how lowering the mobility improves oil recovery.

The mobility ratio, M , between a displacing agent and a displaced fluid is

$$M = \lambda_D / \lambda_d, \dots\dots\dots (1)$$

where λ_D is the mobility of displacing agent(s) and λ_d is the mobility of displaced fluid(s). Practical use of Eq. 1 requires specific definitions of the quantities in the numerator and denominator and of the conditions at which these quantities are evaluated.

For two-phase waterflooding, common specializations of Eq. 1 are the endpoint mobility ratio, M^o , the average mobility ratio, M , and the shock mobility ratio, M^* . Each definition has been used in particular applications in the literature: M has been used to correlate areal sweep relations, M^* is the most direct indicator of viscous instability, and M^o is the most widely cited value in the literature for waterfloods.^{1,2} For the special case of a piston-like displacement all three definitions are identical. From the general definition of Eq. 1, lowering the mobility of the displacing fluid is equivalent to lowering any of the mobility ratios. This recovers oil by increasing both volumetric and displacement sweep efficiency.

Volumetric sweep efficiency, E_V , is the PV of a reservoir contacted by a displacing agent divided by the total PV. E_V is composed of two parts: areal, E_A , and invasion (vertical) sweep efficiency, E_I .

Fig. 47.1—Schematic of polymer flooding.

For more detailed discussions of E_A and E_I see Chaps. 39, 43, and 44 and Refs. 1 through 11. Both quantities depend on throughput and on several fluid, petrophysical, and geometric factors, usually expressed as dimensionless groups. However, E_A and E_I both increase as M decreases—i.e., as the mobility of the displacing agent, λ_D , decreases.

When the displacement is piston-like in a homogeneous, isotropic, horizontal medium and $M > 1$ (an *unfavorable* mobility ratio), the displacement front forms small perturbations, called “viscous fingers,” which grow during propagation. Such fingers also form when $M < 1$, but they are damped out by the *favorable* mobility ratio. The growing viscous fingers can contribute substantially to poor oil recovery because of large-scale bypassing. Mobility control agents prevent viscous fingering either in a conventional waterflood (polymer flooding) or as a part of an otherwise inherently unstable EOR process.

Displacement efficiency, E_D (local or microscopic sweep efficiency), is the volume of oil recovered in a displacement divided by the oil volume just before the displacement, the displacement having maximum volumetric sweep efficiency. The classical solution by Buckley and Leverett can be used to describe the effect of mobility lowering on E_D .¹² Because of the dependence on several factors there is no unique correspondence between M and E_D ; however, lowering M or λ_D results in improved oil recovery through larger E_D .

Lowering M , then, results in improved oil recovery by increasing areal, vertical, and displacement sweep efficiencies. Since it is the products of these factors that determine overall oil recovery, this implies that an increase in any one may not result in a large overall increase in oil recovery, particularly if one of the other efficiencies were low. Even with the combination of the three efficiencies, the incremental oil recovered with a mobility control process must be balanced against the additional expense required to inject the viscous mobility control agent.

Polymer Flooding

Polymers have been used in oil production in three modes.

1. They have been used as near-well treatments to improve the performance of water injectors or high-watercut producers by blocking off high-conductivity zones.

2. Polymers also are used as agents that may be cross-linked in situ to plug high-conductivity zones at depth in the reservoir.¹³ These processes require that polymer be injected with an inorganic metal cation, which will cross-link subsequently injected polymer molecules with ones already bound to solid surfaces.

3. The other mode is use as agents to lower M or λ_D .

The first mode is not truly a chemical flooding process, since the actual oil-displacing agent is not the polymer. The overwhelming majority of polymer EOR projects have been in the third mode, which is the one emphasized here.

Fig. 47.1 is a schematic of a typical polymer flood injection sequence: a preflush, usually consisting of a low-salinity brine; an oil bank; the polymer solution itself; a freshwater buffer to protect the polymer solution from backside dilution; and, finally, chase or drive water. Many times the freshwater buffer contains polymer in decreasing amounts (a grading or taper) to lessen the effects of unfavorable mobility ratio between the chase water and the polymer solution. Because of the driving nature of the process, polymer floods always are performed through separate sets of injection and production wells.

M is lowered in a polymer flood by injecting water that contains a high-molecular-weight, water-soluble polymer. Since the water is usually a dilution of an oilfield brine, interactions with salinity are important, particularly for certain classes of polymers. Salinity in this chapter is the total dissolved solids (TDS) content of the aqueous phase. Typical values are shown in Fig. 47.2.¹⁴ Virtually all chemical flooding properties depend on the concentrations of specific ions rather than salinity only. It is particularly important to monitor the aqueous phase's total divalent

Fig. 47.2—Salinities from representative oilfield brines.

cation content (hardness) separately, since the latter are usually more critical to chemical flood properties than the same TDS concentration. Fig. 47.2 also shows typical brine hardnesses.

Because of the high molecular weight (1 to 3 million is typical) only a small amount (typically about 500 ppm) of polymer will bring about a substantial increase in water viscosity. Furthermore, several types of polymers lower mobility by lowering water relative permeability (permeability reduction effect) in addition to increasing the water viscosity. How polymer lowers mobility, and the interactions with salinity may be qualitatively illustrated with some discussion of polymer chemistry.

Polymer Types. Several polymers have been considered for polymer flooding: xanthan gum, hydrolyzed polyacrylamide (HPAM), copolymers of acrylic acid and acrylamide, copolymers of acrylamide and 2-acrylamide-2 methyl propane sulfonate (AM/AMPS), hydroxyethylcellulose (HEC), carboxymethylhydroxyethylcellulose (CMHEC), polyacrylamide (PAM), polyacrylic acid, glucan, dextran polyethyleneoxide (PEO), and polyvinyl alcohol (PA). Only the first three have actually been field tested; however, the variety of entries in this partial listing emphasizes that there are many potentially suitable chemicals, some of which may prove more effective than those currently used. Nevertheless, virtually all of the commercially attractive polymers fall into two generic classes: polyacrylamides and polysaccharides (biopolymer or xanthan gum). The remainder of this discussion deals with these exclusively. Representative molecular structures are given in Fig. 47.3.¹⁵

POLYACRYLAMIDE

Fig. 47.3A—Molecular structure for partially hydrolyzed polyacrylamide.

Fig. 47.3B—Molecular structure for polysaccharide (biopolymer).

Polyacrylamides. PAM's are polymers whose monomeric unit is the acrylamide molecule. As used in polymer flooding, PAM's have undergone partial hydrolysis, which causes anionic (negatively charged) carboxyl groups ($-\text{COO}^-$) to be scattered along the chain. The polymers are called partially hydrolyzed polyacrylamides (HPAM's) for this reason. Typical degrees of hydrolysis are 30% or more of the acrylamide monomers; hence, the HPAM molecule is quite negatively charged, which accounts for many of its physical properties. The viscosity-increasing feature of HPAM lies in its large molecular weight, which is accentuated by the anionic repulsion between polymer molecules and also between segments on the same molecule. The repulsion causes the molecule in solution to elongate or uncoil and snag on others similarly elongated, an effect that accentuates the mobility reduction at higher concentrations.

If the brine salinity and/or hardness is high, however, this repulsion is decreased greatly through ionic shielding as the freely rotating carbon/carbon bonds allow the molecule to ball up or coil. (Fig. 47.3 shows the molecular structure of hydroxyethylcellulose.) This causes a corresponding decrease in the effectiveness of the polymer, since the snagging effect is reduced greatly. Virtually all HPAM properties show a large sensitivity to salinity and hardness. This is an obstacle to using HPAM in many reservoirs. On the other hand, HPAM is inexpensive, relatively resistant to bacterial attack, and exhibits permeability reduction.

Polysaccharides. A second major class of polymers are the polysaccharides, which are formed from the polymeri-

Fig. 47.4—Polymer solution viscosity vs. shear rate and polymer concentration.

zation of saccharide molecules (Fig. 47.3). Polysaccharides or biopolymers are formed from a bacterial fermentation process. This process leaves substantial debris in the polymer product that must be removed before the polymer is injected.¹⁶ The polymer is also susceptible to bacterial attack after it has been introduced into the reservoir. These disadvantages are offset by the insensitivity of polysaccharide properties to brine salinity and hardness. The origin of this insensitivity is seen in Fig. 47.3, which shows the polysaccharide molecule to be relatively nonionic and, therefore, free of the ionic shielding effects of HPAM. Polysaccharides are more branched than are HPAM's and the oxygen-ringed carbon bond does not rotate fully; hence, the molecule increases brine viscosity by snagging and by adding a more rigid structure to the solution. Polysaccharides do not exhibit permeability reduction, however.

At the present time HPAM is less expensive per unit amount than polysaccharides; however, when compared on a unit amount of mobility reduction, particularly at high salinities, the costs are close enough so that the preferred polymer for a given application is site-specific. Historically, HPAM's have been used in about 95% of the reported field polymer floods.¹⁷ Both classes of polymers tend to degrade chemically at elevated temperatures.

Polymer Properties. Because of the complexity of the subject, a comprehensive treatment of polymer properties is not possible. However, qualitative trends, a few quantitative relations and representative data are presented on these properties: viscosity relations, non-Newtonian effects, retention, permeability reduction, and chemical, biological, or mechanical degradation.

Viscosity Relations and Non-Newtonian Effects. Fig. 47.4 shows polymer solution viscosity, μ_p , vs. shear rate measured in a laboratory viscometer at fixed salinity.¹⁸ At low shear rates, μ_p is independent of shear rate, $\dot{\epsilon}(\mu_p = \mu_p^\infty)$, and the solution is a Newtonian fluid. At higher $\dot{\epsilon}$, μ_p decreases, approaching a limiting ($\mu_p = \mu_p^\infty$) value not much greater than the water viscosity, μ_w , at some critical high shear rate (not shown on Fig. 47.4). A fluid whose viscosity decreases with increasing $\dot{\epsilon}$ is *shear thinning*. The shear thinning behavior of the polymer solution is caused by the uncoiling and

Fig. 47.5—Polymer solution viscosity vs. shear rate at various brine salinities.

unsnagging of the polymer chains when they are placed in a shear flow. Below the critical shear rate the curve is reversible.

Fig. 47.5 shows a viscosity/shear-rate plot at fixed polymer concentration with variable NaCl concentration for an AMPS polymer.¹⁹ Note the profound sensitivity of the viscosity to salinity: as a rule of thumb the polymer solution viscosity decreases a factor of 10 for every factor-of-10 increase in NaCl concentration. The viscosity of HPAM polymers and HPAM derivatives is even more sensitive to hardness, but viscosities of polysaccharide solutions are relatively insensitive to both.

The behavior in Figs. 47.4 and 47.5 is favorable because for the bulk of a reservoir's volume, $\dot{\epsilon}$ is usually low (about 1 to 5 seconds⁻¹), making it possible to attain a design M with a minimal amount of polymer. Near the injection wells, however, $\dot{\epsilon}$ can be quite high, which causes the polymer injectivity to be greater than that expected on the basis of μ_p^∞ . The relative magnitude of this enhanced injectivity effect can be estimated once quantitative definitions of shear rate in permeable media and shear-rate/viscosity relations are given.²⁰

The polymer solution viscosity/shear-rate relationship may be described by a power law model.²¹

$$\mu_p = K(\dot{\epsilon})^{n-1}, \quad \dots \dots \dots (2)$$

where K and n are the power-law coefficient and exponent, respectively. Eq. 2 applies only over a limited range of shear rates: below some low shear rate the polymer solution viscosity is constant at μ_p^∞ , and above the critical shear rate the polymer solution viscosity is also constant μ_p^∞ . The truncated nature of the power law is awkward in calculations; hence, another useful relationship is the Meter model.²²

$$\mu_p = \mu_p^\infty + \frac{\mu_p^\circ - \mu_p^\infty}{1 + \left(\frac{\dot{\epsilon}}{\dot{\epsilon}_{1/2}}\right)^{\alpha-1}}, \quad \dots \dots \dots (3)$$

where α is an empirical coefficient and $\dot{\epsilon}_{1/2}$ is the shear rate at which μ_p is the average of μ_p° and μ_p^∞ . As with all polymer properties, all empirical parameters are functions of salinity, hardness, and temperature.

When applied to permeable media flow these general trends and equations continue to apply. μ_p is usually called the "apparent" viscosity and the effective shear rate, $\dot{\epsilon}_e$, is based on capillary tube concepts.

$$\dot{\epsilon}_e = \frac{u_w}{4\sqrt{\phi k_w S_w}} \quad (4)$$

where

- u_w = superficial flux of polymer-rich (water) phase,
- k_w = permeability to polymer-rich (water) phase,
- S_w = saturation of polymer-rich (water) phase, fraction, and
- ϕ = porosity of medium, fraction.

Polymer Retention. All polymers experience retention on solid surfaces because of adsorption or mechanical trapping within a permeable medium. Polymer retention varies with polymer type, molecular weight, rock composition, brine salinity and hardness, flow rate, and temperature. Field-measured values of retention range from 20 to 400 lbm polymer/acre-ft bulk volume with desirable retention level being less than about 50 lbm/acre-ft. Retention causes the loss of polymer from solution, which can cause the mobility control effect to be destroyed—an effect that is particularly pronounced at low polymer concentrations. Polymer retention also causes a delay in the rate of polymer propagation.

Offsetting the delay caused by retention is an acceleration of the polymer solution through the permeable medium, which is caused by inaccessible PV (IPV). The most common explanation for IPV is that the smaller portions of the pore space will not allow polymer molecules to enter because of their size. Thus, a portion of the total pore space is uninvaded or inaccessible to polymer, and accelerated polymer flow results. Large as they are, however, most polymer molecules will fit easily into all but the smallest pore throats. Hence, a second explanation of IPV is based on a wall exclusion effect whereby the polymer molecules aggregate in the center of a narrow channel.²³ The polymer pore fluid layer near the wall has a lower viscosity than the fluid in the center, which causes an apparent fluid slip.

IPV depends on polymer molecular weight, media permeability, porosity, and pore size distribution, becoming more pronounced as molecular weight increases and the ratio of permeability to porosity (characteristic pore size) decreases. IPV can be 30% of the total pore space or greater.

Permeability Reduction. As mentioned previously HPAM polymers can cause lowered mobility through a permeability reduction effect. This phenomenon has been described through three factors.²⁴ The *resistance factor*, F_R , is the ratio of the injectivity of a single-phase polymer solution to that of brine flowing under the same conditions:

$$F_R = \frac{\lambda_w}{\lambda_p} = \frac{k_w/\mu_w}{k_p/\mu_p} \quad (5)$$

where

- k_p = permeability to polymer solution,
- λ_w = mobility of water-rich phase, and
- λ_p = mobility of polymer solution.

For constant-flow-rate experiments, F_R is the inverse ratio of pressure drops; for constant-pressure-drop experiments, F_R is the ratio of flow rates. F_R is an indication of the total mobility-lowering contribution of a polymer. To describe the permeability reduction effect alone, a *permeability reduction factor*, F_{rk} , is defined as

$$F_{rk} = \frac{k_w}{k_p} = \frac{\mu_w}{\mu_p} F_R \quad (6)$$

A final definition is the *residual resistance factor*, F_{Rr} , which is the mobility of a brine solution before and after polymer injection.

$$F_{Rr} = \frac{\lambda_{wb}}{\lambda_{wa}} \quad (7)$$

where λ_{wb} is the mobility of water-rich phase before polymer injection and λ_{wa} is the mobility of water-rich phase after polymer injection. F_{Rr} is a measure of the permanence of the permeability reduction effect caused by the polymer solution. It is the primary measure of the performance of a channel-blocking application of polymer solutions. For many cases, F_{rk} and F_{Rr} are nearly equal; however, F_R is usually much larger than F_{rk} because the former contains the viscosity-enhancing effect as well as the permeability-reduction effect.

The most common measure of permeability reduction is F_{rk} . F_{rk} is sensitive to polymer type, molecular weight, degree of hydrolysis, shear rate, and permeable media pore structure. Polymers that have undergone even a small amount of mechanical degradation seem to lose most of their permeability reduction effect. For this reason, qualitative tests based on screen factor devices are common to estimate polymer quality.²⁴ F_{rk} has been correlated to polymer adsorption and rheological properties by Hirasaki and Pope.²⁵

Chemical and Biological Degradation. The average polymer molecular weight can be decreased, to the detriment of the overall process, by chemical, biological, or mechanical degradation. Chemical degradation can be minimized by restricting polymer usage to low-temperature applications, and by adding oxygen scavengers (e.g., sodium sulfate or sodium sulfite) to the polymer solution. Biological degradation can be eliminated by adding oxygen scavengers and biocides (e.g., formaldehyde or isopropyl alcohol). In fact, nearly all applications contain some of these chemicals, usually in very small quantities (see Ref. 16 or 26).

Mechanical Degradation. Mechanical degradation, on the other hand, is potentially present under all applications. Mechanical degradation occurs when polymer solutions are exposed to high-velocity flows. These can be present in surface equipment (valves, orifices, pumps, or tubing), downhole conditions (perforations or screens), or in the sandface itself. Perforated completions, particularly, are a cause for concern, since large quantities of

Fig. 47.6—Tertiary polymer flood response from North Burbank Unit, Osage County, OK.

polymer solution are being forced through a number of small holes. For this reason, most polymer injections are done through openhole or gravel-pack completions. Because flow velocity falls off quickly with distance from an injector, little mechanical degradation occurs within the reservoir itself.

All polymers mechanically degrade under high enough flow rates. However, HPAM's are most susceptible under normal operating conditions, particularly if the salinity or hardness of the brine is large. Evidently, the ionic coupling of these anionic molecules is relatively fragile compared with the polysaccharide chains. Also, elongational stress is as destructive to polymer solutions as is shear stress, although the two generally accompany each other. Maerker and others have correlated permanent viscosity of a polymer solution loss to an elongational stretch rate times length product.^{27,28} On a viscosity/shear-rate plot (purely shear flow), mechanical degradation usually begins at shear rates greater than the minimum-viscosity critical shear rate.

Field Results. Fig. 47.6 shows a tertiary polymer flooding field response from the North Burbank unit, Osage

County, OK.²⁹ The figure shows WOR and oil rate before and immediately after polymer injection. Polymer injection began in late 1970, which quickly arrested a declining oil rate and an increasing WOR. The oil rate then resumed its prepolymer decline but at a substantially higher level. The polymer oil or incremental oil recovery (IOR) from a polymer flood is the difference between the cumulative oil actually produced and that which would have been produced by a continuing waterflood. Thus, for a technical analysis of the project it is important to establish a polymer flood oil rate decline and an accurate waterflood decline rate. The IOR for North Burbank is the shaded area in Fig. 47.6.

Table 47.1 summarizes other field results on more than 250 polymer floods on the basis of a comprehensive survey by Manning *et al.*¹⁷ The table emphasizes oil recovery data and screening parameters used for polymer flooding. Approximately one-third of the statistics are from commercial or field-scale floods. The oil recovery statistics in Table 47.1 show average polymer flood recoveries of 3.56% remaining (after waterflood) oil in place, and 2.69 STB of IOR for each pound of polymer injected, with wide variations in both numbers. The large variability reflects the emerging nature of polymer flooding in the previous decades. Considering the STB IOR per pound of polymer average and the average costs of crude and polymer, it appears that polymer flooding could be a highly attractive EOR process. However, such costs always should be compared on a discounted basis reflecting the time value of money, which will decrease the apparent attractiveness of polymer flooding because of the decreased injectivity of the polymer solutions.

Foam Flooding

Gas/liquid foams offer an alternative to polymers for providing mobility control in chemical floods, and have been both proposed and field tested as mobility control agents in steamfloods.

Foams are dispersions of gas bubbles in liquids. Gas/liquid dispersions are normally unstable and usually will break in less than 1 second. If surfactants are added to the liquid, however, stability is improved greatly so that some foams can persist indefinitely. To understand foam

*Partial data available on most projects

properties requires some discussion of surfactants and their classifications. Most of the discussion applies to MP surfactants as well.

Surfactant Chemistry. A typical surfactant monomer is composed of a nonpolar portion (lipophile—i.e., having strong affinity for oil) and a polar portion (hydrophile—i.e., strong affinity for water); the entire monomer is an amphiphile (has affinity for both oil and water) because of this dual nature. Fig. 47.7 shows the molecular structure of two common surfactants (top two panels) and illustrates (lowest panel) a shorthand notation for surfactant monomers: the monomer is represented by a “tadpole” symbol with the nonpolar portion being the tail and the polar head. Surfactants are classified into four groups that depend on their polar portions (see Table 47.2).³⁰

Anionics. As required by electroneutrality, the anionic surfactant molecule is uncharged with an inorganic metal cation (usually sodium) associated with the monomer. In an aqueous solution the molecule ionizes to free cations and the anionic monomer. Anionic surfactants are the most common in EOR because they are good surfactants, relatively resistant to retention, stable, and relatively inexpensive.

Cationics. In this case the surfactant molecule contains a cationic hydrophile and an inorganic anion to balance the charge. Cationic surfactants have little use in EOR because they are adsorbed highly by the anionic surfaces of interstitial clays.

Nonionics. These surfactants do not form ionic bonds, but when dissolved in aqueous solutions, they exhibit surfactant properties simply by electronegativity contrasts between their constituents. Nonionics are much less sensitive to high salinities than anionics or cationics.

Amphoterics. A final class of surfactants are those that contain aspects of two or more of the previous classes. For example, an amphoteric may contain both an anionic group and a nonpolar group. These surfactants have not been used in EOR.

Within any one class there is a huge variety of possible surfactants. Fig. 47.7 illustrates differences in lipophile molecular weight [C_{12} for the sodium dodecyl sulfate (SDS) vs. C_{16} for Texas No. 1], hydrophile identity (sulfate vs. sulfonate), and tail branching (straight chain for SDS vs. two tails for Texas No. 1) all within the same class of anionic surfactants. In addition to these, there are variations in the position of the hydrophile attachment and the number of hydrophiles (monosulfonates vs. disulfonates, for example). Even small variations can change surfactant properties drastically (e.g., sulfates tend to be less thermally stable than sulfonates). For details on the

(non – polar)

Fig. 47.7—Typical surfactant molecular structures.

effect of structure on surfactant properties see Refs. 31 and 32.

Most commercial surfactants contain distributions of surfactants and surfactant types that further add to their complexity. In the following, distinctions between surfactant types are ignored by simply treating the surfactant as the tadpole structure of Fig. 47.7.

Foam Stability. The stability of a foam may be understood by viewing the liquid film separating two gas bubbles in cross section as in the lower panel of Fig. 47.8.³³ The hydrophiles of the surfactant are oriented into the interior of the film and the lipophiles toward the bulk gas phase. Suppose that some external force causes the film to thin as in the lower panel. Since capillary pressure is inversely proportional to interfacial curvature, the pressure in the thinned portion of the film is lower than in the adjacent flat portion. This causes a pressure difference within the film, liquid flow, and healing. The pressure in the gas phase is assumed constant because of its relatively low density if the foam is static, or low viscosity if in motion.

Table 47.2—CLASSIFICATION OF SURFACTANTS AND EXAMPLES

● ⁻ M Anionics	● ⁺ M Cationics	● ⁺ Amphoterics	● ⁻ Nonionics

Fig. 47.8—Upper panel shows surface tension and adsorption of a surfactant vs. concentration. Lower panel is the Gibbs-Marangoni effect.

Fig. 47.9—Effective permeability-viscosity ratio vs. foam quality for consolidated porous media.

The upper panel in Fig. 47.8 shows that the gas/liquid surface tension is a decreasing function of surface adsorption as required by the Gibbs theory. According to this view the thinned portion of the film will have less specific adsorption (since the surface area is locally greater) and greater surface tension. This locally high surface tension also causes healing.

Clearly, the surface tension at the gas/liquid interfaces play an important role in film stability. Very low surface tension would not be favorable; fortunately gas/liquid surface tensions are rarely lower than 20 dynes/cm even with the best foaming agents. In the absence of external forces, the film is at an equilibrium thickness caused by a balance between the repulsion forces of the electrical dou-

ble layer on the interior of the film boundary and the attractive Van der Waal forces between the molecules in the film. If the film becomes substantially smaller than the equilibrium thickness, the free energy barrier between the repulsive and attractive contributions is breached and the film will collapse.

Such thinning can be caused spontaneously by diffusion of the gas from small to large bubbles and by gravity drainage. Patton *et al.*³⁴ reported on the rate of spontaneous collapse of a large number of foams as a function of surfactant type, temperature, and pH.³⁴ The half-life of the foam heights reported in their static tests ranges from 1 to about 45 minutes. They report that anionic surfactants have greater stability than nonionics, and that the stability of sulfonate foams is affected greatly by water hardness. Foams were generally more unstable at high temperatures, and many could be stabilized by adding a second surfactant.

External effects that may cause the foam to collapse are the presence of a foam breaker (oil or a high electrolyte concentration could do this), local heating, or contact with a hydrophobic surface.

Foam Physical Properties. Physically, foams are characterized by three measures.

Quality. Foam quality, Γ , is the percentage of the total (bulk) foam volume that is gas volume. The quality can increase with increasing temperature and decreasing pressure both because the gas volume can increase, and also because gas dissolved in the bulk liquid phase can evolve from solution. Foam qualities can be quite high, approaching 97% in many cases. A foam with quality greater than 90% is a *dry* foam.

Texture. This measure is the average bubble size. The texture determines how the foam will flow through a permeable medium. If the average bubble size is larger than the average pore diameter, the foam flows as a progression of films separating individual gas bubbles. Given typical foam textures and pore sizes, this condition is most nearly realized in permeable flow, particularly for high foam qualities.

Bubble Size Range. Foams with a large distribution range are more likely to be unstable because of the gas diffusion from large to small bubbles.

Mobility Lowering. Foams can reduce the mobility of a gas phase drastically. Fig. 47.9 shows the steady-state mobility of foams of differing quality in Berea cores at three different permeabilities as a function of quality.³⁵ On the extreme right of this figure ($\Gamma \rightarrow 100\%$), the mobility should approach the respective air permeability divided by the air viscosity; this mobility is two to three factors of 10 greater than any of the experimental points on the figure. When $\Gamma \rightarrow 0$ the mobility should approach the water permeability divided by μ_w . Thus, the mobility of the foam is lower than that of either of its constituents alone. The mobility of the foam decreases with increasing quality until the films between the gas bubbles begin to break and the foam collapses (not shown on Fig. 47.9). Foams are effective in reducing the mobility at all three permeabilities in Fig. 47.9, but the effect of foam quality is more pronounced at the highest permeability. This is a consequence of the contrast between the texture of the foam and the mean pore size of the medium.³⁶

The mobility reduction caused by the foam can be viewed as an increase in a single-phase viscosity or as a decrease in the gas-phase permeability. Representative data of the second type are in Fig. 47.10, which shows the gas-phase permeability, both with and without foam, and gas saturation plotted against the liquid injection rate.³⁷ Note that the foam causes a great decrease in gas permeability at the same rate and even at the same gas saturation compared to the nonfoaming displacement. The analogous analysis performed on the aqueous-phase relative permeability shows that neither the gas saturation nor the presence of the foaming agent affects the aqueous-phase relative permeability.³⁸

The low foam mobilities in permeable media flow are postulated to be caused by at least two different mechanisms: (1) the formation of or the increase in a trapped residual gas phase saturation and (2) a blocking of pore throats caused by the gas films. From Fig. 47.10 the effect of a trapped gas saturation, which would lower the gas mobility through a relative-permeability lowering, is much smaller than the pore-throat-blocking effect. The trapped gas-phase saturation effect may become important, however, during the later stages of a displacement where the lower pressures could cause more gas to come out of solution.

The mobility reduction of foams, viewed as a viscosity enhancement, has been studied in capillary tubes.³⁹ General observations on these data are that foams are generally shear-thinning fluids whose power law coefficient increases with the capillary tube radius. Using theoretical arguments based on a Newtonian fluid and an inviscid gas, Hirasaki and Lawson showed that the film thickness of a single moving bubble increases as the bubble velocity to the two-thirds power.⁴⁰ Since shear stress in a capillary is inversely proportional to film thickness, the apparent viscosity of a foam in a capillary tube decreases with increasing velocity. Thus, the shear-thinning effect observed in capillary tubes is actually a consequence of the film thickening as velocity increases. A second implication in the Hirasaki-Lawson theory is that foam texture occupies as great an importance in determining rheological behavior as does foam quality.

Field Results. Field tests of foam injection alone have been scarce. Holm reports on the injection of an air/brine foam into a single well in the Siggins field.⁴¹ Though there was no measureable oil response, the mobility to both air and brine were reduced significantly, and the injection profile into the central well became more uniform.

Low-IFT Processes

In addition to stabilizing gas dispersions, surfactants used in MP flooding or generated in situ can recover oil by lowering oil/water IFT.

Lowering ROS

The basic tool for illustrating how lowering IFT reduces ROS is the capillary desaturation curve (CDC) shown in Fig. 47.11. The CDC is a plot of nonwetting- or wetting-phase residual saturation on the y axis vs. a dimensionless ratio of viscous to local capillary forces on a logarithmic x axis. On Fig. 47.11, S_{orw} is the residual oil (assumed nonwetting), and S_{iw} is the irreducible water-(wetting)-phase saturation. The CDC has been calculat-

Fig. 47.10—Effect of liquid flow rate and gas saturation on gas permeability with and without foam.

Fig. 47.11—Schematic capillary desaturation curves.

ed theoretically,⁴²⁻⁴⁴ but the most common source of this curve is experimental measurement.^{45,46} The ratio of viscous to local capillary forces is the capillary number, N_c , one form of which is

$$N_c = u_w \mu_w / \sigma_{wo} \quad (8)$$

For a waterflood, u_w and μ_w are the superficial flux and viscosity of the displacing water, and σ_{wo} is the IFT between the water and oil phases. For a MP flood a more general definition is appropriate, but Eq. 8 and the CDC can illustrate this case also.

The CDC is a nearly horizontal plateau at small N_c until a critical value above which both residual phase saturations decrease. At a second critical N_c , the residual phase saturations are zero and complete recovery of the

Fig. 47.12—Schematic of an MP flooding process.

originally trapped phase occurs. The shape of the CDC is determined by the pore geometry of the medium and the wetting behavior of the two phases. The wetting phase requires a larger N_c for complete recovery. To a lesser extent, the CDC shape is affected by the mean pore size and pore size distribution of the medium, and the initial saturations. Typical N_c 's for waterflooding are quite small, which indicates that ROS and S_{iw} may be assumed constant for this purpose (see Fig. 47.11). Because of the logarithmic x axis, a decrease by several factors of 10 in N_c is necessary to significantly change either residual phase saturation. Of the three quantities in Eq. 8 only the IFT can be changed this drastically; a typical value for causing good ROS reduction is in the range of 10^{-3} dyne/cm, a value that can be obtained only with a good surfactant.

Fig. 47.13—Schematic of the CMC.

MP Flooding

MP flooding has appeared in the technical literature under many names: detergent, surfactant, low-tension, soluble oil, microemulsion, and chemical flooding. There are also several company names that imply a specific sequence and type of injected fluids as well as the specific nature of the oil-recovering MP slug itself. Though there are differences among company processes, the common aspects are more numerous and important.

An idealized version of a MP flooding sequence is in Fig. 47.12. The process is applied invariably to tertiary floods (those producing at high WOR's) and is always implemented in the drive mode (not cyclic or huff 'n' puff). The complete process consists of the following.

Preflush. A volume of brine whose purpose is to change (usually lower) the salinity and hardness of the resident brine so that mixing with the surfactant will not cause the loss of interfacial activity. Preflushes have ranged in size from 0 to 100% of the reservoir PV. In some processes a sacrificial agent is added to lessen the subsequent surfactant retention and also to precipitate divalent cation.⁴⁷

MP Slug. This volume, ranging from 5 to 40% PV in field applications, contains the main oil-recovering agent, the *primary* surfactant, in concentrations ranging from 1 to 20 vol%. Several other chemicals (cosurfactants, alcohols, oil, polymer, biocide, and oxygen scavenger) are usually necessary for good oil recovery.

Mobility Buffer. This fluid is a dilute solution of a water-soluble polymer whose purpose is to drive the MP slug and banked-up fluids to the production wells. Much of polymer flooding technology carries over to designing and implementing the mobility buffer.⁴⁸

Freshwater Buffer. This is a volume of brine containing a concentration of polymer grading between that of the mobility buffer at the front end and zero at the back. The gradual concentration decrease mitigates the effect of the unfavorable mobility ratio between the chase water and mobility buffer.

Chase Water. The purpose of the chase water is simply to reduce the expense of continually injecting polymer. If the mobility and freshwater buffers have been designed properly, the MP slug will be depleted before it is penetrated by the chase water.

Surfactant Solutions. If an anionic surfactant is dissolved in brine, the surfactant disassociates into a cation and a monomer. If the surfactant concentration then is increased, the lipophilic portions of the surfactant begin to associate among themselves to form aggregates or *micelles* containing several monomers each. A plot of surfactant monomer concentration vs. total surfactant concentration (Fig. 47.13) is a curve that begins at the origin, increases with unit slope, then levels off at the critical micelle concentration (CMC). Above the CMC all further increases in surfactant concentration cause increases only in the micelle concentration. CMC's are typically quite small (about 10^{-5} to 10^{-4} mol/L). At nearly all practical concentrations for MP flooding the surfactant is predominantly in the micelle form; hence, the name micellar/polymer flooding. The representations of the micelles in Fig. 47.13 and elsewhere are schematic. The actual micelle structures can take on various forms, which can fluctuate with time.

When this solution contacts an oleic phase (the term "oleic" indicates that this phase can contain more than oil) the surfactant tends to accumulate at the intervening interface. The lipophilic tail dissolves in the oleic phase, and the hydrophilic in the aqueous phase. The accumulation at the interface causes the IFT between the two phases to lower. The extent of the IFT lowering is proportional to the excess surface concentration of the surfactant—the difference between the surface and bulk surfactant concentration—from Gibbs' theory, as was the case in Fig. 47.8. The surfactant itself and the attending conditions should be adjusted to maximize the excess surface concentration; however, in doing so the solubility of the surfactant in the bulk oleic and aqueous phases also is affected. Since this solubility also impinges on the mutual solubility of brine and oil, which also affects IFT's, this discussion leads naturally to the topic of surfactant/brine/oil phase behavior. Curiously, and this is true of many micellar properties, the surfactant concentration itself plays a rather minor role in what follows, compared with the temperature, brine salinity, and hardness.

Surfactant/Brine/Oil Phase Behavior. Surfactant/brine/oil phase behavior is illustrated conventionally on a ternary diagram. A ternary diagram is an equilateral triangle whose apexes represent pure components, boundaries represent two-component mixtures, and interior represents three-component mixtures. For complicated mixtures the three apexes must represent "pseudocomponents" whose composition remains constant throughout the diagram. The pressure and temperature are also fixed. The diagram can represent both the overall composition of a surfactant/brine/oil mixture, and the equilibrium composition of each phase if the mixture forms more than one phase. Ternaries and their accompanying definitions are discussed in Chap. 23.

MP phase behavior is affected strongly by the salinity of the brine pseudocomponent. Consider the sequence of phase diagrams (Figs. 47.14 through 47.16) as the brine salinity is increased. The phase behavior about to be de-

Fig. 47.14—Schematic of low-salinity surfactant/brine/oil phase behavior.

scribed was presented originally by Winsor⁴⁹ and adapted to MP flooding later.^{50,51}

At low brine salinity, a typical MP surfactant will exhibit good aqueous (water-rich) phase solubility and poor oleic (oil-rich) phase solubility. Thus, an overall composition near the brine/oil boundary of the ternary will split into two phases: an *excess oil* phase that is essentially pure oil and a (water-external) *microemulsion* phase that contains brine surfactant, and some solubilized oil. The solubilized oil occurs when globules of oil occupy the central core of the *swollen* micelles. The tie lines within the two-phase region have a negative slope. This type of phase environment is called variously a Winsor Type I system, a lower-phase microemulsion (because it is more dense than the excess oil phase), or a Type II system. The latter terminology is adopted here—II means that no more than two phases can (not necessarily will) form and (–) means that the tie lines have negative slope (Fig. 47.14). The right plait point in such a system, P_R , usually is located quite close to the oil apex. Any overall composition above the binodal curve is single phase.

For high brine salinities (Fig. 47.15) electrostatic forces drastically decrease the surfactant's solubility in the aqueous phase. An overall composition within the two-phase region now will split into an *excess brine* phase and an

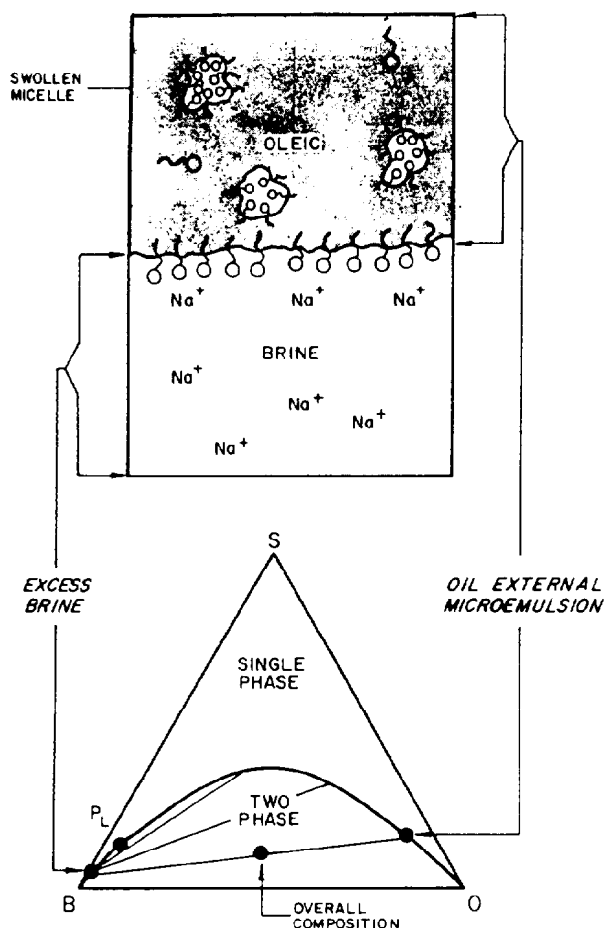

Fig. 47.15—Schematic of surfactant/brine/oil high-salinity phase behavior.

(oil-external) microemulsion phase, which contains most of the surfactant and some solubilized brine. The brine is solubilized through the formation of inverted swollen micelles (Fig. 47.15) with brine globules at their cores. The phase environment is a Winsor Type II system, an upper-phase microemulsion, or a Type II(+) system. The plait point, P_L , is now close to the brine apex.

The two extremes presented thus far are roughly mirror images; note that the microemulsion phase is water-continuous in the Type II(−) systems and oil-continuous in Type II(+) systems. The induced solubility of oil in a brine-rich phase, Type II(−), suggests an extraction mechanism in oil recovery. Though extraction does play some role, it is dwarfed by the IFT effect discussed later, particularly when phase behavior at intermediate salinities is considered.

At salinities between those of Figs. 47.14 and 47.15, there is a continuous change between Type II(−) and II(+) systems and a third surfactant-rich phase is formed, as shown in Fig. 47.16. An overall composition within the three-phase region separates into excess oil and brine phases as in the Type II(−) and II(+) environments, and into a microemulsion phase whose composition is represented by an invariant point. This environment is called

Fig. 47.16—Schematic of surfactant/brine/oil phase behavior at optimal salinity.

a Winsor Type III, a middle-phase microemulsion, or a Type III system. Above and to the right and left of the three-phase region are Type II(−) and II(+) lobes wherein two phases will form as before. Below the three-phase region there is a third two-phase region (as required by thermodynamics) whose extent is usually so small that it is neglected.⁵² In the three-phase region there are now two IFT's between the microemulsion and oil, σ_{mo} , and the microemulsion and water, σ_{mw} .

Fig. 47.17, a prism diagram, shows the entire progression of phase environments from Type II(−) to II(+). The Type III region forms through the splitting of a critical tie line that lies close to the brine/oil boundary as the salinity increases to C_{el} (low effective salinity limit for Type III phase environment).⁵³ A second critical tie line also splits at C_{eu} (high effective salinity limit for Type III phase environment) as salinity is decreased from a Type II(+) environment. Over the Type III salinity range the invariant point, M , migrates from near the oil apex to near the brine apex before disappearing at the appropriate critical tie lines. The migration of the invariant point implies essentially unlimited solubility of brine and oil in a single phase, which has generated an intense research interest into the nature of the Type III microemulsion.⁵⁴

Fig. 47.17—Prism diagram showing sequence of phase environment transition.

Several variables other than salinity can bring about the Fig. 47.17 phase environment shifts. In general, changing any condition that enhances the surfactant's oil solubility will cause the shift from Type II(−) to II(+). Some of the more important are: (1) decreasing temperature,⁵¹ (2) increasing surfactant molecular weight,³¹ (3) decreasing tail branching,³¹ (4) decreasing oil specific gravity⁵⁵⁻⁵⁷ and (5) increasing concentration of high-molecular-weight alcohols.⁵⁸ Decreasing the surfactant's oil solubility will cause the reverse change. Thus, Fig. 47.17 could be redrawn with any of the above variables (and several others) on the base of the prism with the variable C_e (effective salinity) increasing in the direction of increased oil solubility.

Nonideal Effects. In much the same manner as the ideal gas law approximates the behavior of real gases, Fig. 47.17 is an approximation to actual MP phase behavior. Some of the more important nonidealities are as follows.

1. At high surfactant concentrations and/or at low temperatures^{54,59} or even in the presence of pure surfactants,⁶⁰ phases other than those on Fig. 47.17 have been observed. These phases tend to be high-viscosity liquid crystals or other condensed phases. The large viscosities are detrimental to oil recovery since they can cause local viscous instabilities during a displacement. Frequently, low- to medium-molecular-weight alcohols (cosolvents) are added to MP formulations to "melt" these undesirable viscosities. When the brine contains polymer, a condensed phase can be observed at low surfactant concentration because of exclusion of the polymer from the microemulsion phase. Cosurfactants can be used to eliminate this polymer/surfactant incompatibility.⁶¹

2. When cosurfactants are present it is frequently inappropriate to lump all of the chemicals into the surfactant apex of the Fig. 47.17 prism. If the cosurfactants do not partition with the primary surfactant during a displacement the benefit of adding the chemical is lost; hence, surfactant/cosurfactant separation effects are important. Efforts to account for the preferential partitioning of the cosurfactant include a quaternary phase behavior representation and a pseudophase theory.^{62,63}

3. The Type III salinity limits (C_{el} and C_{eu}) are func-

tions of surfactant concentration. This dependency may be visualized by tilting the vertical triangular planes in Fig. 47.17 about their bases. This dilution effect^{64,65} forms the basis for the salinity requirement diagram design procedure.^{66,67} The dilution effect is particularly pronounced when the brine contains significant quantities of divalent ions.

4. The Fig. 47.17 phase-behavior shifts are specific to the exact ionic composition of the brine, not simply to the total salinity. For anionic surfactants, other anions in solution have little effect on the MP phase behavior; however, cations readily cause phase-environment changes. Divalent cations (calcium and magnesium are the most common) are usually 5 to 20 times as potent as monovalent cations (usually sodium). Divalents are usually present in oilfield brines in smaller quantities than monovalents as shown in Fig. 47.2, but their effect is so pronounced that it is necessary, as a minimum, to separately account for salinity and hardness. Nonconstant monovalent/divalent ratios also will cause electrolyte interactions with clay minerals through cation exchange. The disproportionate effects of the salinity and hardness are accounted for by defining a weighted sum of the monovalent and divalent concentrations as an effective salinity. The C_e 's in Fig. 47.17 imply effective salinities.

Phase Behavior and IFT. Early MP flooding literature contains considerable information about the techniques of measuring IFT's and what causes them to be low.⁶⁸ IFT's were found to vary with the types and concentration of surfactant, cosurfactant, electrolyte, oil, and polymer and with temperature. However, in what was surely one of the most significant advances in all of MP technology, all IFT's were shown to correlate directly with the MP phase behavior. The correlation was proposed originally by Healy and Reed,⁵⁹ theoretically substantiated by Huh,⁶⁹ and since verified experimentally by several others.^{31,70} The practical benefit of this correlation is that relatively difficult measurements of IFT's can be largely supplanted by simple phase behavior measurements. Indeed, in the recent literature, the behavior of IFT's has been inferred by a narrower subset of phase-behavior studies based on the solubilization parameter.⁶⁵

Fig. 47.18—Correlation of solubilization ratios with IFT.

Fig. 47.19—IFT and solubilization ratios.

To investigate further the relation between IFT's and phase behavior, let V_o , V_w , and V_s be the volume fractions of oil, brine, and surfactant in the microemulsion phase, respectively. According to Figs. 47.14 through 47.16, the microemulsion phase is present at all salinities; hence, all three quantities are well-defined and continuous. Considering the Type II(-) behavior of Fig. 47.14, for example, V_o , V_w , and V_s are the coordinates of the microemulsion phase composition on the binodal curve.

Solubilization parameters between the microemulsion-oil phases, F_{mo} , for Type II(-) and III phase behavior, and between the microemulsion-aqueous phases, F_{mw} , for Type II(+) and III are defined as

$$F_{mo} = V_o / V_s \quad \dots \dots \dots (9a)$$

and

$$F_{mw} = V_w / V_s \quad \dots \dots \dots (9b)$$

The IFT's between the corresponding phases, σ_{mo} and σ_{mw} , are functions only of F_{mo} and F_{mw} . Fig. 47.18 shows a typical correlation.⁷⁰

The corresponding behavior of the solubilization parameters and IFT's are shown in Fig. 47.19 in a different manner. Consider a locus at constant oil, brine, and surfactant overall concentrations in Fig. 47.17 but with a variable salinity. If the nonideal effects are unimportant and the locus is at low surfactant concentration and intermediate brine/oil ratios, σ_{mo} will be defined from low salinity up to C_{eu} , and σ_{mw} from C_{el} to high salinities. Both IFT's are the lowest in the three-phase Type III region, between C_{el} and C_{eu} , where both solubilization parameters are also large. There is, further, a precise salinity where both IFT's are equal at values low enough ($\sim 10^{-3}$ dyne/cm) for good oil recovery. This salinity is the *optimal salinity* for this particular surfactant/brine/oil combination and the common IFT is the *optimal IFT*. Optimal salinities have been defined on the basis of equal IFT's, as in Fig. 47.19, equal solubilization parameters, maximum oil recovery in corefloods, and equal contact angles.^{50,71,72} All definitions of optimal salinity give roughly the same value; hence, since optimal phase behavior salinity is the same as maximum oil recovery salinity, generating an interfacially active MP slug translates into generating this optimal salinity in situ in the presence of the surfactant material.

Generating Optimal Conditions. Historically there have been three techniques for generating optimal conditions in an MP displacement.

1. The MP system's optimal salinity can be raised to that of the resident brine salinity in the candidate reservoir. This procedure philosophically is the most satisfying of the three design procedures given here and usually the most difficult. Though it has been the subject of intensive research, surfactants that have high optimal salinities that are not (at the same time) thermally unstable at reservoir conditions, excessively retained by the solid surfaces, or expensive have not yet been discovered. Field successes with synthetic surfactants have demonstrated the technical feasibility of this approach, however.⁷³ A sec-

Fig. 47.20—Schematic of surfactant adsorption on metal oxide surface.

ond way to make the optimal salinity of the MP formulation equal to the resident brine salinity is to add cosurfactant.

2. Resident salinity of a candidate reservoir can be lowered to match the MP slug's optimal salinity. This is the main purpose of the preflush step illustrated in Fig. 47.12. A successful preflush is appealing because, with the resident salinity lowered, the MP slug would displace oil wherever it goes in the reservoir. Preflushes generally require quite large volumes to lower the resident salinity significantly owing to mixing effects and cation exchange.^{74,75} With some planning, the function of the preflush could be accomplished during the waterflood preceding the MP flood.

3. The salinity gradient design attempts to dynamically lower the resident salinity to an optimum during the displacement by sandwiching the MP slug between the overoptimal resident brine and an underoptimal mobility-buffer salinity.^{66,67} The success of this procedure relies on it being necessary that only a portion of the MP slug be in the active region for good oil recovery. For salinity gradient floods the salinity of the mobility buffer is the most significant factor in bringing about good oil recovery.⁷⁶ The salinity gradient design has several other advantages in being resilient to design and process uncertainties, in providing a favorable environment for the polymer in the mobility buffer, minimizing retention, and being relatively indifferent to the surfactant dilution effect.

Surfactant Retention. Surfactants are retained through one of at least four mechanisms.

1. On metal oxide surfaces (Fig. 47.20) the surfactant monomer will adsorb physically through hydrogen bonding and micelle-like associations with the monomer tails, and ionically bond with cationic surface sites (I).⁷⁷ At higher surfactant concentrations, C_s , this association includes tail-to-tail interactions with the solution monomers with proportionally greater adsorption (II and III). At and above the CMC (IV), the supply of monomers becomes

constant as does the retention (\hat{C}_s is the adsorbed surfactant concentration).

2. In hard brines the prevalence of divalent cations causes the formation of surfactant/divalent complexes, which have a low solubility in brine.⁷⁸ Precipitation of this surfactant/divalent complex will lead to retention. When oil is present this effect is lessened by the surfactant's solubility in the oleic phase.

3. At hardness levels somewhat lower than those required for precipitation, the preferred multivalent/surfactant complex will be a monovalent cation that can exchange chemically with cations originally bound to the reservoir clays just as inorganic cations do.⁷⁹

4. In the presence of oil in a II(+) phase environment the surfactant will reside in the oil-external microemulsion phase. Because this region is above the optimal salinity, the IFT is relatively large (Fig. 47.18) and this phase and its dissolved surfactant can be trapped.⁶⁴ A similar phase trapping effect does not occur in the II(−) environment because the aqueous mobility buffer miscibly displaces the trapped aqueous-external microemulsion phase without permanent retention.

Most studies of surfactant retention have not made the previously mentioned mechanistic distinctions; therefore, which mechanism predominates in a given application is not obvious. All mechanisms retain more surfactant at high salinity and hardness, which, in turn, can be attenuated by adding cosurfactants. Precipitation and phase trapping can be eliminated by lowering the mobility buffer salinity, at which conditions the chemical adsorption mechanism on the reservoir clays is predominant. Therefore, there should be some correlation of surfactant retention with reservoir clay content. Fig. 47.21 is an attempt to make this correlation by plotting laboratory and field surfactant retention data against clay fraction.⁸⁰ The correlation is by no means perfect since it ignores variations in MP formulation and clay type distribution as well as salinity effects. However, the figure does capture a general trend that is useful for a first-order estimate of retention in a given reservoir.

Fig. 47.21—Surfactant retention and weight fraction of clays.

Fig. 47.22—MP production response from Well 12-1, Bell Creek Pilot.

Recovery Efficiency vs. Mobility Buffer Size

Fig. 47.23—Recovery efficiencies from 21 MP field tests.

A useful way to estimate the volume of surfactant required for an MP slug is through the dimensionless frontal advance lag, F_D .⁸¹

$$F_D = \frac{1 - \phi}{\phi} \frac{\rho_r}{\rho_s} \frac{\hat{C}_s}{C_s} \quad (10)$$

where

F_D = frontal advance lag, dimensionless,

ρ_r = density of rock, mass/volume rock,

ρ_s = density of surfactant slug, mass/volume solution,

C_s = concentration of surfactant, mass surfactant/mass solution, and

\hat{C}_s = retained surfactant concentration, mass surfactant/mass rock (includes all forms of surfactants).

F_D expresses the volume of surfactant retained at its injected concentration as a fraction of the PV. For best surfactant usage, the volume of surfactant injected should be large enough to contact all of the PV, but small enough to prevent excessive production of the surfactant. Therefore, the MP slug size, V_{ps} , should be equal to or somewhat larger than F_D .

Field Response. Fig. 47.22 shows the produced fluid analyses of Well 12-1 in the Bell Creek (Carter and Powder River Counties, MT) MP flood. This flood used a high oil content MP slug preceded by a preflush that contained sodium silicate to lessen surfactant retention and reduce divalent cation concentration. Well 12-1 was a producer in the center of a unconfined single 40-acre, five-spot pattern. Further details on the flood are available in Refs. 47 and 82.

Before MP slug injection in Feb. 1979, Well 12-1 was experiencing low and declining oil cuts. MP oil response beginning in late 1980 is superimposed on this decline, reaching peak cuts of about 13% about 6 months later. Note that, just as in polymer flooding, the pre-MP decline must be clearly established for accurate evaluation of the MP oil recovery. The surfactant is preceding the oil in Fig. 47.22 because of an excessively large content of water-soluble, inactive disulfonate in the MP slug. Simultaneous oil and surfactant production is a persistent feature of field MP floods, probably because of heterogeneities and dispersive mixing. Other significant features in Fig. 47.22 are the evident presence of the preflush preceding the MP slug, inferred from the maxima in the pH and silicate concentrations, and the very efficient removal of the calcium cations ahead of the surfactant.

Fig. 47.23 shows oil recovery efficiency, E_R (incremental oil recovered/OIP at start of MP process), from a survey of more than 40 MP field tests correlated as a function of mobility-buffer slug size. As of the date of the survey there were no commercial projects reported. Similar analyses on other process variables showed no or weak correlation.⁸³ The strong correlation in Fig. 47.23 indicates the importance of mobility control in MP design.⁴⁸ Note also from this figure that ultimate oil recovery efficiency averages about 30% in field tests.

Performance Prediction. Generally, three things must be achieved for efficient oil recovery.⁸⁴ (1) the MP surfactant slug must be propagated in an interfacially active mode, (2) enough surfactant must be injected so that some of it is unretained by the permeable media surfaces, and (3) the MP displacement must be designed so that the active surfactant sweeps a large portion of the reservoir without excessive dissipation (because of dispersion) or channeling.

Attaining the first goal is the result of formulation work based on the phase-behavior concepts discussed previously. The extent to which the second and third goals are satisfied depends on prevailing economics, which, in turn, depends on the oil-recovering ability of the entire process. The next few paragraphs describe a simple procedure by which oil recovery and oil rate-time curves may be estimated for an interfacially active MP process. Since there are innumerable ways in which interfacial activity may be lost, the procedure is most accurate for processes that clearly satisfy the first design goal.

Recovery Efficiency. This procedure has two steps: estimating the recovery efficiency of an MP flood and then proportioning this recovery according to injectivity and fractional flow to give an oil rate-time curve. Space considerations will limit many of the details, which may be found in Ref. 80.

The recovery efficiency, E_R , of an MP flood is the product of a volumetric sweep efficiency, E_V , a displacement efficiency, E_D , and a mobility buffer efficiency, E_{MB} .

$$E_R = E_D E_V E_{MB} \quad (11)$$

Each quantity must be calculated independently.

Displacement Efficiency. The displacement efficiency of an MP flood is the ultimate (time-independent) volume of oil displaced divided by the volume of oil contacted.

$$E_D = 1 - \frac{S'_{or}}{S_{orw}} \quad (12)$$

where S'_{or} and S_{orw} are the ROS to an MP and waterflood, respectively. S_{orw} must be known, but S'_{or} can be obtained from a large slug (free from the effects of surfactant retention) laboratory coreflood. Low values of S'_{or} indicate successful attainment of good interfacial activity in the MP slug. If coreflood results aren't available, S'_{or} may be estimated from a CDC by using a "field" capillary number.⁸³

$$N_c = 0.565 q \mu_o \gamma_o / (h \sqrt{A}), \quad (13)$$

where

- N_c = capillary number, dimensionless,
- q = injection/production rate,
- μ_o = oil viscosity,
- h = net thickness, and
- A = pattern area.

Eq. 13 is in consistent units. For screening purposes, assume a controlling IFT of 10^{-3} dyne/cm [$1 \mu\text{N/m}$]; the CDC curve chosen to estimate S'_{or} should be consistent,

Fig. 47.24—Relationship between MP volumetric sweep efficiency, heterogeneity, and slug-size retention ratio.

as much as possible, with conditions of the candidate reservoir.

Volumetric Sweep Efficiency. Volumetric sweep efficiency, E_V , is the volume of oil contacted divided by the volume of target oil. E_V is a function of MP slug size, V_{PS} , retention, F_D , and heterogeneity based on the Dykstra-Parsons coefficient, K_{DP} . Fig. 47.24 shows this relationship. K_{DP} may be estimated from geologic study, from matching the previous waterflood, or from core data (a typical value would be 0.6). The F_D is estimated from Eq. 10 on the basis of the retention level, \hat{C}_s , surfactant slug concentration, C_s , porosity, and rock and fluid densities. \hat{C}_s can come from a laboratory coreflood, Fig. 47.21 (if clay fraction is known), or by using $\hat{C}_s = 0.4$ mg/g as a default. V_{PS} and C_s are from the proposed design.

Mobility Buffer Efficiency. The mobility buffer efficiency, E_{MB} , is a function of E_V and K_{DP} .

$$E_{MB} = (1 - E_{MBe}) [1 - \exp(0.4 V_{MB} / E_V^{1.2})] + E_{MBe}$$

and

$$E_{MBe} = 0.71 - 0.6 K_{DP} \quad (14a)$$

where E_{MBe} is the mobility buffer efficiency extrapolated to $V_{MB} = 0$ and V_{MB} is the mobility buffer volume, fraction V_p . Eq. 14a was obtained from a numerical simulation.

The recovery efficiency now may be calculated from Eqs. 11 through 14a. The reasonableness of the value may be checked with Fig. 47.23.

Calculation of q_o vs. t Plot. The production function (oil rate vs. time) is based on E_R and the following procedure. The dimensionless production function is assumed to be triangular with oil production beginning at oil bank arrival time, increasing linearly to a peak (maximum) oil cut when the surfactant breaks through, and decreasing linearly to sweepout time. The triangular shape is imposed by the reservoir heterogeneity.

The first step is to calculate the dimensionless oil bank and surfactant breakthrough times for a homogeneous laboratory coreflood.

$$t_{Dob} = \left(\frac{S_{ob} - S_{oi}}{f_{ob} - f_{oi}} \right) t_{DS} \quad (14b)$$

Fig. 47.25—Comparison between predicted and observed oil rate-time responses for the Sloss MP pilot.

and

$$t_{Ds} = 1 + F_D - S'_{or} \quad (14c)$$

where

- t_{Dob} = oil bank arrival time, dimensionless,
- S_{ob} = oil bank saturation, fraction,
- S_{oi} = initial oil saturation, fraction,
- f_{ob} = oil bank oil fractional flow, fraction,
- f_{oi} = initial oil fractional flow, fraction, and
- t_{Ds} = surfactant arrival time, dimensionless.

S_{ob} and f_{ob} may be estimated from the oil/water relative permeability curve as described previously in Refs. 80 and 85, or from laboratory experiment.

The second step is to correct these values for the heterogeneity of the candidate reservoir by using an effective mobility ratio, M_e , where

$$\log(M_e) = \frac{K_{DP}}{(1 - K_{DP})^{0.2}} \quad (15)$$

The corrected breakthrough times are now

$$t'_{Dob} = t_{Dob}/M_e \quad (16a)$$

and

$$t'_{Ds} = t_{Ds}/M_e \quad (16b)$$

where t'_{Dob} is the corrected oil bank arrival time, dimensionless, t'_{Ds} is the corrected surfactant arrival time,

dimensionless, and the peak oil cut, f_{opk} , is

$$f_{opk} = \frac{M_e - M_e \left(\frac{t_{Dob}}{t_{Ds}} \right)^{1/2}}{(M_e - 1)} f_{ob} \quad (17)$$

The final step is to convert the dimensionless production function to oil rate, q_o , vs. time, t . This follows from

$$q_o = q f_o \quad (18a)$$

and

$$t = V_p t_D / q \quad (18b)$$

where f_o is the oil cut, t_D is the dimensionless time, and f_o and t_D are any points on the triangular oil recovery curve, which begins at (t'_{Dob}, f_{oi}) , peaks at (t'_{Dob}, f_{opk}) , and ends at $(t'_{Dsw}, 0)$. The dimensionless time at complete sweepout, t'_{Dsw} , is selected to make the area under the $f_o - t'_D$ curve equal to E_R ,

$$t'_{Dsw} = t'_{Dob} + 2E_R S_{orw} / f_{opk} \quad (19)$$

A comparison of the results of this procedure with the Sloss field MP pilot is in Fig. 47.25. Details of this match and other matches are in the original references.

High-pH Processes

The final chemical flooding EOR process is high-pH flooding (Fig. 47.26). As in polymer and MP flooding, there is usually a brine preflush to precondition the reservoir, a finite volume of the oil-displacing chemical, a graded mobility buffer driving agent, and the entire process is driven by chase water. Moreover, for both high-pH and MP flooding the oil-displacing chemical is a surfactant; however, for MP flooding the surfactant is injected while in high-pH flooding it is generated in situ.

High-pH Chemistry

High pH's indicate large concentrations of the hydroxide anions (OH^-). The pH of an ideal aqueous solution is defined as

$$\text{pH} = -\log_{10} C_{\text{H}^+} \quad (20)$$

where the concentration of hydrogen ions, C_{H^+} , is in mol/L. As the concentration of OH^- is increased, the concentration of H^+ decreases, since the two concentrations are related through the dissociation of water,

$$K_w = \frac{(C_{\text{OH}^-})(C_{\text{H}^+})}{C_{\text{H}_2\text{O}}} \quad (21)$$

and the water concentration is nearly constant. These considerations suggest two means for introducing high pH's into a reservoir: dissociation of a hydroxyl-containing species or adding chemicals that preferentially bind hydrogen ions.

Many chemicals could be used to generate high pH, but the most commonly used are sodium hydroxide (caustic, NaOH), sodium orthosilicate, and sodium carbonate (Na_2CO_3). NaOH generates OH^- by dissociation; the

Fig. 47.26—Schematic of high-pH flooding process.

latter two through the formation of weakly dissociating acids (silicic and carbonic acid, respectively) that remove free H^+ ions from solution. High-pH chemicals generally have been used in field applications in concentrations ranging up to 5 wt% (injected pH's of 11 to 13) and with slug sizes up to 20% PV. The resulting amounts of chemicals are quite comparable with the surfactant usage in MP flooding; however, high-pH chemicals are substantially less costly. This cost advantage must be discounted by the historically lower oil recoveries in high-pH flooding.

OH^- by itself is not a surfactant, since the absence of a lipophilic tail makes it exclusively water-soluble. If the crude oil contains an acidic hydrocarbon component, HA_o , some of this, HA_w , can partition to the aqueous phase where it can react.⁸⁶

The exact nature of HA_o is unknown and probably highly dependent on crude oil type. The deficiency of hydrogen ions in the aqueous phase will cause the extent of this reaction to be to the right. The anionic species A_w^- is a surfactant that can have many of the properties and enter into most of the phenomena described above for MP flooding.

If there is no HA_o originally present in the crude, little surfactant can be generated. A useful procedure for characterizing crudes for their attractiveness to high-pH flooding is through the *acid number*. The acid number is the milligrams of potassium hydroxide (KOH) required to neutralize 1 gram of crude oil. To make this measurement, the crude is extracted with water until the acidic species HA is removed. The aqueous phase containing HA_w , A_w^- , and H^+ is then brought to pH=7 by adding the KOH. For a meaningful value, the crude must be free of acidic additives (e.g., scale inhibitor) and acidic gases (CO_2 or H_2S). A good high-pH flooding crude will have an acid number of 0.5 mg/g or greater, but acid numbers as low as 0.2 mg/g may be candidates, since only a small

amount of surfactant is required to saturate oil/brine interfaces. Fig. 47.27 presents a histogram of acid numbers based on the work of Jennings.^{87,88}

Displacement Mechanisms

Oil recovery mechanisms in high-pH flooding have been attributed to eight separate phenomena.⁸⁹ This chapter concentrates on only three: IFT lowering, wettability reversal, and emulsion formation. The last two mechanisms also are present in MP flooding but are dwarfed by the low-IFT effect. With smaller ultimate oil recoveries, the distinction among effects becomes important in high-pH flooding.

Fig. 47.27—Histogram of acid numbers.

Fig. 47.28—IFT's for caustic/crude/brine systems.

The generated surfactant, A_w^- , aggregates at oil/water interfaces, which can lower IFT.⁸⁶ In general, such lowering is not as pronounced as in MP flooding but, under certain conditions, can be large enough to produce good oil recovery. Fig. 47.28 shows IFT measurements of caustic solutions against Long Beach crude oil at various brine salinities. The IFT's are sensitive to both NaOH concentration and salinity, showing minima in the NaOH concentration range of 0.01 to 0.1 wt%. The decrease in IFT in these experiments is limited by the spontaneous emulsification of the oil/water mixture when the IFT reaches a minimum.

There are many similarities in the low-IFT effects in MP and high-pH flooding. The data in Fig. 47.28 show a clear resemblance to the data in the upper plot of Fig. 47.19 except they are plotted vs. NaOH concentration (presumed proportional to A_w^- concentration) instead of salinity. This suggests an optimal salinity of about 1.0 wt% NaCl for a 0.03 wt% NaOH solution. Indeed, the work of Jennings *et al.*⁸⁷ has shown that there is an optimal NaOH concentration for a given salinity in oil recovery experiments. Moreover, the presence of the emulsification effect when IFT's are low is exactly what one would expect from Fig. 47.17 at a surfactant concentration above the invariant point surfactant concentration. This suggests that the data in Fig. 47.28 showing a Type II(-) phase environment at low NaOH concentrations are Type II(+) at high (similar to what would be expected from the dilution effect in MP flooding). Further work is necessary to establish the connection to MP phase-behavior definitively, since the actual surfactant concentration A_w^- is likely to be much lower in a high-

pH system. However, Nelson *et al.*⁹⁰ show that a cosurfactant can increase the optimal salinity in a high-pH system much like in MP systems.

See Chap. 28 for a discussion of wettability and its effects on petrophysical properties. Owens and Archer⁹¹ showed that increasing the water wetness increased ultimate oil recovery, where the wettability was reported as decreasing the water/oil contact angle measured on polished synthetic surfaces. This has also been shown by others using high-pH chemicals.^{92,93} The increased oil recovery is the result of two mechanisms: a relative permeability effect, which causes the mobility ratio of a displacement to decrease, and a shifting of the CDC (see Fig. 47.11).

Cooke *et al.*⁹⁴ have reported improved oil recovery with increased oil wetness. Other data show that oil recovery is a maximum when the wettability of a permeable medium is neither strongly water- nor oil-wet.⁹⁵ Given the latter information, the important factor may be the change in the wettability rather than the actual wettability of the final state of the medium. In the original wetting state of the medium, the nonwetting phase occupies large pores and the wetting phase small pores. If the wettability of a medium is reversed, there will be nonwetting fluid in small pores and wetting fluid in large pores. The resulting fluid redistribution, as the phases attempt to return to their natural state, would make both phases vulnerable to recovery through viscous forces.

High-pH chemicals can cause improved oil recovery through the formation of emulsions. The emulsification produces additional oil in at least two ways: through a mobility ratio lowering since many of these emulsions have a substantially increased viscosity and through solubilization and entrainment of oil in a flowing aqueous stream. The first mechanism improves displacement and volumetric sweep as do the mobility control agents discussed previously. Local formation of highly viscous emulsions should be discouraged, however, as these would promote viscous fingering from the less viscous oil-free high-pH solution. The solubilization and entrainment mechanism would be more important when the IFT between the swollen water phase and the remaining crude is low. Fig. 47.28 shows that for certain conditions, emulsification and low IFT's occur simultaneously. McAuliffe showed that emulsions injected in a core and those formed in situ give comparable oil recoveries.^{96,97}

Rock/Fluid Interactions

Interactions of the high-pH chemicals and the permeable media minerals can cause excessive retardation in the propagation of these chemicals throughout the permeable medium. This chapter discusses three aspects of rock-fluid interactions: formation of divalent/hydroxide compounds, cation exchange, and mineral dissolution.

OH^- ions themselves are not appreciably bound to the solid surfaces; however, in the presence of multivalent cations they can form hydroxyl compounds,

which, being relatively insoluble, can precipitate from solution. This reaction, in turn, lowers the pH of the solution, and also can cause formation damage through pore

blockage and fines migration. The anionic surfactant species A_w^- can interact with the inorganic cations in solution just as in MP flooding; however, the interaction with the divalent cations usually takes precedence, particularly in hard brines (see Fig. 47.3) or where there are substantial quantities of soluble multivalent minerals. Because of these interactions and those involving the surfactants A_w^- , high-pH processes are as sensitive to brine salinity and hardness as are MP processes.

Other high-pH rock/fluid interactions are intimately associated with the clay minerals. Clays are hydrous aluminum/silicate compounds that occupy the smallest (less than 2 microns) particle size in typical media. Macroscopically, clays occur as segregated streaks of variable degree of continuity throughout a typical reservoir, or as distributed clays, which can line pore walls or fill pore throats. Distributed clays are of most concern here, since these have quite large surface areas (15 to 40 m²/g clay), and therefore can exhibit considerable reactivity.⁹⁸ Chemically, clays can take on a variety of formulas that differ substantially in their reactivity even though the differences in their molecular formulas are apparently minor.

The ability of a clay mineral to exchange divalent cations with an aqueous solution can drastically change the ionic environment of a solution with which it is in contact. Clays have excess negative charges caused by the substitution of +2-valence minerals for +3-valence minerals within the octahedral or tetrahedral crystal lattice.⁹⁹ The cation exchange capacity, Z_V , is a measure of this excess negative charge; typical Z_V 's are 1 to 10 meq/100 g clay for kaolinite and 100 to 180 meq/100 g clay for montmorillonite. These free anionic sites are covered with cations from the solution, each of which has a specific degree of selectivity for the particular clay site. In general, H^+ has high clay selectivity, and divalent cations are bound more strongly than are monovalents. This means that the anionic sites can be occupied predominantly by H^+ and/or divalents even when clays are in contact with relatively soft brines. Any subsequent change in the electrolyte environment of the contacting solution can cause the clays to take or give up these cations with a possible detrimental effect on high-pH (and MP) flooding.

H^+ cations can exchange on the clay sites with the injected sodium according to

where "clay" represents a mineral exchange site.¹⁰⁰ The reversible reaction Eq. 24 will clearly cause the H^+ concentration to increase with a resulting pH decline. Fig. 47.29 shows the extent of the OH^- retardation caused by cation exchange in laboratory floods. Note that many of the lower pH's may require more than 3 PV of fluid injection to attain the injected pH.

Unlike MP flooding, high-pH chemicals can react directly with clay minerals and the silica substrate to cause consumption of OH^- ions. The reactions with clays are manifest by the elution of soluble aluminum and silica species from core displacements.¹⁰¹ The resulting soluble species subsequently can cause precipitates through hydroxyl reactions as in Eq. 24.¹⁰² The rate of hydroxyl consumption from this slow reaction (cation exchange is generally fast enough so that local equilibrium applies)

Fig. 47.29—Effluent histories pH from laboratory corefloods. Experimental curves are solid lines with points, theoretical results are dashed lines.

is determined by a dimensionless Damköhler number, N_{Da} ,

$$N_{Da} = \phi k L / u_w, \quad (25)$$

where k is the reaction rate constant, time⁻¹, and L is the medium length for a first-order reaction. N_{Da} is the ratio of the reaction rate to the bulk fluid rate. If all conditions are equivalent between a laboratory experiment and a prototype field flood, N_{Da} clearly will be much larger in the field than in the laboratory owing to the much larger length scale. A larger N_{Da} implies more reaction relative to the residence time within the system. Thus, it follows that the penetration distance—the distance traveled by full-strength OH^- ions—will be considerably smaller in the field than in the laboratory. Bunge and Radke, who illustrate this with several numerical calculations, caution against extrapolating laboratory-measured values of OH^- consumption to field cases unless the discrepancies in N_{Da} have been taken into account.¹⁰¹

Field Results

High-pH field tests of particular interest include a wettability reversal test,⁹⁴ an emulsion flood,⁹⁶ and a polymer-driven flood.¹⁰³ Fig. 47.30 shows the production data from a high-pH flood conducted in the Whittier field.¹⁰⁴ The crude oil was 20°API with a 40-cp viscosity, and the 0.2 wt% NaOH chemical was injected as a 0.23-PV slug.

There are many features in these data that are common to the responses of the other chemical flooding processes in Figs. 47.6 and 47.22. The oil production rate declines as the total fluid production increases, indicating a declining oil cut. The oil rate response to the caustic injection is again superimposed on the waterflood decline, which is extrapolated to estimate the IOR. (There are two waterflood decline curves in Fig. 47.28, one based on the actual decline and one based on computer simulation.) The 350,000 to 470,000 STB of oil produced by the caustic injection was considered a success by the operators.

Table 47.3 shows a summary of data from completed high-pH field floods. Note the wide range in reservoir and oil characteristics and in oil saturation at the start of the flood.¹⁰⁵ IOR, expressed as a fraction of PV, ranges from 0.0006 to 8.0, which translates into recoveries, expressed as a fraction of the OIP at the project start, that

TABLE 47.3—SUMMARY OF HIGH-pH FIELD TESTS

Field, Location, Operator	μ_o at Residual Reservoir Temperature (cp)	Residual Reservoir Temperature (°F)	Oil Saturation at Project Start (%)	Porosity (%)	Net Thickness (ft)	Injection Water Salinity (ppm TDS)	Depth (ft)
Bradford, PA (Several tests by several operators)	—	—	60	16 to 20	30	—	—

Orcutt Hill, CA (Union)	17 to 60	140	50	22.5	155	15,000	2,200

are comparable with but slightly smaller than those reported from polymer floods (Table 47.1). Of equal importance is the STB of IOR produced per pound of chemical injected (0.015 to 0.43 in Table 47.3). This is substantially lower than the polymer flood values; however, the cost of the high-pH chemical is also substantially lower.

Summary

Fig. 47.31 presents screening guides for the three major chemical flooding processes presented in this chapter based on the work of Taber and Martin.¹⁰⁶ Though there are many other possible guidelines, the figure focuses on three common reservoir parameters: oil viscosity at reservoir conditions, permeability, and depth. The guides are intended as rules of thumb for candidate reservoir selection and are not substitutes for detailed reservoir evaluation.

Chemical flooding application usually is limited to moderate to low oil viscosities because of economics. As the oil viscosity increases, more of the respective chemical is required to attain good mobility control. This causes a direct penalty in chemical cost and an indirect penalty in increased project life. Similar considerations place a

lower limit on the reservoir permeability, although in the case of polymers used in polymer or MP flooding there is a technical limit imposed by the inability to propagate large molecules through very small pore spaces. Deep reservoirs usually imply the ability to apply larger surface pressures with accompanying increase in injection rates. This beneficial effect is offset by the susceptibility of polymers to chemical degradation at elevated temperatures. High-pH processes are also more reactive at high temperature, which causes excessive consumption.

The information in Fig. 47.31 suggest the avenues of future development for chemical flooding EOR processes: (1) the development of more cost-effective chemicals such as surfactants and polymers that are more salinity resistant, have minimal retention, can be manufactured onsite, or can be recycled, (2) development of more efficient design procedures such as applying MP technology to high-pH flooding design, (3) removing technical limitations on the use of water-soluble polymers, particularly as they relate to temperature sensitivity, and (4) more reliable prediction techniques, particularly as they relate to risk estimates. Each general area will continue to prompt considerable research so that the economic viability of chemical flooding will become commonplace.

ortho-silicate	0.6	0.42	0.017	0.028	0.0006	0.015 to 0.030

Nomenclature

- A = pattern area
 C_{el} = low effective salinity limit
 C_{eu} = high effective salinity limit
 C_s = concentration of surfactant, mass surfactant/mass solution
 \hat{C}_s = retained surfactant concentration, mass surfactant/mass rock (includes all of the previously mentioned forms of surfactants)
 $\dot{\epsilon}_e$ = effective shear rate
 $\dot{\epsilon}_{1/2}$ = shear rate when polymer solution viscosity is 1/2 of high and low values, Eq. 3
 E_{MB} = mobility buffer efficiency
 E_{MBe} = mobility buffer efficiency extrapolated
 f_{ob} = oil bank oil fractional flow, fraction
 f_{oi} = initial oil fractional flow, fraction
 f_{opk} = peak oil cut
 F_D = frontal advance lag, dimensionless
 F_{mo} = solubilization ratios between the microemulsion/oleic phases
 F_{mw} = solubilization ratios between the microemulsion/aqueous phases
 F_{rk} = permeability reduction factor
 F_R = resistance factor
 F_{Rr} = residual resistance factor
 k_p = permeability to polymer solution
 k_w = permeability to polymer-rich (water) phase
 K = power-law coefficient
 K_{DP} = Dykstra-Parsons coefficient
 K_w = dissociation coefficient of water
 M_e = effective mobility ratio
 M^* = shock mobility ratio
 M° = endpoint mobility ratio

OIL VISCOSITY - CENTIPOISE AT RESERVOIR CONDITION

PERMEABILITY, md

DEPTH, FEET

Fig. 47.31—Comparative evaluation of reservoir parameters for chemical flooding.

- n = power-law exponent
 N_c = capillary number, dimensionless
 P_L = left plait-point designation
 P_R = right plait-point designation
 S_{ob} = oil bank saturation, fraction
 S_{oi} = initial oil saturation, fraction
 S'_{or} = ROS to an MP flood
 S'_{orw} = ROS to a waterflood
 S_w = saturation of polymer-rich (water) phase
 t_{Dob} = oil bank arrival time, dimensionless
 t'_{Dob} = corrected oil bank arrival time, dimensionless
 t_{Ds} = surfactant arrival time, dimensionless
 t'_{Ds} = corrected surfactant arrival time, dimensionless
 t'_{Dsw} = dimensionless time at complete sweepout
 u_w = superficial flux of polymer-rich (water) phase, L/t
 v_w = superficial velocity of water phase
 V_{MB} = mobility buffer volume, fraction
 V_{ps} = MP slug size
 Z_V = cation exchange capacity
 λ_d = mobility of displaced fluid(s)
 λ_D = mobility of displacing agent(s)
 λ_p = mobility of polymer solution
 λ_w = mobility of water-rich phase
 λ_{wa} = mobility of water-rich phase after polymer injection
 λ_{wb} = mobility of water-rich phase before polymer injection
 μ_p = apparent viscosity of polymer solution
 μ_p^o = polymer solution viscosity below some low shear rate
 μ_p^∞ = polymer solution viscosity above the critical shear rate
 μ_w = viscosity of the displacing water
 ρ_r = density of rock, mass/volume rock
 ρ_s = density of surfactant slug, mass/volume solution
 σ_{mo} = IFT between the microemulsion phase and oil
 σ_{mw} = IFT between the microemulsion phase and water
 σ_{wo} = IFT between the water and oil phases

Chapter 48

Reservoir Simulation

K.H. Coats, Scientific Software-Intercom

Introduction

Webster's dictionary defines *simulate* as *to assume the appearance of without the reality*. Simulation of petroleum reservoir performance refers to the construction and operation of a model whose behavior assumes the appearance of actual reservoir behavior. The model itself is either physical (for example, a laboratory sandpack) or mathematical. A mathematical model is simply a set of equations that, subject to certain assumptions, describes the physical processes active in the reservoir. Although the model itself obviously lacks the reality of the oil or gas field, the behavior of a valid model simulates (assumes the appearance of) that of the field.

The purpose of simulation is estimation of field performance (e.g., oil recovery) under one or more producing schemes. Whereas the field can be produced only once, at considerable expense, a model can be produced or run many times at low expense over a short period of time. Observation of model performance under different producing conditions aids selection of an optimal set of producing conditions for the reservoir.

The tools of reservoir simulation range from the intuition and judgment of the engineer to complex mathematical models requiring use of digital computers. The question is not whether to simulate but, rather, which tool or method to use. This chapter attempts to summarize the evolution and current status of reservoir simulation practice involving usage of the mathematical, computerized models. The relatively modern nature of this practice is indicated by the first edition of this handbook (1962) not including a chapter on reservoir simulation.

The nearly exponential growth in annual rate of simulation-related publications from the mid-1960's to the present indicates the industry's widespread acceptance of mathematical simulation as an engineering tool. This acceptance has been and remains qualified by questioning and improvement of accuracy in simulation model results. Thus a significant portion of the extensive literature deals

with model (1) evaluation or validation through comparison of field (laboratory) and model results and (2) improvement by use of new techniques related to model mathematics and representation of reservoir fluid and rock description parameters.

The volume and increasing complexity of publications related to the latter item preclude a detailed mathematical description of current simulation technology in this chapter. Rather, emphasis is given to a general description of reservoir simulation models, how and why they are used, choice of different types of models for different reservoir problems, and reliability of simulation results in the face of model assumptions and uncertainty in reservoir fluid and rock description parameters. The chapter concludes with an abbreviated description of simulation model technology consisting of comments on a number of highly technical publications. Various texts¹⁻⁴ give detailed descriptions of simulation technology through the late 1970's, including finite-difference approximations, model formulations, iterative solution techniques, and stability analyses.

A Brief History

In a broad sense, reservoir simulation has been practiced since the beginning of petroleum engineering in the 1930's. Before 1960, engineering calculations consisted largely of analytical methods,^{5,6} zero-dimensional material balances,^{7,8} and one-dimensional (1D) Buckley-Leverett^{9,10} calculations.

The term *simulation* became common in the early 1960's, as predictive methods evolved into relatively sophisticated computer programs. These programs represented a major advancement because they allowed solution of large sets of finite-difference equations describing two- and three-dimensional (2D and 3D), transient, multiphase flow in heterogeneous porous media. This advancement was made possible by the rapid evolution of

Fig. 48.1—1-, 2-, and 3D grids.

large-scale, high-speed digital computer, and development of numerical mathematical methods for solving large systems of finite-difference equations.

During the 1960's, reservoir simulation efforts were devoted largely to two-phase gas/water and three-phase black-oil reservoir problems. Recovery methods simulated were limited essentially to depletion or pressure maintenance. It was possible to develop a single simulation model capable of addressing most reservoir problems encountered. This concept of a single, general model always has appealed to operating companies because it significantly reduces the cost of training and usage and, potentially, the cost of model development and maintenance.

During the 1970's, the picture changed markedly. The sharp rise in oil prices and governmental trends toward deregulation and partial funding of field projects led to a proliferation of enhanced-recovery processes. This led to simulation of processes that extended beyond conventional depletion and pressure maintenance to miscible flooding, chemical flooding, CO₂ injection, steam or hot-water stimulation/flooding, and in-situ combustion. A relatively comfortable understanding of two-component (gas and oil) hydrocarbon behavior in simple immiscible flow was replaced by a struggle to unravel and characterize the physics of oil displacement under the influence of temperature, chemical agents, and complex multicomponent phase behavior. In addition to simple multiphase flow in porous media, simulators had to reflect chemical absorption and degradation, emulsifying and interfacial tension (IFT) reduction effects, reaction kinetics, and other thermal effects and complex equilibrium phase behavior. This proliferation of recovery methods in the

1970's caused a departure from the single-model concept as individual models were developed to represent each of these new recovery schemes.

Research during the 1970's resulted in many significant advances in simulation model formulations and numerical solution methods. These advances allowed simulation of more complex recovery processes and/or reduced computing costs through increased stability of the formulations and efficiency of the numerical solution methods.

General Description of Simulation Models

A number of papers¹¹⁻¹⁴ present general, largely non-mathematical discussions of reservoir simulation. Odeh¹¹ gives an excellent description of the conceptual simplicity of a simulation model. He illustrates the subdivision of a reservoir into a 2- or 3D network of gridblocks and then shows that the simulation model equations are basically the familiar volumetric material balance equation^{7,8} written for each phase for each gridblock. The phase flow rates between each gridblock and its two, four, or six (in 1D, 2D, or 3D cases, respectively) adjacent blocks are represented by Darcy's law modified by the relative permeability concept. Fig. 48.1 illustrates 1-, 2-, and 3D grids representing a portion of a reservoir. The block and its two or four neighbors are denoted by B and N in the 1D and 2D grids. One can visualize an interior block of the 3D grid with its six neighbors, two on either side of the block in the x, y, and z directions.

The subsea depths to the top surface of each grid in Fig. 48.1 vary with areal position, reflecting reservoir formation dip. Reservoir properties such as permeability and porosity, and fluid properties such as pressure, temperature, and composition, are assumed uniform throughout a given gridblock. However, reservoir and fluid properties vary from one block to another; fluid properties for each gridblock also vary with time during the simulation period.

A simulation model is a set of partial-difference equations requiring numerical solution as opposed to a set of partial differential equations amenable to analytical solution. The reasons for this are (1) reservoir heterogeneity—variable permeability and porosity and irregular geometry, (2) nonlinearity of relative permeability and capillary pressure vs. saturation relationships, and (3) nonlinearity of fluid PVT properties as functions of pressure, composition, and temperature. The models require high-speed digital computers because of the large amount of arithmetic associated with the solutions.

The large amount of arithmetic performed by a simulation model stems from the large number of gridblocks representing the reservoir and from the number and complexity of equations describing the oil-recovery process. Total arithmetic or computing expense for a given model run is at least linearly proportional to the total number of gridblocks, $N_x N_y N_z$, where N_x , N_y , and N_z are the numbers of gridblocks specified in the x, y and z directions, respectively.

The individual gridblocks are customarily identified by subscripts i, j, k , where blocks are numbered $i=1,2,\dots,N_x$ in the x direction, $j=1,2,\dots,N_y$ in the y direction, and $k=1,2,\dots,N_z$ in the z direction. Most simulators use no-flow or closed boundary conditions at the exterior boundaries [$x=(0,L_x)$, $y=(0,L_y)$ and $z=(0,L_z)$] with provision

for aquifer influx along the areally exterior boundary. The nonrectangular, areal ($x-y$) shapes of most reservoirs are represented by zero gridblock porosity and permeability in the appropriate areal portions of the $x-y$ grid.

Preceding statements described the simulation model as a set of equations expressing conservation of mass for each phase for each gridblock. More precisely, the model equations express conservation of mass of each reservoir fluid *component* for each block. The number and identity of these components depend on the nature of the original reservoir fluid and the particular oil-recovery process, as discussed in the following. The total number of mass conservation equations is then $N_x N_y N_z N$, where N is the number of components necessary to describe the reservoir fluids.

Each conservation equation states that the mass rate of flow into a gridblock minus the mass rate of flow out must equal the rate of change or accumulation of mass within the block. These N mass-balance equations (one for each component) apply to each gridblock. The block is an open system, in the thermodynamic sense, because of fluid flow between the block and its six neighbors and fluid injection or production if a well is perforated in the block.

The center of gridblock (i, j, k) is located at (x_i, y_j, z_k) . This block has six neighboring blocks $(i \pm 1, j, k)$, $(i, j \pm 1, k)$ and $(i, j, k \pm 1)$. For brevity and clarity, the interblock flow rates are written here in terms of only x -direction flow between blocks $(i-1, j, k)$ and (i, j, k) , the indices j and k are suppressed, and the general symbol C_I denotes concentration (mass/volume) of component I in the various phases. The three immiscible phases (water, oil, and gas) are denoted by subscripts w , o , and g , respectively.

The interblock flow rate of component I , according to Darcy's law modified by relative permeability, is

$$q_I = \frac{kA}{L} \left[\frac{k_{rw}}{\mu_w} C_{Iw} (\Delta p_w - \gamma_w \Delta Z) + \frac{k_{ro}}{\mu_o} C_{Io} (\Delta p_o - \gamma_o \Delta Z) + \frac{k_{rg}}{\mu_g} C_{Ig} (\Delta p_g - \gamma_g \Delta Z) \right], \quad (1)$$

where

- q_I = component I interblock flow rate, mass/time,
- k = absolute permeability,
- $A = \Delta y_i \Delta z_k$ = cross-sectional area normal to flow,
- L = distance between adjacent block centers, $(\Delta x_{i-1} + \Delta x_i)/2$,
- k_{rp} = relative permeability to phase P ($P = w, o, g$),
- μ_P = viscosity of phase P
- C_{IP} = concentration of component I in phase P , mass/volume,
- Δp_P = pressure of phase P
- γ_P = specific weight of phase P
- $\Delta_x = x_{i-1} - x_i$, where x is p or Z , and
- Z = subsea depth, measured positively downward.

If subscript $J=1,2,3$ is used to denote phases w, o, g respectively, then Eq. 1 simplifies to

$$q_I = \left(\sum_{J=1}^3 \frac{kA}{L} \frac{k_{rJ}}{\mu_J} C_{IJ} \right) (\Delta p_J - \gamma_J \Delta Z). \quad (2)$$

The first term in parentheses is the interblock *transmissibility*, T_{IJ} , for flow of component I in phase J , requiring evaluation here at $(i-1/2, j, k)$ —i.e., between blocks $i-1$ and i . The kA/L portion of T is normally calculated as the harmonic or series-resistance mean value using block $i-1$ and block i properties. The remaining portion of T normally is evaluated at the upstream gridblock—i.e., the block from which the phase is flowing. Thus Eq. 2 becomes simply

$$q_I = \sum_{J=1}^3 (T_{IJ})_{i-1/2} (\Delta p_J - \gamma_J \Delta Z), \quad (3)$$

representing interblock flow of component I from gridblock $i-1$ to gridblock i .

The right-hand or accumulation terms of the mass balances are

$$\frac{V}{\Delta t} \left[\phi \sum_{J=1}^3 (S_J C_{IJ}) \right], \quad (4)$$

where

- V = grid block volume, $\Delta x_i \Delta y_j \Delta z_k$
- $\bar{\delta}$ = time difference operator, $\delta X \equiv X_{n+1} - X_n$,
- n = time level, $t_{n+1} = t_n + \Delta t$,
- Δt = timestep,
- ϕ = porosity, fraction, and
- S_J = saturation of phase J , fraction of pore space.

Eqs. 3 and 4 give the final form of the component I mass-balance equation for gridblock (i, j, k) as

$$\sum_{J=1}^3 \Delta [T_{IJ} (\Delta p_J - \gamma_J \Delta Z)] - q_{pI} = \frac{V}{\Delta t} \sum_{J=1}^3 \bar{\delta} (\phi S_J C_{IJ}), \quad (5)$$

where q_{pI} is the mass rate of production of component I from the block resulting from any well perforated in the block and the Laplacian term of type $\Delta(T\Delta p)$ is defined as

$$\Delta(T\Delta p) \equiv \Delta_x (T_x \Delta_x p) + \Delta_y (T_y \Delta_y p) + \Delta_z (T_z \Delta_z p)$$

and

$$\Delta_x (T_x \Delta_x p) \equiv T_{i+1/2, j, k} (p_{i+1, j, k} - p_{i, j, k}) - T_{i-1/2, j, k} (p_{i, j, k} - p_{i-1, j, k}).$$

For the general case where each component is present (soluble) in all three phases, Eq. 5 is N equations in $3N+6$ unknowns. The unknowns are $3N$ C_{IJ} values, 3 phase saturations, and 3 phase pressures. Thus an additional $2N+6$ equations are required for a determinate or solvable model having equal numbers of equations and unknowns. The N Eqs. 5 are referred to as *primary* equations while the additional $2N+6$ equations are denoted *constraint* equations. The constraint equations are manipulated in the model programming to eliminate $2N+6$ variables (unknowns) in terms of the remaining N (primary) unknowns. The result is then the set of N primary Eqs. 5 in N primary unknowns. The constraint equations are relations between unknowns pertaining only to the particular gridblock (i,j,k) to which Eqs. 5 apply. The N primary Eqs. 5, however, involve unknowns (e.g., p_J) at the gridblock (i,j,k) and its six neighboring blocks, owing to the nature of the interblock flow terms on the left-hand side.

The $2N+6$ constraint equations are illustrated here for the case of an isothermal, compositional model where the N components are H_2O and $N-1$ hydrocarbon components (e.g., methane, ethane... C_7). The first three constraints are

$$S_w + S_o + S_g = 1.0, \dots\dots\dots (6)$$

$$p_o - p_w = P_{cwo}(S_w), \dots\dots\dots (7)$$

and

$$p_g - p_o = P_{cgo}(S_g), \dots\dots\dots (8)$$

where P_{cwo} = water/oil capillary pressure and P_{cgo} = gas/oil capillary pressure.

These constraints express the requirement that the phase saturations sum to unity and also eliminate the water and gas phase pressures in terms of the unknown oil pressure phase using capillary pressure curves. For this compositional case, concentration $C_{IJ} = \rho_J x_{IJ}$ where ρ_J is the molar density of phase J (mols/volume) and x_{IJ} is mol fraction of component I in phase J . The next three constraints require that the mol fractions of all components sum to unity in each of the three phases,

$$\sum_{I=1}^N x_{IJ} = 1.0 \dots\dots\dots (9)$$

where $J = w, o, g$ or 1, 2, 3. The remaining $2N$ constraints express equilibrium of each component among the three phases,

$$f_{Iw} = f_{Io} \dots\dots\dots (10a)$$

and

$$f_{Io} = f_{Ig} \dots\dots\dots (10b)$$

where f_{IJ} is the fugacity of component I in phase J . These fugacities can be expressed in terms of mol fractions and pressure by use of an equation of state (EOS). Alternatively, they can be replaced by equilibrium K -value relation-

ships (e.g., $y = Kx$) with K -values given as functions of pressure or of pressure and composition.

The $2N+6$ constraint Eqs. 6 through 10 are manipulated to eliminate one-phase saturation, two-phase pressures and $2N-3$ mole fractions (x_{IJ}) from the N primary Eqs. 5. The final result is a model consisting of the N Eq. 5 in N unknowns consisting of two saturations, one pressure, and $N-3$ mole fractions. Each coefficient or term remaining in the N primary equations is then either one of the N primary unknowns or a function of one or more of the primary unknowns.

Types of Models

Different types of simulation models are used to describe different mechanisms associated with different oil-recovery processes. The most widely used types are black oil, compositional, thermal, and chemical flood. The four basic recovery mechanisms for recovering oil from reservoirs are (1) fluid expansion, (2) displacement, (3) gravity drainage, and (4) capillary imbibition. Simple fluid expansion with pressure decline results in oil expulsion from and subsequent flow through the porous matrix. Oil is displaced by gas and injected or naturally encroaching water. Gravity drainage, caused by positive (water/oil and oil/gas) density differences, aids oil recovery by causing upward drainage of oil from below an advancing bottom-water drive and downward drainage from above a declining gas/oil contact. Finally, imbibition, generally normal to the flow direction, can be an important recovery mechanism in lateral waterfloods in heterogeneous sands with large vertical variation of permeability.

Accommodation of compositional and the enhanced-recovery processes in this discussion requires the addition of a fifth mechanism, oil *mobilization*. This loosely defined term includes widely differing phenomena that create or mobilize recoverable oil. Some of these phenomena are not really distinct from the first four.

The black-oil model accounts for the four basic mechanisms in simulation of oil recovery by natural depletion or pressure maintenance (e.g., waterflooding). This isothermal model applies to reservoirs containing immiscible water, oil, and gas phases with a simple pressure-dependent solubility of the gas component in the oil phase. The two-component representation of the hydrocarbon content¹⁵ presumes constant (pressure-independent) compositions of the oil component and the gas component, no volatility of the oil component in the gas phase, no solubility of the oil and gas components in the water phase, and no volatility of water (H_2O) in the oil and gas phases. The oil component is stock-tank oil and its unit of mass is 1 STB (1 bbl at stock-tank pressure and temperature). The gas component is surface system gas and its unit of mass is 1 standard cubic foot (scf). The water component unit of mass is 1 STB. For water and gas, components and phases are identical while the oil phase is a mixture of the oil component and the gas component.

The number of components (N) and therefore the number of Eqs. 5 per gridblock is three for the black-oil model. Table 48.1 gives the definitions of component concentrations, C_{IJ} , for this model. The water phase, gas phase, and saturated oil phase, reciprocal formation volume factors, b_w (STB/RB), b_g (scf/RB), and b_o (STB/RB), respectively, are given single-valued functions of pressure. For undersaturated oil, b_o is dependent on

pressure and solution gas (R_s , scf/STB). As discussed later original work in formulations¹⁶⁻¹⁸ led to a number of papers¹⁹⁻²⁴ describing black-oil models during the 1960's.

The remaining model types discussed here account for some mobilization mechanisms in addition to the four basic recovery mechanisms. The isothermal compositional model represents reservoir fluids by N components, including water and $N-1$ hydrocarbon components. Generally, but not necessarily, solubilities of water in the oil and gas phases and of hydrocarbon components in the water phase are considered negligible. For water, then, the concentration in Eqs. 5 is as given in Table 48.1. The hydrocarbon component I concentration C_{IJ} is $\rho_J x_{IJ}$, as mentioned earlier, for $J=o, g$ or 2, 3. Gas/oil phase equilibrium and phase densities within each gridblock are calculated using equilibrium K -values from pressure- and composition-dependent correlations or, more recently, from EOS's.²⁵⁻²⁸ Unlike the black-oil model, the compositional model can represent the mobilization of oil by outright (single-contact) or dynamic (multicontact) miscibility, oil swelling and viscosity reduction by solution of an injected nonequilibrium gas (e.g., CO_2), and stripping or vaporization of an oil's lighter ends by injection of a dry gas. With one exception,²⁹ recent papers²⁹⁻³³ describing compositional models are based on equilibrium K -values obtained from EOS's.

A thermal simulation model is a set of N conservation equations, similar to Eq. 5, which expresses conservation of mass of H_2O and $N-2$ hydrocarbon components and conservation of energy. With energy designated as "component" N , the last ($I=N$) of Eqs. 5 becomes the energy balance upon addition of terms representing heat conduction and overburden heat loss. An additional requirement is the use of $\rho_J H_J$ for C_{NJ} in the well and interblock flow terms and $\rho_J U_J$ for C_{NJ} in the right side accumulation term. H_J and U_J are enthalpy and internal energy, respectively, energy/mole. If the in-situ combustion capability is included then the mass conservation equations include source (sink) terms represented by Arrhenius reaction rate expressions for cracking and oxidation of hydrocarbon components and the energy balance includes heat of reaction terms. For the same number of fluid components, a thermal model has one more (energy) conservation equation than the compositional model and one additional unknown, temperature T .

For steam-injection processes, thermal model components are typically H_2O , heavy (nonvolatile) and light (solution gas or distillable) hydrocarbon components and energy. For in-situ combustion studies, typical components are H_2O , heavy-oil component, a lighter (distillable) oil component, solid coke, O_2 , CO_2 , N_2 , and energy. Frequently CO_2 and N_2 are lumped as one component to reduce computing expense. The steam tables and/or an EOS are used to calculate liquid H_2O (water phase) properties and the H_2O gas/water phase K -value as functions of pressure and temperature. In most applications, H_2O is assumed insoluble in the oil phase. In most current models, the distribution of other (non- H_2O) components among all phases is represented by user-provided K -values dependent on only pressure and temperature.

Thermal simulators are applied to steam-injection or in-situ combustion processes in heavy-oil reservoirs where oil is mobilized primarily by (1) reduction of oil viscosi-

TABLE 48.1—DEFINITIONS OF CONCENTRATIONS C_{IJ} FOR THE BLACK-OIL MODEL

I	Component	Phase		
		$J=1$ Water	$J=2$ Oil	$J=3$ Gas
1	water	b_w	0	0
2	oil	0	b_o	0
3	gas	0	$b_o R_s$	b_g

ty with increased temperature, (2) distillation of intermediate hydrocarbon components from the oil phase to the more mobile gas phase, and (3) cracking of the oil phase [usually above 500°F (260°C)] with subsequent distillation. Thermal models developed from 1965 to 1982³⁴⁻⁴⁰ generally exhibit a trend toward inclusion of more dimensions, more components and dual capability of steamflood and in-situ combustion.

Chemical flood models include polymer, micellar (surfactant), and alkaline (caustic). Polymer waterflooding improves oil recovery by lowering the oil/water mobility ratio, by reducing the effective permeability to water, and/or by increasing water viscosity. In micellar flooding, surfactants greatly reduce oil/water IFT, thereby solubilizing oil into the micelles and forming an oil bank.⁴¹ The surfactant slug and mobilized oil normally are propelled toward the production well by a graded bank of polymer-thickened water. The mechanisms responsible for improved oil recovery in alkaline flooding are thought to include low IFT, wettability alteration, and emulsification.⁴² Chemical flooding processes involve complicated fluid/fluid and rock/fluid interactions such as adsorption, ion exchange, viscous shear, and three- (or more) phase flow. Several recent papers⁴³⁻⁴⁵ describe implementation of these complex chemical flood mechanisms in numerical simulators.

The four types of models described above are defined or distinguished by the recovery process and the nature of the original reservoir fluid. Considering the nature of the reservoir formation leads to a fifth, *fractured-matrix* type of simulation model. While in theory any recovery process can be implemented in a fractured-matrix reservoir, most simulation work reported to date is concerned with black oil fractured-matrix models. Three-dimensional models are described by Thomas *et al.*⁴⁶ for the three-phase case and by Gilman and Kazemi⁴⁷ for two-phase water-oil flow. Their models consider a discontinuous array of matrix blocks in a continuous 3D fracture network. Flow throughout the reservoir and to the wells occurs in the fracture system and the matrix blocks are treated as sink/source terms in that system. Their model equations include the set of N conservation Eqs. 6 written for each gridblock in the fracture system. Each *gridblock* may contain a number of similarly behaving *matrix blocks*. However, additional terms are added to Eqs. 6, representing matrix-fracture flow. Also, for each gridblock additional equations are required to express mass conservation of each component in the matrix blocks included in the gridblock. These additional equations can be eliminated or combined with the basic N (fracture system) flow equations^{46,47} so that the final model includes only N equations (per block) possessing interblock flow terms. Blaskovich *et al.*⁴⁸ describe a fractured-matrix model

which allows for reservoir-wide flow through the matrix as well as the fracture system. This extension leads to a model including $2N$ equations (per block) possessing interblock flow terms.

Model Input Data and Calculated Results

A simulation model requires three types of input data. First, reservoir description data include (1) overall geometry, (2) grid size specification, (3) permeability, porosity, and elevation for each gridblock, and (4) relative permeability and capillary pressure vs. saturation functions or tables. Geological and petrophysical work, which involves logs and core analyses, is necessary for Items 1 and 3. Laboratory tests on core samples yield estimates of relative permeability and capillary pressure relationships. Second, fluid PVT properties, such as formation volume factors, solution gas or component equilibrium K -values, and viscosities are obtained by laboratory tests. Finally, well locations, perforated intervals, and productivity indices (PI's) must be specified. Each well must be assigned a production (injection) rate schedule and/or a limiting producing (injecting) pressure for use in calculating well deliverability (injectivity).

Model output or calculated results include spatial distributions of fluid pressure, saturations and compositions, and producing GOR and WOR and injection/production rate (for wells on injectivity/productivity) for each well at the end of each timestep of the computations. Internal manipulation of these results gives average reservoir pressure and instantaneous rates and cumulative injection/production of oil, gas, and water by well and total field vs. time.

Current models offer various levels of visual output display features that ease the engineer's assimilation and interpretation of simulator results. Example features are contour maps of pressure, saturations, compositions and temperature, concise tabular summaries of individual well or well-group performance, and field or well timeplots of quantities such as production rates and WOR's and GOR's.

Purpose of Reservoir Simulation

Reservoir simulation is used to estimate recovery for a given existing producing scheme (forecasting) to evaluate the effects on recovery of altered operating conditions, and to compare economics of different recovery methods. Black-oil models have been widely applied to forecast oil recovery and to estimate the effects on oil recovery of (1) well pattern and spacing, (2) well completion intervals, (3) gas and/or water coning as a function of rate, (4) producing rate, (5) augmenting a natural water drive by water injection and desirability of flank or peripheral as opposed to pattern waterflooding, (6) infill drilling, and (7) gas vs. water vs. water-alternating-gas (WAG) injection.

A few of many reported studies are briefly mentioned here. Henderson *et al.*⁴⁹ applied a single- (gas) phase model to optimize the locations and numbers of wells necessary to meet peak deliverability requirements in a gas storage field. Mann and Johnson⁵⁰ showed good agreement between model-predicted and actual field performance. Thomas and Driscoll⁵¹ applied a black-oil model in estimating locations of bypassed oil for the purpose of designing an infill drilling plan. Two studies^{52,53}

report extensive results related to rate-sensitivity of various Alberta reservoirs subjected to water-oil displacements. Thakur *et al.*⁵⁴ applied a black-oil model to characterize (through history matching) offshore Nigerian reservoirs and estimate incremental recovery of waterflooding over natural depletion, with infill drilling and removal of allowable rates.

Compositional models also are used for most of Purposes 1 through 7 listed previously, but only in cases where the black-oil assumption of constant composition oil and gas components is invalid. Example compositional model applications include (1) depletion of a volatile oil or gas condensate reservoir where hydrocarbon phase compositions and properties vary significantly with pressure below bubble- or dewpoint, (2) injection of non-equilibrium gas (dry or enriched) into an oil reservoir to mobilize oil by vaporization into the more mobile gas phase or by attainment of outright (single-contact) or dynamic (multicontact) miscibility, and (3) injection of CO₂ into an oil reservoir to mobilize oil by stripping of light ends, oil viscosity reduction, and oil swelling.

Compositional simulation has been performed to estimate (1) loss of recovery caused by liquid dropout during depletion of retrograde gas condensate reservoirs and the reduction of this loss by full or partial cycling (re-injection of gas from surface facilities) and (2) effects of pressure level, injected gas composition, and CO₂ or N₂ injection on oil recovery by vaporization or miscibility. Graue and Zana⁵⁵ describe application of a compositional model in estimating Rangely (CO) field oil recovery by CO₂ injection as a function of injected composition and pressure level. Results of compositional simulation of a CO₂ project include CO₂ breakthrough time and rate and composition of produced fluids. These are required to design production facilities and CO₂ recycling strategies.⁵⁶ Modeling is also useful to optimize pattern size and CO₂/water-injection rates to overcome the effects of reservoir heterogeneity.⁵⁷

Thermal models are applied in reservoir studies of in-situ combustion and are used to simulate performance of cyclic steam simulation and steamflooding. In steam injection, questions addressed by simulation relate to effects of injected steam quality and injection rate, operating pressure level, and inclusion of gas with the injected steam. One question in cyclic stimulation concerns the optimal time periods per cycle for steam injection, soak, and production. The flooding case introduces the issues of well pattern and spacing. A number of steam-injection field studies using models have been published. Herrera and Hanzlik⁵⁸ compare field data and model results for a cyclic stimulation operation. Williams⁵⁹ discusses field performance and model results for stimulation and flooding, and Meldau⁶⁰ discusses field and model results related to addition of gas to the injected steam. Gomaa *et al.*⁶¹ and Moughamian *et al.*⁶² applied steamflood simulation in identifying and optimizing operating parameters in pilot and field drive operations.

Numerical simulation has been used to estimate chemical flood performance in a reservoir environment where the processes are very complex and many reservoir parameters affect the results. Chemical flood simulation has been used to construct a screening algorithm for the selection of reservoirs suitable for micellar/polymer flooding⁶³ and to examine competing EOR strategies—

e.g., CO₂ vs. surfactant flooding.⁶⁴ For caustic⁶⁵ and polymer⁶⁶ applications, as well as for the micellar process, chemical flood modeling is useful to discern controlling process mechanisms and to identify laboratory data required for process description.

In recent years, simulation has been used increasingly to estimate and compare recoveries from a given reservoir under alternative enhanced-recovery processes, such as CO₂ injection, thermal methods (steam injection and in-situ combustion), and several types of chemical flooding.

Considerations in Practical Application of Simulation Models

This section describes the procedure followed and certain questions faced by the engineer conducting a reservoir simulation study. The engineer must select the appropriate type of simulation model, select the grid network, and specify rock and fluid description data. Then the engineer must attempt to reduce or at least estimate inaccuracies in simulation results which stem from uncertain rock/fluid description data and from spatial truncation error.

Selection of Model Type

As mentioned earlier, selection of model type may depend on both the nature of the original reservoir fluid and upon the recovery process(es) to be studied. As a rough guide, an original reservoir oil solution gas or GOR value, R_s , below 2,000 scf/STB indicates a black oil, whereas a higher value indicates a volatile oil or retrograde gas condensate requiring compositional treatment.

For a black-oil reservoir, a black-oil model may be used to study natural depletion, water injection and/or equilibrium gas injection operations. However, a compositional model is generally necessary to estimate recovery by injection of dry or enriched gas, solvent, or CO₂. An exception here is the applicability of a modified black-oil model⁶⁷ in simulation of CO₂ or solvent injection where outright (single-contact) miscibility occurs.

Compositional simulation is generally employed for volatile oil reservoirs. However, a less expensive black-oil model study is adequate for simulating above-bubblepoint waterflooding performance. Compositional models have generally been employed to study retrograde gas condensate reservoirs. The compositional model is necessary in the case of below-dewpoint cycling. However, in some cases natural depletion or above-dewpoint cycling can be simulated at less expense using a black-oil model modified to account for volatility of the oil (condensate) component in the gas phase.⁶⁸⁻⁷⁰

The alkaline and surfactant-flood processes generally require use of the complex chemical flood simulation model. However, some (augmented) black-oil models offer the capability to simulate polymer and alkaline flooding.

Selection of Model Grid

Selection of the x - y - z gridblock network involves many factors, including available budget and the engineer's judgment and experience. For any type of model, the arithmetic or computing expense per timestep is at least linearly proportional to the total number of gridblocks

employed. The computing expense of a single model run is proportional to the product of the number of gridblocks and the number of timesteps required by the model to cover the total time period of interest. In many cases, the timestep size is controlled by the maximum rate of change (overall gridblocks) in one or more calculated quantities such as pressure and saturations. This maximum rate of change generally occurs at or near a well or in the vicinity of a flood front. A doubling of the number of gridblocks can result approximately in a doubling of this maximum rate of change since each gridblock is (on the average) one-half as large. The average timestep size, then, might decrease by a factor of two if the number of blocks were doubled. The final result is a computing expense per model run which can approach a proportionality to the square of the total number of gridblocks. This indicates the importance of selecting the smallest number of gridblocks consistent with reservoir/well description, recovery process characteristics, and the questions asked regarding reservoir performance.

The number of gridblocks and resultant study computing expense are the lowest in cases where the engineer can justify use of a representative element of the total field as the basis for the model study. This may be possible in reservoirs developed with repeated well patterns, for any recovery process—waterflooding, CO₂ injection, steamflooding, etc. In such cases, the representative element ideally should be a *symmetrical* element of the reservoir. In strict terms, this requires (1) a repeated, regular pattern of identically completed and operated wells, (2) a horizontal, areally homogeneous reservoir formation of uniform thickness, and (3) areally uniform initial fluid saturation distributions. If these conditions were met, then questions regarding total field optimization, forecasting and comparative evaluation of recovery processes could be addressed inexpensively by simulation of the single pattern (element).

While actual reservoirs never satisfy these conditions exactly, representative-element simulation studies are frequently performed for repeated pattern processes. In some cases, a substantial portion of the reservoir may exhibit only moderate areal heterogeneity and thickness variation. Resultant variation in performance from one pattern to another may be sufficiently small for engineering purposes to justify scale-up of single-pattern results to total field performance.

Representative-element simulation is often performed where the study purpose is comparative evaluation of alternative recovery processes as opposed to forecasting of total field performance for a specific process and operating scheme. The justification of single-element simulation implied in such cases is that the resultant ranking of alternative processes is unaffected by the variations in pattern (element) properties over the field. This justification can be and frequently is checked by repeating the various process simulations for two or more patterns of different properties representative of different portions of the reservoir.

Finally, the relatively inexpensive single-element simulation applies to design or optimization studies of a specific recovery process operated in a repeated pattern mode. For a repeated-pattern steamflood, single-pattern model runs have been performed to "optimize" pattern type (e.g., five-, seven- or nine-spot) and size, injected

steam quality and rate, well completions, etc. Occasional publications describe single-pattern simulation studies using a one-quarter five-spot or one-quarter nine-spot as the symmetrical element of the respective pattern. Actually, a one-eighth five-spot or nine-spot (and $\frac{1}{2}$ seven-spot) are the smallest symmetrical elements and should be used to minimize computing expense.⁷¹

Currently, a major portion of the industry-wide effort and computing expense in simulation studies is associated with total-field forecasting of black-oil reservoir performance under a sequence of recovery processes. Typically, the engineer must select a 3D grid for a large reservoir with significant heterogeneity, large areal variation in dip and thickness, irregular well locations and increasing numbers of wells with successive development stages. The engineer may face a several- to many-year period of historical performance under natural depletion, frequently with some natural water encroachment. Study objectives may include history matching, followed by matching and forecasting for a waterflood period, in turn followed by forecasting for some tertiary scheme such as CO₂ injection.

The total number of gridblocks is the product of the number of areal blocks, $N_x N_y$, and the number of grid layers, N_z . Different considerations enter into selection of these two numbers of spacings. Factors indicating a need for fine areal grid spacing are high well density and sharp or rapid changes (areally) in permeability, porosity, thickness, and dip. Since these factors frequently vary over the field, the x - and y -direction grid spacings are often nonuniform. Grid spacings generally increase toward the downdip reservoir boundaries and increase greatly with distance into the aquifer if the latter is present and included in the grid.

In general, of course, the number of areal gridblocks required increases with the size of the reservoir and the number of wells. However, grid spacings ranging from very fine to very coarse may be appropriate for different reservoirs of comparable size. The smallest numbers of areal blocks (coarsest areal spacings) are associated with reservoir studies limited to natural depletion and crestal or flank gas and/or water injection. In such a case, a coarse grid may result in a number of areal blocks that include two or more similar type (e.g., production) wells, with little loss in engineering significance of the simulator results. Large numbers of areal blocks may be required in cases of pattern waterfloods or enhanced recovery processes. A rough guide in this case is the need for at least two, preferably three or more, gridblocks separating each injection-production well pair. However, recent studies describe estimation of pseudorelative-permeability curves, which allow adjacent-block placement of an injector/producer well pair.^{72,73}

The major factors affecting the number of grid layers (vertical gridblocks) required are the formation stratification, vertical communication, and total thickness. Many reservoirs possess a number of formation layers, which correlate from well to well over much of or all the field. Variations of layer thickness, permeability, and porosity may be significant areally and even greater from one layer to another. The vertical communication (vertical permeability) between adjacent layer-pairs may vary from zero to very high, both areally and from one layer-pair to another. In general, at least one grid layer should be

used for each correlatable formation layer. However, common sense and budget constraints argue against definition of a large number of very thin grid layers. Three-dimensional reservoir studies typically employ 4 to 12 grid layers, and one or more of these grid layers may be a lumped representation of several thin formation layers.

The need for subdivision of one formation layer into two or more grid layers depends on the layer thickness and fluid-segregation characteristics of the recovery process and operating rates. Most recovery processes result in moderate to severe gravity segregation of oil and injected fluids; injected water or gas tend to underrun or override oil, respectively; many steamflood projects exhibit severe override of oil by the steam. A formation layer that has significant thickness and zero to poor vertical communication with layers above and below may exhibit a pronounced phase segregation and require two or more grid layers. In the idealized example of a fieldwide, pronounced gravity override in a vertically homogeneous reservoir, a variable grid spacing increasing from top to bottom might be specified. That is, four layers of thicknesses 5, 10, 20, and 25 ft might give more accurate results than four layers of equal 15-ft thickness.

A customary approach to determining N_z involves use of the simulation model itself in 2D cross-sectional (x - z slice) mode. For the particular recovery process of interest, x - z model runs are performed by using different numbers of grid layers. Pseudorelative-permeability curves reflecting phase segregation are calculated from model runs performed with fine vertical grid spacing.⁷⁴⁻⁷⁶ These pseudocurves are then used in equivalent x - z model runs using fewer grid layers to obtain coarse (vertical) definition results similar to the fine-spacing "correct" results. The fewer grid layers of the coarse definition are then employed in the 3D reservoir study grid. This concept of generating pseudocurves for coarse vertical grids that reproduce vertical fine-grid results (using rock or laboratory relative permeabilities) has been extended to the areal spacing problem,^{72,75} as mentioned earlier.

Obviously, a minimum computing expense follows from use of a single grid layer representing the entire formation thickness. This results in a 2D x - y areal grid as opposed to a 3D grid and occasionally is justified in the two extremes of a very high vertical permeability and a layered formation with zero vertical permeability. Pseudorelative permeability and capillary pressure curves are discussed for the former case in papers describing the vertical equilibrium (VE) concept^{21,77} and for the latter case by Hearn.⁷⁸

Specification of Reservoir Rock and Fluid Description Data

Geological and petrophysical work based on logs and core analyses yields maps of structure, net ϕh , and kh products for each of the several reservoir layers. The kh and ϕh data often are augmented or modified by results of drillstem, pressure buildup, and pulse tests. For each layer, the engineer can overlay his areal x - y grid spacing network on these maps and read off the values of subsea depth, ϕh , and kh at the center of each gridblock. These values along with gross thickness of each block are then transposed to a data file in a format compatible with that

required by the simulation model. Current research effort is directed toward developing computer programs that accept digitized core analysis, log and geological data, the selected grid network, and, through mapping and interpolation techniques, automatically prepare the simulation input data file.

Laboratory core analysis work includes measurement of relative-permeability, k_r , and capillary-pressure, P_c , curves for a number of field cores. Variations in rock lithology may result in different sets of k_r and P_c curves for different layers and/or different areal portions of the reservoir. Most simulation models allow multiple sets of such data in tabular form with assignment of each set to a user-specified layer/portion of the reservoir. If the rock water/oil (gas/oil) capillary pressure values are small, the water/oil (gas/oil) transition zone in the reservoir may be a very small fraction of total formation thickness. In such cases, pseudocapillary-pressure curve(s) should be used.⁷⁷

For black-oil studies, laboratory tests are performed to determine gas compressibility factor and saturated oil and gas viscosities vs. pressure. Differential and/or constant-composition expansion tests on oil samples yield the saturated oil pressure-dependent formation volume factor, B_o (RB/STB), and solution gas, R_s (scf/STB). The resulting oil and associated gas properties vs. pressure are entered in the data file in tabular form compatible with simulator input requirements. For gas condensate depletion studies, constant-volume and constant-composition expansion tests yield the required pressure-dependent liquid content, C_L (STB/scf), and condensate density values.

A wide variety of laboratory tests are performed for compositional model studies that involve injection of a nonequilibrium fluid (dry or enriched gas, CO_2 , N_2 , etc.). Swelling tests yield relative volumes, saturation pressures, and equilibrium phase compositions for each of a sequence of mixtures of, say, 1 mole of original reservoir oil and injected fluid.⁷⁹ Various single- and multicontact tests may be augmented by 1D corefloods and/or slim-tube displacements. Orr *et al.*^{80,81} discuss a variety of CO_2 -oil laboratory tests. Much of the laboratory PVT test data must be processed to yield correlations or a calibrated EOS⁸²⁻⁸⁵ for simulator input requirements.

History Matching

In most simulation studies, reservoirs have some period of historical performance data that include WOR, GOR, individual phase rates and cumulatives, and pressure measurements by well. Ideally, periodic (e.g., monthly), accurate measurements of all these data would be recorded and available for all wells. In the typical case, many of these data are unrecorded or unavailable and some of the reported values may be of questionable accuracy.

The reservoir description based on log and core analysis data reflects a very small (volumetric) sampling of the reservoir. The historical reservoir-performance data reflect the reservoir description, and its impact on pressure/fluid movement behavior, on a much larger scale. The previously mentioned geological and petrophysical work yields an initial reservoir description. History matching yields a refinement of that description, which improves agreement between model results and observed reservoir behavior. The history-match phase of

the simulation study entails a sequence of model runs in which input reservoir description parameters are altered to improve this agreement. This is a trial-and-error procedure frequently requiring considerable engineering judgment and experience. The description parameters obtained from the geological/petrophysical work often are used to establish legitimate ranges of parameter variation in the history-match model runs.

This history-match phase can consume half or more of the total simulation study (match plus prediction) computing effort and expense, depending on the length of the history period, complexity of the reservoir, and amount of available performance data.

Refs. 86 through 90 describe methods and applications of inverse simulation or automatic history matching. This concept requires user-specification of a finite set of reservoir description parameters to be determined (e.g., zonal permeability, porosity values), a finite set of observed reservoir performance data to be matched, and a regression procedure coded interactively with the simulator. A single computer submittal is then performed, which in turn executes many model history runs. The regression procedure automatically varies description-parameter values from run to run to determine that set of description-parameter values that maximize agreement between model results and the set of observed data. This concept is especially appealing to the engineers who have experienced the frequently high frustration levels associated with trial-and-error matching of complex reservoir behavior. However, to date the trial-and-error procedure still predominates with isolated successes reported with automatic history matching. Two factors complicating the latter approach are (1) the expense of the required single computer submittal can be very large, (2) the a priori choice of description parameters (or zonation) can be difficult, subjective, and lead to a questionable reservoir description.

Validity of Simulation Results

Uncertainties or errors in simulation model results may arise from (1) questionable assumptions or mechanisms not represented in the differential form of the model, (2) spatial and time truncation error introduced by replacement of the model differential equations by finite-difference approximations, and (3) inadequately known reservoir rock and/or fluid description data. In addition, the exact solution of the difference equations is not attained because of round-off error introduced by the finite word length of the computer. Round-off error is generally negligible compared with errors from the other three sources. With some exceptions, the above sources of error are listed in order of increasing importance. However, successful history matching can reverse the importance of the second and third sources.

Comparisons of model and laboratory experiment results can indicate model validity in the absence of the Uncertainty 3 above. Several such comparisons show good model-experiment agreement for gas/oil systems,^{91,92} water/oil coning,⁹³ and fractured-matrix imbibition.⁹⁴

Model Assumptions

An assumption common to many black-oil models is complete re-solution of free gas in accordance with the

saturated $R_s(p)$ curve during repressurization. This may be a poor assumption in a case where gridblock thickness is large and gas/oil gravity (vertical) segregation is pronounced. Prior to repressurization in a given block, the free gas may exist as a high gas saturation in only the upper portion of the block. This contradicts its representation in the model as a lower saturation distributed throughout the entire block volume. In the segregated state, the gas will redissolve only in the lower or residual oil saturation in the upper, gas-occupied portion of the block volume. However, the model will allow re-solution in the entire block's oil volume. Pressure hysteresis in the $R_s(p)$ curve has been used to cope with this problem; an alternative remedy where the computing budget permits is the use of more grid layers.

An assumption common in early black-oil models was that the reservoir oil obeyed a single pair of $B_o(p)$ and $R_s(p)$ curves. Some black-oil reservoirs exhibit a significant variation of oil API gravity and PVT behavior with depth or with depth and areal location. In some such cases, this variation can be represented in a black-oil model by simply allowing initial solution gas R_{si} to vary with depth in the undersaturated oil column, retaining a single set of $B_o(p)$ and $R_s(p)$ curves. In other cases, multiple sets of these curves and two oil components are necessary and the single oil-type assumption in a black-oil model can lead to appreciable error.

Mechanisms or phenomena that are significant in some reservoirs and may not be represented in the model include compaction, hysteresis in wetting and nonwetting relative permeabilities, and interlayer wellbore crossflow. The latter is a particularly difficult modeling problem and the subject of continuing research. A production well completed in a number of layers may exhibit production from some layers and, simultaneously, injection (backflow or recirculation) into others. Factors that promote this possibility are low-pressure drawdown (high PI and/or low rate) and poor vertical communication between the reservoir layers in the vicinity of the well. A rigorous treatment of this problem requires modeling of wellbore multiphase hydraulics and phase segregation combined with calculation of correct phase mixtures for the layers undergoing injection.

Spatial Truncation Error

Spatial and time truncation error theoretically can be reduced to any desired low level by sufficiently reducing gridblock dimensions and timestep size. However, the resultant increased number of blocks and timesteps frequently lead to prohibitive computer expense and memory storage requirements.

Time truncation error is generally insignificant. In most applications timestep size is restricted by considerations other than time truncation error, such as model stability, frequencies of printout, and frequencies of changes in well data (rates, completions, new wells, etc.). In any given case, the level of time truncation error can be estimated by repeating a run or portion of a run with a smaller (or larger) timestep. Insensitivity of results to timestep size indicates low-time truncation error.

Spatial truncation error appears in the forms of numerical dispersion, grid-orientation effects, and error in calculated well WOR and GOR values. Spatial truncation error can be expressed in mathematical terms through

complex manipulation of the model differential equations and Taylor series expansions. In simpler terms, this error can be viewed as a consequence of replacing the physical continuum (reservoir formation) by a 3D network of mixing cells (gridblocks). This consequence is the contradictory requirements that any variable value (pressure, saturation, temperature, concentration) simultaneously represents the value at the grid point (e.g. block center) and the entire block's volumetric average value. This requirement is not met (1) during a frontal displacement as a sharp front enters the gridblock, (2) when gravity forces result in phase segregation within the block's thickness, and/or (3) when areal cusping or coning causes sharp localized saturation gradients within the block volume.

Numerical dispersion generally appears as falsely smeared spatial gradients of water saturation in waterflooding, temperature in steamflooding, solvent in miscible flooding, and chemical agent in chemical flooding. This excessive smearing occurs primarily in the areal (x or y) directions and, if uncontrolled, results in too early calculated breakthrough times of water (heat, solvent, etc.) at production wells. This numerical dispersion generally increases with increasing areal gridblock size (Δx and Δy). Lantz⁹⁵ quantitatively related the difference equation truncation error term to an artificial, second-order diffusion term in the differential equation.

The engineer can anticipate possibly significant numerical dispersion effects in simulating two types of miscible displacement. The first type is slug or bank, as opposed to continuous, injection of solvent or CO_2 . Numerical dispersion erodes the calculated solvent concentration within the bank. If miscibility requires maintenance of solvent bank integrity or a certain solvent peak concentration, then this numerical dispersion can result in a calculated (false) loss of miscibility. The second type is multicontact miscibility. For continuous solvent injection in 1D simulations, several studies^{31,96,97} report the need for 100 to 300 gridblocks to reduce the effect of numerical dispersion on miscible front velocity.

Kyte and Berry⁷⁵ describe control of numerical dispersion in simulation of waterflooding through large areal gridblocks. They use pseudorelative-permeability curves obtained from detailed (fine-grid) cross-sectional simulations. Harpole and Hearn⁹⁸ used their method in a 3D black-oil study. To date, steamflood simulation generally has been confined to pattern studies for which a sufficient number of gridblocks between unlike wells is used to minimize numerical dispersion effects. Killough *et al.*⁷³ describe their reduction of numerical dispersion in a stratified, heterogeneous, repeated pattern black-oil reservoir study. They performed fine-grid, 3D single-pattern simulations and then used regression to determine pseudorelative permeabilities for a 2×2 four-block areal grid representation of the pattern. Agreement between the 3D fine-grid results and four-block pattern results was good enough to allow fieldwide simulation by use of the latter coarse, areal definition. Several recent papers⁹⁹⁻¹⁰¹ describe local grid refinement, the method of characteristics, and other methods to reduce numerical dispersion effects.

Pronounced grid-orientation effects have been noted in simulation of adverse mobility ratio floods with models incorporating the commonly used five-point difference scheme and single-point upstream weighting. The value

Fig. 48.2—Five-point and nine-point difference schemes.

of the coefficient $k_{rj}C_{Hj}/\mu_j$ in Eq. 2 obviously affects the interblock Darcy flow rate from gridblock $i-1$ to block i . Intuition might dictate evaluation of this coefficient at some average of variable values (pressure, saturations, etc.) in the two blocks. However, considerations of stability and numerical dispersion frequently have led to its evaluation at conditions existing in the block from which the flow occurs—i.e., the upstream block. This is referred to as single-point upstream weighting. The five-point difference scheme is reflected in the form of terms of type $\Delta(\tau\Delta p)$ in Eq. 5 for the case of 2D flow. These terms represent the interblock Darcy flow rates in the mass balance equation for each gridblock. The solid arrows of Fig. 48.2 illustrate these flow rates between the gridblock and each of its four neighbors.

A strong grid-orientation effect was first reported by Todd *et al.*¹⁰² for highly adverse mobility waterfloods and later observed for pattern steamfloods.¹⁰³ An areal grid with the usual perpendicular x and y axes may be placed over a five-spot pattern with the x axis either parallel to or at a 45° angle to the line connecting the injector to a producer (Fig. 48.3). These parallel and diagonal grids¹⁰² can result in markedly different calculated shapes of the water or steam front and the breakthrough times. This difference was reduced by the nine-point finite difference formulation described by Yanosik and McCracken,¹⁰⁴ illustrated by the four extra dashed-line diagonal flow terms in Fig. 48.2. The nine-point scheme has been programmed into many simulators treating adverse mobility ratio waterfloods, steamfloods, and CO_2 solvent displacements.

As an example of this grid orientation effect, Fig. 48.3 shows a 3-acre nine-spot steamflood pattern with the diagonal grid and 45° -shifted parallel grid. This pattern

Fig. 48.3—Nine-spot grids.

has three types of wells—labeled 1 (injector), 2 (near producer), and 3 (far producer). Reservoir formation and fluid properties and well rates used in the simulation model are reported elsewhere.¹⁴ The calculated results in Table 48.2 show the pronounced effect of grid orientation on steam breakthrough times calculated by use of the five-point difference scheme. Obviously, steam should arrive at the near producer, Well 2, before it reaches the far producer, Well 3. The parallel grid with the five-point scheme actually gives breakthrough at Well 3 at 117 days, before breakthrough at Well 2 (204 days). Table 48.2 shows that the nine-point difference scheme virtually eliminates the effect of grid orientation for this problem. Figure 48.4 uses parallel and diagonal grids to show calculated steam-front shapes at 80 days for the two different schemes. The difference between the nine-point fronts for two grids is small and about equal to the error of manual interpolation.

A two-point, upstream weighting method¹⁰² was proposed to reduce both numerical dispersion and grid-orientation effects. Abou-Kassem and Aziz¹⁰¹ discuss this and other methods¹⁰⁶⁻¹⁰⁸ for reducing the orientation effect. They conclude that the nine-point scheme is the most effective in reducing steamflood grid-orientation effects. Two studies¹⁰⁵⁻¹⁰⁹ show very significant reduction of grid-orientation effects in pattern steamflood simulation results when areally homogeneous, square grids ($\Delta x = \Delta y = \text{constant}$) are used with the Yanosik and McCracken nine-point scheme. However, the effects persist for a non-square, uniform grid ($\Delta x = 2\Delta y$)¹⁰⁹ and the latter scheme yields physically unreasonable results for the cases of heterogeneity and nonuniform grids where Δx (or Δy) varies with x (y). The latter shortcoming is addressed by several recent papers¹¹⁰⁻¹¹² that propose new or altered nine-point schemes. Frauenthal *et al.*¹¹³ describe a modified five-point difference scheme and Pruess *et al.*¹¹⁴ present a seven-point, hexagonal gridblock scheme for reducing grid-orientation effects.

The engineer can anticipate possibly significant grid-orientation effects in simulating single- or repeated-pattern, adverse mobility ratio displacements. Preliminary areal, single-pattern model runs allow estimation of the level of such effects and the need for use of a nine-point scheme or other remedy.

The discussion and references cited obviously indicate the current concern regarding effects of numerical-dispersion and grid-orientation effects on the validity of

Fig. 48.4—Calculated shape of steamflood front in a nine-spot pattern.

simulation results. However, these numerical effects are not serious in many simulation studies. Numerical-dispersion effects are generally demonstrated as smearing of theoretically sharp fronts in 1- or 2D horizontal displacements in homogeneous formations. Actual reservoir behavior frequently reflects strong gravity effects such as a gas or solvent override or a water underrun. These gravity effects combined with reservoir structure (areal variation in dip angle) can have an influence on fluid movement patterns, which dominates the numerical effects just discussed. In addition, reservoir heterogeneity can play the same relatively dominant role as gravity forces. In highly stratified or layered reservoirs, the different rates of travel of injected fluid through different layers can dominate the numerical dispersion effect at the leading edges of the individual layer displacement fronts. Finally, a given level of numerical-dispersion or grid-orientation effect is acceptable if its impact on calculated reservoir performance is inconsequential in an engineering sense—i.e., in light of the questions being asked.

The model itself often can be used to estimate the level of these numerical errors and the degree of their acceptability. Before selecting the full study grid, preliminary model runs using grids of varying coarseness can be performed for a representative cross-section or 3D portion

of the reservoir. The results can be helpful in selecting the coarsest grid spacing compatible with acceptably low numerical dispersion.

In fieldwide simulation, spatial truncation error may affect calculated values of well productivity, wellbore producing pressure, and WOR and GOR. Without special measures, the model calculates the well behavior with only the gridblock's average values of pressure, saturations, etc. However, the actual well behavior may reflect near-well coning, liquid dropout, or gas evolution effects. The dimensions of this near-well region may be two orders of magnitude smaller than the areal block dimensions (Δx , Δy). Thus the block's average conditions may provide a poor basis for calculating well behavior. This problem can be significant for a well completed throughout formation thickness and even more significant for a partially penetrating well.

The simplest remedy to this problem is applicable in some cases where good vertical communication results in a high degree of vertical phase segregation. In this case, well pseudorelative-permeability curves have been used.^{115,116} These curves reflect the location of the completion interval and relate well behavior to average block conditions. A more complicated approach requires use of multivariable correlations relating well WOR and GOR to average block conditions.^{117,118} These correlations are developed from a number of single-well r - z (radial-depth) model runs with fine grid spacing near the wellbore. The most rigorous treatment of this problem incorporates individual 1D radial or 2D r - z simulations for each well simultaneously within the fieldwide 3D simulation.^{119,120} Again, in any given case, the model itself can be used to estimate the severity of this problem through comparison of single-well, r - z and representative 3D (portion of reservoir) model results.

Uncertain Reservoir Description Data

Errors in reservoir description data clearly contribute to errors in simulation model results. Since the description data are never exactly known, one might infer that model results are necessarily erroneous and unreliable. A number of considerations contribute, in contradiction of this inference, to model results being widely used to select and to design oil-recovery processes and to forecast oil recovery.

Accurate determination of all reservoir description data is not necessary for reliability of model results. The required accuracy of any description parameter is proportional to its influence on computed results (reservoir performance). The simulation model should be used to perform preliminary sensitivity runs to determine which description data are important. Expense and effort should then be concentrated on obtaining or refining only those "sensitive" description data. The particular parameters found to be important will vary from study to study, depending on the nature of the reservoir, the recovery process(es) of interest, and study objectives or questions. For example, if computed oil recovery is insensitive to wide variations in the gas relative-permeability curve, then the accuracy of this curve might deserve little attention. In a case where the gravity drainage mechanism is dominant, the oil relative-permeability curve at low and midrange oil saturations has a large effect on oil recovery and deserves effort of definition. Gas viscosity, relative

TABLE 48.2—CALCULATED STEAM BREAKTHROUGH TIMES (DAYS) FOR A NINE-SPOT PATTERN

	Well 2		Well 3	
	Diagonal	Parallel	Diagonal	Parallel
Five-point	47.8	204	1,400	117
Nine-point	87.7	75.5	900	1,000

permeability, and capillary pressure may play virtually no role and their accuracies are irrelevant. All phase relative permeabilities may be unimportant in a natural or flank waterflood of a relatively clean, thick high-relief sand where gravity forces are dominant with pronounced phase segregation. Only relative-permeability curve endpoints may be important in such cases. However, thinner sand or stratification, lower permeability and/or higher rates can increase the importance of water and oil relative-permeability curve shapes. While capillary pressure is unimportant in many reservoir studies, it can provide the dominant, cross-imbibition, mechanism in waterflooding thin, heterogeneous water-wet sands.

In some studies, the engineer is less concerned with the absolute accuracies of both model results and description data than with the sensitivity of calculated results to variations in those data. An example is a study performed to compare oil recoveries under alternative recovery processes. Model runs performed for each process, with reservoir description data varied over estimated ranges of uncertainty, may yield substantially invariant process rankings and incremental oil recovery differences. If so, any significant history-matching effort may be unnecessary and the only concern regarding accuracy of description data should be the estimated ranges of uncertainty. Another example is a design study of a given recovery process performed to optimize pattern type and size, well completions, and rates. Model runs, as just described, may show that minimal history-match and/or laboratory efforts for reservoir description are necessary to meet the study objective.

As previously mentioned, reservoir description data are altered through history matching to improve agreement between model results and reservoir performance data. Frequently, the study objectives involve estimation of reservoir performance under displacement conditions not present or recovery processes not active during the history period. In such cases, some description parameters that significantly influence future performance may not be reflected in the historical performance. An example is a heavy-oil reservoir that was produced for nearly 40 years under natural depletion with no water drive. Solution gas was very low and interstitial water saturation was immobile. A 50% water cut developed in time as a large pressure decline caused water mobility through water expansion and porosity reduction. Performance data included WOR, GOR, and pressure data for a number of wells. The only description parameters influencing these data were formation permeability, compressibility, critical gas saturation, water relative permeability at saturations slightly above S_{wc} , and gas relative permeability at saturations slightly above S_{gc} . The history-match effort gave a good match of performance with a unique set of these parameter values. However, it provided no information regarding the full-range relative-permeability curves necessary to estimate oil recovery under waterflood and steam stimulation or flooding. Laboratory relative-permeability measurements and waterflood and thermal pilots were conducted in this case.

Laboratory work and well pressure testing can be performed to estimate values of some reservoir description parameters that are not reflected in performance data. These parameters, together with others determined by history matching, can be used in model runs to estimate

oil recovery under the various alternative recovery schemes within the study scope. Field pilot tests then may be planned for one or more of the recovery processes, subject to the model results and engineering judgment.

Argument has persisted for years regarding uniqueness of the reservoir description obtained by history matching. A thorough treatment of this question requires length and mathematical complexity beyond the scope of this chapter. Any such treatment requires careful definition of terms. For example, define a reservoir description as a bounded set of m numbers $\{x_i\}$ representing selected zonal permeabilities and porosities and parameters characterizing relative permeability curves. Let the sets of N numbers $\{d_j^*\}$, $\{d_j\}$ represent observed and model calculated performance data where $d_j = d_j(x_1, x_2, \dots, x_m)$. If $N > m$, each x_i affects one or more d_j , and the d_j are independent functions of $\{x_i\}$ (in a mathematical sense undefined here), then with rare exceptions a unique set of parameter values $\{x_i\}$ will minimize the difference between the observed and calculated data. An altered zonation gives a physically different parameter set $\{\hat{x}_i\}$. Again, a unique set of values of $\{\hat{x}_i\}$ generally will minimize the difference between observed and calculated data. However, for this two-parameter set "experiment," comparable matches of observed data would allow a claim of non-uniqueness.

As a practical matter, study budget and time constraints prevent exhaustive trials of different parameter sets and even limit the number of model runs with different combinations of parameter values within a given set. Generally, difficulty encountered in a history-match effort is that of finding any reasonable description that gives good agreement with history. The effort rarely ends with difficulty in selecting among significantly different reservoir descriptions that give comparably good matches. In any event, the pertinent question regarding reservoir-description data is not related to correctness or uniqueness in an absolute sense. The pertinent question concerns the engineering significance of variations in parameter values within ranges of uncertainty. As discussed previously, the model itself is useful in estimating this significance.

Simulation Technology

Simulation technology can be divided roughly into the categories of model definition, model formulation, solution techniques, and special techniques related to numerical dispersion control, viscous fingering, and grid-orientation effects. Model definition includes specification of the problem (process) addressed, component identities, mass transport laws or expressions, fluid PVT and rock property relationships and, finally, the set of finite-difference equations expressing conservation of mass for each gridblock. These equations are generally nonlinear. Before they can be solved for pressures, saturations, etc., they must be linearized and manipulated into a set of simultaneous linear algebraic equations. The term *formulation* refers to these manipulations and the final form of this set of linearized equations. In a general sense, this set of equations can be expressed in the matrix form $AP = b$ where A is a very sparse, banded $N_b \times N_b$ matrix and the known b and unknown P are column vectors of dimension N_b . A rapidly expanding portion of the simulation literature describes increasingly efficient, iterative solution techniques for this problem.

Model Formulations

In 1959, Douglas *et al.*¹⁶ proposed *leap-frog* and *simultaneous* formulations for incompressible 2D two-phase flow. During 1960–69 a number of authors^{21–24} described two- and three-phase, 2D and 3D black-oil models based on this simultaneous formulation. In 1960, Stone and Garder¹⁸ and Sheldon *et al.*¹⁷ introduced the concept of eliminating saturation derivatives among the black-oil model equations to obtain a single difference equation in pressure. Fagin and Stewart¹⁹ in 1966 and Breitenbach *et al.*²⁰ in 1968 described three-phase black-oil models based on this implicit-pressure/explicit-saturation (IMPES) formulation. The IMPES formulation is explicit in saturation and composition in that relative permeabilities and concentrations are expressed explicitly in the interblock flow terms. Solution of the pressure equations over the grid is followed by an explicit updating of phase saturations and compositions in each gridblock.

In 1969, Blair and Weinaug¹²¹ published a fully *implicit* formulation which expresses all terms in the interblock flow and well production expressions implicitly. This requires simultaneous solution of all N model equations. A number of later papers describe implementation of the implicit formulation in black-oil,¹²² compositional³¹ and thermal³⁹ models.

In 1970, MacDonald¹²³ improved the stability of the IMPES method for the two-phase water/oil case by following the pressure equation solution with solution of a water-saturation equation over the grid using implicit (new-time-level or end-of-timestep) values of relative permeabilities in the interblock flow terms. Spillette *et al.*¹²⁴ extended this concept to the three-phase case and called the formulation *sequential*.

The IMPES formulation can become unstable if the volumetric flow through a gridblock in a timestep exceeds a small fraction of the block PV. The more stable sequential formulation remains stable to much larger ratios of gridblock volumetric throughput/PV. The tolerable throughput ratio for the implicit formulation is significantly larger than that of the sequential method. Arithmetic (or computing cost) per timestep and timestep size both increase from IMPES to sequential to implicit formulations. Since the total cost of simulating a given time period is proportional to the product of arithmetic per timestep and timestep size, all three formulations are used widely today.

The sequential formulation can fail to preserve material balances in some problems where adjacent gridblock compositions differ greatly.¹²⁵ Meijerink¹²⁶ described a *stabilized* IMPES formulation, which improves the stability of IMPES to a lesser extent than the sequential method but reduces material balance error in regions of steep composition gradients.

Thomas and Thurnau¹²⁷ describe an *adaptive implicit* formulation, which allows different levels of implicitness in different gridblocks. These various levels may change with timestep number and with iteration number within a given timestep. As previously mentioned, the implicit formulation¹²¹ requires simultaneous solution of N equations for each block over the entire grid. The corresponding arithmetic effort of solution is proportional to N^3 . Since $N=1$ for IMPES, the implicit formulation obviously requires considerably more computing time per timestep

than does IMPES. For each gridblock, the adaptive implicit method internally senses (without user intervention) which dependent variables (e.g., saturations, pressure, mole fractions) require implicit dating for stability. For most practical reservoir problems this results in one equation per gridblock for a major fraction of the grid and an overall average number of equations per block considerably less than N . Thus the method can attain the stability of the implicit formulation with considerably less computing expense. Also, computer storage requirements are reduced significantly. Future implementations of this formulation may contribute to increased model reliability (stability) and efficiency in simulations of all types of recovery processes.

Single-well coning studies generally involve radial grid spacings, resulting in very small gridblocks near the well and large throughput ratios. For these studies, the IMPES formulation is unsuitable, and the implicit formulation is generally the most efficient.¹²⁸ For field-scale, 3D black-oil studies, the overall computing time is frequently less with the sequential than with the IMPES or implicit formulation. The typical black-oil simulator applied today in 1,000- or more gridblock, field-scale studies is an IMPES model with a user-specified option of sequential solution. Smaller black-oil studies and preliminary cross-sectional, coning, and sensitivity studies associated with the large problems frequently employ the implicit formulation. Recent thermal models involve implicit formulations. With one exception³¹ recent compositional models^{29–33} are based on the IMPES formulation.

The popular IMPES and more recent implicit formulations are illustrated here for the case of 3D two-phase flow of water and undersaturated oil. This illustration is in the form of the Newton-Raphson procedure, which Blair and Weinaug¹²¹ used in describing their implicit formulation. For clarity, rock compressibility, gravity, and capillary pressure are neglected, and phase (component) production rates are fixed, independent of pressure and saturations. The terms *explicit* and *implicit* refer to the time level of evaluation for variables or terms in the left side, interblock flow terms of Eqs. 5. Explicit dating denotes evaluation at the beginning of the timestep, t_n (level n), while implicit dating denotes evaluation at the end of the timestep, t_{n+1} (level $n+1$). The implicit formulation of Eq. 5, then, appears for each gridblock as

$$\Delta(T_w \Delta_p) - q_{pw} - \frac{V_p}{\Delta t} [b_w S_w - (b_w S_w)_n] \\ \equiv f(S_w, p) = 0 \quad \dots \dots \dots (11a)$$

and

$$\Delta(T_o \Delta p) - q_{po} - \frac{V_p}{\Delta t} [b_o S_o - (b_o S_o)_n] \\ \equiv g(S_w, p) = 0, \quad \dots \dots \dots (11b)$$

where

T = interblock transmissibility,

p = pressure,

q_{pP} = production rate of phase P, oil or water

V_p = PV of gridblock,

Δt_P = timestep
 b_P = reciprocal formation volume factor of
 phase P, ST vol/res vol,
 S_P = saturation of phase P, and
 f, g = function of.

Gridblock indices i, j , and k on all terms are suppressed for clarity. All terms at time level n are known from the previous timestep's calculations. The absence of time level subscript denotes the implicit level, $n+1$. Thus all terms $T_w, T_o, b_w, b_o, S_w, S_o, p$ in Eq. 11 represent unknown values at time level $n+1$. For all N_b gridblocks, Eqs. 11 are $2N_b$ equations in the $2N_b$ unknowns $\{S_{wi,j,k,n+1}, p_{i,j,k,n+1}\}$. For a particular gridblock, Eqs. 11 are two equations in the 14 unknowns consisting of (S_w, p) pairs in the block and its six neighbors. These six neighbor pairs are introduced by the Laplacian interblock flow terms. Oil saturations are not additional unknowns since $S_o = 1 - S_w$; the transmissibilities T and reciprocal formation volume factors (b) are functions of S_w and p .

Application of the well-known Newton-Raphson iterative procedure to Eq. 11 gives

$$f(S_w, p) \equiv f(S_w^\ell, p^\ell) + \left(\frac{\delta f}{\delta S_w} \right)^\ell \delta S_w + \left(\frac{\delta f}{\delta p} \right)^\ell \delta p = 0 \quad (12a)$$

and

$$g(S_w, p) \equiv g(S_w^\ell, p^\ell) + \left(\frac{\delta g}{\delta S_w} \right)^\ell \delta S_w + \left(\frac{\delta g}{\delta p} \right)^\ell \delta p = 0, \quad (12b)$$

where ℓ is iteration number, superscript ℓ denotes evaluation at (S_w^ℓ, p^ℓ) , $\delta p \equiv p^{\ell+1} - p^\ell$, and S_w^ℓ, p^ℓ approach the desired S_w, p values as ℓ increases. The terms containing derivatives are actually sums of seven terms because of the previously mentioned functional dependence on neighboring block unknowns. Substituting from Eqs. 11 into Eqs. 12, performing the differentiation and rearranging the result gives

$$\Delta(T_{11}^\ell \Delta \delta S_w) + \Delta(T_{12}^\ell \Delta \delta p) - \frac{V_p}{\Delta t} b_w^\ell \delta S_w - \frac{V_p}{\Delta t} (S_w b_w c_w)^\ell \delta p + f(S_w^\ell, p^\ell) = 0 \quad (13a)$$

and

$$\Delta(T_{21}^\ell \Delta \delta S_w) + \Delta(T_{22}^\ell \Delta \delta p) + \frac{V_p}{\Delta t} b_o^\ell \delta S_w - \frac{V_p}{\Delta t} (S_o b_o c_o)^\ell \delta p + g(S_w^\ell, p^\ell) = 0, \quad (13b)$$

or in condensed matrix form,

$$\Delta(T \Delta P) - C P + R = 0, \quad (14)$$

where T and C are 2×2 matrices and P and R are 2×1 column vectors:

$$T = \begin{Bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{Bmatrix} \quad C = \begin{Bmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{Bmatrix} \quad P = \begin{Bmatrix} \delta S_w \\ \delta p \end{Bmatrix} \quad R = \begin{Bmatrix} f^\ell \\ g^\ell \end{Bmatrix} \quad (15)$$

The coefficients T_{11}, T_{21} arise from saturation derivatives of relative permeabilities in the transmissibilities. The C matrix elements are obvious upon inspection of Eqs. 13 (e.g., $c_{12} = V_p / \Delta t (S_w b_w c_w)$). The compressibilities (c_w, c_o) appear through the definition $c = (1/b) db/dp$.

Eq. 14 written for all gridblocks is a set of N_b linear parabolic difference equations in the N_b unknowns $\{P_{i,j,k}\}$. Following solution by a direct or iterative technique, the new iterates are calculated as $S_w^{\ell+1} = S_w^\ell + \delta S_w, p^{\ell+1} = p^\ell + \delta p$. Coefficients are recalculated at $(S_w^{\ell+1}, p^{\ell+1})$ for all blocks and Eq. 14 is solved again. These *outer* or *Newton* iterations are continued until the maximum values over the grid of $\{|\delta S_w|, |\delta p|\}$ are less than some prescribed tolerances. The term *inner* iterations refers to iterations performed by an iterative solution technique in solving Eq. 14 for a given Newton iteration.

The IMPES formulation treats transmissibilities explicitly so that the first terms in Eqs. 11 are $\Delta(T_{wn} \Delta p)$ and $\Delta(T_{on} \Delta p)$, where T_{wn} and T_{on} are calculated from known saturations at time level n . This results, upon application of Eq. 12, in zero values for transmissibility derivatives with respect to neighboring block saturations and Eq. 16 replaces Eq. 13:

$$\Delta(T_{wn} \Delta \delta p) - \frac{V_p}{\Delta t} b_w^\ell \delta S_w - \frac{V_p}{\Delta t} (S_w b_w c_w)^\ell \delta p + f(S_w^\ell, p^\ell) = 0 \quad (16a)$$

and

$$\Delta(T_{on} \Delta \delta p) + \frac{V_p}{\Delta t} b_o^\ell \delta S_w - \frac{V_p}{\Delta t} (S_o b_o c_o)^\ell \delta p + g(S_w^\ell, p^\ell) = 0 \quad (16b)$$

The single saturation unknown, δS_w , can be eliminated by multiplying Eqs. 16a and 16b by B_w^ℓ and B_o^ℓ , respectively, and adding to obtain

$$B_w^\ell \Delta(T_{wn} \Delta \delta p) + B_o^\ell \Delta(T_{on} \Delta \delta p) - \frac{V_p}{\Delta t} (S_w c_w + S_o c_o)^\ell \delta p + B_w^\ell f^\ell + B_o^\ell g^\ell = 0, \quad (17)$$

where B is the formation volume factor, $1/b$.

This is a set of N_b single or scalar, linear parabolic difference equations in the N_b pressure unknowns $\{\delta p_{ijk}\}$. As described before, a number of outer or Newton iterations are performed with pressure updated and coefficients

recalculated after each iteration. After convergence, saturation S_w is explicitly calculated, block by block, from Eq. 11a (with T_{wn} in the first term). Eq. 17 can be written more simply for the section to follow as

$$\Delta(T\Delta\delta p) - c\delta p + r = 0, \dots\dots\dots (18)$$

where T , δp , c , and r are scalars.

Solution Techniques

Eq. 18 written for all N_b gridblocks can be expressed in matrix form as

$$AP = b, \dots\dots\dots (19)$$

where A is a nonsymmetric, sparse $N_b \times N_b$ matrix and P is the $N_b \times 1$ column vector $\{\delta p_{ijk}\}$. Direct solution (Gaussian elimination) or iterative methods can be used to solve Eq. 19. The arithmetic effort required in direct solution strongly depends on the pattern of nonzero elements in the A matrix. This pattern in turn depends upon the particular linear ordering or numbering of the N_b gridblocks. An ordering is simply a one-to-one correspondence between a linear index $m = 1, 2, \dots, N_b$ and the gridblock indices $\{i, j, k\}$, $i = 1, 2, \dots, N_x$, $j = 1, 2, \dots, N_y$, $k = 1, 2, \dots, N_z$. Here the term *natural* ordering denotes numbering the blocks consecutively first in the shortest direction, then in the next shortest direction, and finally in the longest direction. For example, if $N_x > N_y > N_z$, then

$$m = k + (j-1)N_z + (i-1)N_yN_z. \dots\dots\dots (20)$$

Breitenbach *et al.*,¹²⁹ Peaceman,¹ and others illustrate the diagonal-band form of the A matrix and minimum direct solution effort which result from this natural ordering.

The half bandwidth of the A matrix is N_yN_z and the arithmetic effort (number of multiplications) of direct solution is roughly proportional to $N_b(N_yN_z)^2$. Iterative methods require an arithmetic effort roughly proportional to N_b . Thus increasing problem size, N_b , renders iterative solution increasingly preferable to direct solution. For large problems, computer storage requirement is also significantly less for iterative than direct solution.

Price and Coats¹³⁰ described reduced bandwidth direct solution methods based on diagonal (D2) and alternate-diagonal (D4) gridblock orderings. For certain test problems and iterative methods, they showed a D4 direct/iterative work ratio less than unity for half bandwidths up to about 30. Compared with natural ordering, D4 ordering can reduce direct solution computational effort by factors up to four and six for the 2D and 3D cases, respectively. Woo *et al.*¹³¹ described other techniques that take advantage of matrix sparsity to reduce direct solution effort. In spite of these advancements in direct solution, iterative methods remain preferable for large reservoir studies.

Successive-overrelaxation (SOR) iterative methods described by Young^{132,133} have been used in simulators from the early 1960's. Block SOR (BSOR) methods, including line (LSOR), two-line, and planar SOR, have proved especially popular. The BSOR methods require direct solution within each block, which means that direct

solution must be performed for tridiagonal matrices in LSOR and pentadiagonal matrices in planar SOR. As the block size is increased the arithmetic work per iteration increases because of the increased arithmetic associated with this direct solution within each block. However, convergence rate generally increases and the total number of iterations correspondingly decreases with increasing block size. To some extent, optimal block size can be determined by mathematical analysis^{133,134} of this tradeoff between work per iteration and number of iterations. The SOR methods remain popular because of ease of coding, low computer storage requirement and automatic determination of the optimum value of the single iteration parameter. Varga¹³⁴ describes the *power method* for this parameter determination and Breitenbach *et al.*¹²⁹ illustrate its application.

In 1971, Watts¹³⁵ presented an additive correction method which improves LSOR convergence rate in highly anisotropic problems. A highly anisotropic problem is one where, throughout the grid, transmissibilities in one direction are much greater than those in other direction(s). Set-tari and Aziz¹³⁶ extended Watts' method to other iterative solution techniques.

Alternating-direction iterative methods (ADI) were developed for 2D by Peaceman and Rachford¹³⁷ in 1955 and for 3D by Douglas and Rachford¹³⁸ in 1956. These methods were widely used in simulation throughout the 1960's and into the 1970's. The ADI methods require a sequence or set of iteration parameters. While mathematical analysis yields an optimal parameter set for certain cases,^{1,137} actual reservoir cases frequently require some trial-and-error effort.

In 1968, Stone¹³⁹ described the *strongly-implicit procedure* (SIP); Weinstein *et al.*¹⁴⁰ described SIP in 3D. Again, a set of iteration parameters is required. Parameter estimation methods associated with ADI have proved useful for SIP¹ but, again, some trial-and-error effort is required or beneficial in many reservoir studies.

A number of studies^{129,136,139,141} compare direct solution, LSOR, ADI, and SIP methods for a variety of test and reservoir problems. There is no simple answer to which method is best. The ranking of the methods is problem-dependent in that it depends on the range of variation in coefficient (transmissibility) values in the A matrix and the pattern (e.g., highly anisotropic), if any, of their variation. In general, the more difficult reservoir problems have a very large range from the smaller to larger transmissibilities and this large ratio is not uniformly associated with a particular direction throughout the grid. SIP became widely used throughout the 1970's and remains in use today because it frequently outperforms the other methods in these difficult cases.

A new class or type of iterative methods is the subject of a number of papers¹⁴¹⁻¹⁵⁰ published since the mid 1970's. Basically, the methods involve approximate factorization of the A matrix into an LU product, followed by an iterative sequence

$$LU(\underline{p}^{k+1} - \underline{p}^k) = \underline{r}^k, \dots\dots\dots (21)$$

where

L = a lower triangular matrix (all entries $\ell_{ij} = 0$ for $j > i$),

U = an upper triangular matrix (all entries u_{ij}
 $= 0$ for $j < i$),
 k = iterate number, and
 $r^k = b - Ap^k$.

Convergence is accelerated by the conjugate gradient,¹⁴¹ orthomin,¹⁴³ or other techniques. Because of the sparse, banded nature of the lower and upper triangular matrices L and U , the arithmetic work per iteration of solving Eq. 21 is a very small fraction of that required in direct solution of the original problem, Eq. 19.

These new methods seem very attractive in that they require no iteration parameter and are more robust than previous methods. That is, they generally exhibit fast or reasonable convergence rates, even for difficult reservoir problems where older methods fail or converge slowly. Two studies^{148,150} showed convergence for the difficult thermal (steamflood) problem where negative transmissibilities can occur.¹⁵¹ The interested reader should consult the reference sections of Refs. 141 through 150 for a number of equally good papers dealing with these new iterative methods.

Code Vectorization

The computational speed, storage, and vectorization capabilities of computer hardware have increased sharply in the past few years. As an example, the Cray-1S computer provides up to 4,000,000 decimal-words of storage, compared with a typically available 100,000 words on most machines used until 1975. Recently introduced computers offer sharp increases in computational speeds and speed/cost ratios. In addition, vector processing capabilities of Control Data Corp. and Cray supercomputers significantly increase the efficiency of simulators coded to use this vectorization.

This increased machine size, speed, and vector processing contribute to the feasibility of larger reservoir studies. Until the middle 1970's, most black-oil studies involved grids of 3,000 or fewer blocks. In 1980, Mrosovsky *et al.*¹⁵² described a Prudhoe Bay field study with more than 16,000 active gridblocks. Studies on the supercomputers with grids of more than 30,000 blocks have been performed recently.

The vector-processing capability has had a strong impact on simulation technology. The resultant increase in feasible study size has spurred the development of new, faster iterative solution techniques. Several papers¹⁵²⁻¹⁵⁶ describe the contribution of code vectorization to reduced computing expense and the need to develop or redesign model code to take advantage of the vectorization.

Nomenclature

A = a nonsymmetric, sparse $N_b \times N_b$ matrix
 $A = \Delta y_i \Delta z_k$ = cross-sectional area normal to flow
 b_P = reciprocal formation volume factor of phase P , ST vol/res vol
 C = 2×2 matrix
 C_{IJ} = concentration of component I in phase J
 C_{IP} = concentration of component I in phase P
 C_{NJ} = concentration of component N in phase J
 f_{IJ} = fugacity of component I in phase J

H_J = enthalpy, energy/mole
 k_{rP} = relative permeability to phase P ($P=w,o,g$)
 L = a lower triangular matrix (all entries $\ell_{ij}=0$ for $j > i$), see Eq. 21
 L = distance between adjacent block centers, $(\Delta x_{i-1} + \Delta x_i)/2$, see Eq. 1
 $m = 1, 2, \dots, N_b$, linear index
 N_b = total number of gridblocks, $N_x N_y N_z$
 N_x = number of gridblocks in x direction
 N_y = number of gridblocks in y direction
 N_z = number of gridblocks in z direction
 n = time level, $t_{n+1} = t_n + \Delta t$
 P = $N_b \times 1$ column vector $\{\delta p_{ijk}\}$, see Eq. 19
 P_{cgo} = gas/oil capillary pressure
 P_{cwo} = water/oil capillary pressure
 q_I = component I interblock flow rate, mass/time
 q_{pl} = mass rate of production of component I
 q_{pP} = production rate of phase P (water or oil)
 R = 2×1 column vector
 S_{gc} = critical gas saturation
 S_J = saturation of phase J
 S_{wc} = critical water saturation
 T = interblock transmissibility and $T=2 \times 2$ matrix
 T_{IJ} = interblock transmissibility for flow of component I in phase J
 T_{on} = oil transmissibility at time level n
 T_{wn} = water transmissibility at time level n
 U = an upper triangular matrix (all entries $u_{ij}=0$ for $j < i$)
 U_J = internal energy, energy/mole
 V = grid block volume, $\Delta x_i \Delta y_j \Delta z_k$
 $\Delta x = x_{i-1} - x_i$, where x is p or Z
 x_{IJ} = mol fraction of component I in phase J
 γ_P = specific weight of phase P
 δ = time difference operator, $\delta X \equiv X_{n+1} - X_n$
 μ_P = viscosity of phase P

Subscripts

i, j, k = gridblock indices
 J = w, o, g or $1, 2, 3$,
 n = step number

Superscripts

k = iteration number
 ℓ = iteration number

Chapter 49

Electrical Logging

M.P. Tixier, Consulting Engineer *

Fundamentals

Well logging is an operation involving a continuous recording of depth vs. some characteristic datum of the formations penetrated by a borehole. The record is called a log. In addition, a magnetic tape is usually made.

Many types of well logs are recorded by appropriate downhole instruments called *sondes*, lowered into the wellbore on the end of a cable. The winch of the logging cable is generally brought to the well on a special logging truck (Fig. 49.1), which also carries the recorders, power sources, and auxiliary equipment. The parameters being logged are measured in situ as the sonde is moved along the borehole. The resulting signals from the sonde are transmitted through electrical conductors in the cable to the surface, where the continuous recording, or log, is made.

Electrical logging is an important branch of well logging. Essentially, it is the recording, *in uncased sections of a borehole*, of the *resistivities* (or their reciprocals, the *conductivities*) of the subsurface formations, generally along with the *spontaneous potentials* (SP) generated in the borehole.

Electrical logging has been accepted as one of the most efficient tools in oil and gas exploration and production. When a hole has been drilled, or at intervals during the drilling, an electrical survey is run to obtain quickly and economically a complete record of the formations penetrated. This recording is of immediate value for geological correlation of the strata and detection and evaluation of possibly productive horizons. The information derived from the electrical logs may at the same time be supplemented by sidewall samples of the formations taken from the wall of the hole or by still other types of borehole investigations that can be performed by using additional wireline equipment available for use with the logging truck [deviation surveys, caliper (hole-diameter) surveys, dipmeter surveys, temperature surveys, radioactivity (gamma ray, density, neutron, and nuclear

spectrometry) surveys, acoustic surveys, wireline formation tester, etc.].

As explained later, several types of resistivity-measuring systems are used that have been designed to obtain the greatest possible information under diverse conditions—e.g., conventional devices (normals and laterals), induction log (IL), Laterolog™ (LL), microresistivity devices, and electromagnetic propagation logs. Table 49.1 gives the service company nomenclature for various logging tools.

The typical appearance of a standard electrical log is illustrated in Fig. 49.2. The left track of the log contains the SP curve. The middle track contains a 16-in. short normal (shallow-investigation resistivity curve), recorded on both regular and amplified sensitivity scales as solid curves, and a 64-in. normal (medium-investigation resistivity curve, dashed curve). The right track contains an 18-ft 8-in. lateral (deep-investigation curve).

Logs recorded with other combinations of resistivity-measuring devices have a similar general appearance, although the corresponding devices differ in principle and performance. Microresistivity logs generally include a microcaliper curve (hole-diameter recording), which is useful in the location of permeable zones. Of late, four-logarithmic tracks are often replacing the two-arithmetic track mentioned previously.

The curves are recorded on the most appropriate of several available sensitivity scales. The usual depths of scales are 2 in.=100 ft (regular) and 5 in.=100 ft (detail). Less frequently a scale of 1 in.=100 ft is used. For cases where great detail is involved, as in micrologging and dipmeter logging, special expanded scales are available. In many parts of the world, metric depth scales are used instead of English scales.

Earth Resistivities

Formation resistivities are important clues to probable lithology and fluid content. With a few exceptions that are rare in oilfield practice, such as metallic sulfides and

*Authors of the original chapter on this topic in the 1962 edition included this author, H.G. Doll, M. Martin, and F. Segesman.

Fig. 49.1—Setup for wireline logging operations in wells (schematic).

graphite, dry rocks are very good insulators but, when their pores are impregnated with water, they conduct electric current. Subsurface formations in general have finite measurable resistivities because of the water contained in their pores or adsorbed on their interstitial clay. Formation resistivity also depends on the shape and the interconnection of the pore spaces occupied by the water. These depend on the formation lithology and, in the case of reservoir rocks, on the presence of nonconductive oil or gas.

Units of Resistivity and Conductivity. In electrical logging, the resistivity is usually measured. An exception is induction logging, in which the conductivity is recorded along with its reciprocal, the resistivity. Measurements made with electromagnetic propagation are discussed later.

The resistivity (specific resistance) of a substance to the flow of electrical current, at any given temperature, is the resistance measured between opposite faces of a unit cube of that substance. In electrical-logging work,

the meter was chosen as the unit of length; so the unit of resistivity is taken as the $(\Omega \cdot \text{m})^2/\text{m}$, or more simply, the ohm-meter, $\Omega \cdot \text{m}$.

Since conductivity is the reciprocal of resistivity ($C=1/R$), a possible unit of conductivity would be $1/(\Omega \cdot \text{m})$, or \mathcal{U}/m . However, since this unit would necessitate extensive use of decimal fractions, a unit one-thousandth as large, the millimho/meter ($\text{m}\mathcal{U}/\text{m}$), is employed. Thus, formations having resistivities of 10, 100, or 1,000 $\Omega \cdot \text{m}$ have conductivities of 100, 10, or 1 $\text{m}\mathcal{U}/\text{m}$, respectively.

Dependence of Water Resistivity on Salinity and Temperature. The resistivity of an electrolytic solution decreases as the amount of chemicals therein increases. At any given temperature the electrical conductivity of a formation water or a drilling mud will depend on the concentration and nature of the dissolved chemicals.

In most cases the predominant solute is sodium chloride (NaCl); therefore, the NaCl conversion chart (Fig. 49.3) may generally be used to obtain resistivity from concentration. If other chemicals are present in relatively large amounts, it is possible to convert the concentrations of such chemicals into equivalent concentrations of NaCl to find the resistivity. To make the conversion, apply the appropriate multipliers given in Table 49.2 for the concentration of each separate ion [in parts per million (ppm) or (m^3/m^3) by weight, or in grains per gallon (gr/gal) or (kg/m^3)], and add the products.¹ Note that concentrations expressed in milligrams per liter (mg/L) and in ppm may be appreciably different at high concentrations. Below about 50,000 ppm, however, measurements at room temperature in the two units may be used interchangeably without serious error.

Fig. 49.2—Typical electrical log.

Fig. 49.3—Resistivity vs. concentration for NaCl solutions at various temperatures.

The resistivity of an electrolytic solution decreases as its temperature increases. This is of great importance, since temperature in the earth increases with depth.

Before the resistivity of the drilling mud (measured at surface temperature) can be compared with that of a formation (measured at a much higher temperature in a deep well) the resistivities must be converted to values that would have been observed at a common temperature. The temperature conversion is accomplished by means of Fig. 49.3, which shows for NaCl solutions the effects of both salinity and temperature on resistivity. Downhole temperatures may be estimated from a so-called "bottomhole temperature" (BHT) obtained by means of a maximum-reading thermometer inserted in the body of the sonde.

Resistivities of Formation Waters. Formation waters can vary remarkably with geographic location, depth, and geological age. Shallow groundwaters are usually fresh (not saline), with resistivities sometimes exceeding 20 to 50 $\Omega \cdot m$ at room temperature. They also may contain appreciable amounts of calcium and magnesium salts, which make them "hard." At great depths, formation waters generally tend to be more saline. In deep wells, formation-water resistivities sometimes may correspond to complete saturation (0.014 $\Omega \cdot m$ at 200°F).

A knowledge of R_w , the formation-water resistivity, is important in electrical-log interpretation. R_w may be obtained from the readings of the SP curve (Eq. 9) or from resistivity measurements on samples of formation water recovered from production or in drillstem tests. It also may be estimated from measurements of the resistivity of the permeable formations of interest when they are 100% water-saturated, R_0 , if the porosity or formation factor is known (Eqs. 1 and 2). R_w may be computed, as has been explained, from analyses of formation waters. Resistivity of formation waters is discussed further in Chap. 24.

Mud, Mudcake, and Mud-Filtrate Resistivities. Resistivities of the mud, R_m , the mudcake, R_{mc} , and the mud filtrate, R_{mf} , are all important in log interpretation. R_m is obtained by direct measurement on a mud sample. R_{mf} and R_{mc} are obtained by direct measurements on filtrate and mudcakes pressed from a sample of the mud, or they can be estimated from average statistical data on the basis of mud resistivity.²⁻⁴ Correction for the variation of these resistivities with temperature is made by use of Fig. 49.3.

Formation Resistivity Factor. If R_0 is the resistivity of a clean (nonshaly) formation completely saturated with water of resistivity R_w , the ratio R_0/R_w will be a constant that depends on the lithologic structure of the for-

mation and not on the resistivity, R_w , of the saturating water. This constant is the *formation resistivity factor*, F_R , commonly called "formation factor."

$$F_R = \frac{R_0}{R_w} \quad (1)$$

Dependence of Formation Factor on Porosity and Lithology. The formation factor, F_R , of a clean formation can be related to its porosity, ϕ , by an empirical formula of the form $F_R = a/\phi^m$, where a and m are constants. The exponent m , sometimes called the cementation exponent or factor, varies with the lithology.

In the construction of many graphs for log interpretation,² the "Humble formula" proposed by Winsauer *et al.*⁵ has been generally adopted:

$$F_R = \frac{0.62}{\phi^{2.15}} \quad (2)$$

An early formula proposed by Archie, which fits particularly well for consolidated formations such as hard sandstones and limestones, is

$$F_R = \frac{1}{\phi^2} \quad (3)$$

Limestones often contain vugs, interconnected with fissures, which add their porosity to that of the matrix. When the vugs and fissures are spaced closely, compared with the spacings of the resistivity-measuring devices, Eq. 3 often can be used as in the case of sandstones or limestones with only granular porosity. Nevertheless, it is sometimes advisable to use values of m greater than two as required to fit local observations.

Shaly (Dirty) Formations. Shales and clays are themselves porous and are generally impregnated with mineralized water. Therefore, they have appreciable conductivity, which is enhanced by ion-exchange conduction through the shale matrix. (This shale conduction is sometimes, though not quite properly, referred to as resulting from "conductive solids.") On the other hand, the size of the shale pores is so small that practically no movement of fluid is possible. Accordingly, shale, whether deposited in thin laminations or dispersed in the interstices of the sand, contributes to the conductivity of the formation without contributing to its effective porosity.

The relation between formation resistivity and porosity becomes more complex for shaly formations than for clean formations. Because of the additional shale conductance, the ratio of formation resistivity to water resistivity (i.e., the formation factor) is not constant when the resistivity of the impregnating water changes.⁶ Nevertheless, if the shale content is not too great, experimental observations show that for low enough values of water resistivity this ratio is almost constant, as though the conductance of the shale were then negligible in comparison with that of the water; and a limiting formation factor is found, which is related approximately to the effective porosity in the same way as the formation factor of a clean sand.

TABLE 49.2—CONVERSIONS FOR CATIONS AND ANIONS

Cations		Anions	
Na	1.0	Cl	1.0
Ca	0.95	SO ₄	0.5
Mg	2.0	CO ₃	1.26
		HCO ₃	0.27

Relation Between Formation Resistivity and Saturation. When a part of the pore space is occupied by an insulating material such as oil or gas, the resistivity of the rock, R_t , is greater than the resistivity that it has when 100% water-bearing, R_0 . The resistivity of such rock is a function of the fraction of the PV occupied by water.

For substantially clean formations, the water saturation, S_w , is related to R_t (resistivity of formation containing hydrocarbons and formation water, with a water saturation S_w) and R_0 (resistivity of same formation when 100% saturated with the same water) by an empirical relation known as the Archie equation.⁷

$$S_w = \left(\frac{R_0}{R_t} \right)^{1/n} \quad \dots \dots \dots (4)$$

Empirically determined values of n range between 1.7 and 2.2, depending on the type of formation. Experience shows that $n=2$ should give a sufficiently good approximation. Then, combining Eqs. 4 and 1 gives

$$S_w = \left(\frac{R_0}{R_t} \right)^{1/2} = \left(\frac{F_R R_w}{R_t} \right)^{1/2} \quad \dots \dots \dots (5)$$

The ratio R_t/R_0 is sometimes designated as the resistivity index, I_R ; accordingly, $S_w = (I_R)^{-1/n}$.

The relation between formation resistivity and water saturation is more complex when the formations contain some shale or clay because of the additional conductance resulting from the interstitial shale.^{8,9}

Ranges of Resistivity—Formation Classifications. Clays and shales are porous, practically impervious formations and are often very uniform throughout their mass. Their resistivity is comparatively low and practically constant over wide intervals. Compact and impervious rocks, such as gypsum, anhydrite, dense calcareous formations, or certain kinds of coal, are highly resistive because of their very small interstitial water content.

Resistivities of porous and permeable formations, such as sands, vary widely, depending on their lithology and fluid content. In electrical logging it is convenient to classify reservoir rocks as follows.

Soft Formations. These formations are chiefly poorly consolidated sand/shale series. The porosity of the sands is intergranular and exceeds 20%. Resistivities range from 0.3 $\Omega \cdot m$ for saltwater-bearing sands to several $\Omega \cdot m$ for oil-saturated sands.

Intermediate Formations. These are chiefly moderately consolidated sandstones but frequently limestones and/or dolomites. Reservoir porosity is generally intergranular, ranging from about 15 to 20%. The reservoir formations are interbedded with shales and very often with tight rocks. Resistivities range from 1 to about 100 $\Omega \cdot m$.

Hard Formations. These are chiefly limestones and/or dolomites, and also consolidated sandstones. They consist mostly of tight rocks containing porous and permeable zones, and shale streaks. The porosity of reservoirs is less than 15%. Most often, the porous and

permeable zones contain fissures and vugs. Resistivity range is from 2 to 3 $\Omega \cdot m$ to several hundred. For the completely tight formations, such as salt and anhydrite, the resistivity may be practically infinite.

Anisotropy. In many sedimentary strata, the mineral grains have a flat or plate-like shape with an orientation parallel to the sedimentation. Current travels with great facility along the water-filled interstices, which are mostly parallel to the stratification. These strata, therefore, do not possess the same resistivity in all directions. Such *microscopic anisotropy* is observed mostly in shales.

Moreover, in electrical logging, the distance between electrodes or coils on the measuring devices is great enough that the volume of formation involved in the measurements very often includes sequences of interbedded resistive and conductive streaks. Since current flows more easily along the beds than perpendicular to them, the formation has *macroscopic anisotropy*.

Both kinds of anisotropy may add their respective effects to influence the apparent resistivity. The longitudinal, or horizontal, resistivity, R_H , measured along the bedding planes is always less than the transverse, or vertical (perpendicular) resistivity, R_V .

Resistivity-measuring devices whose readings are not appreciably affected by the borehole [the deep induction log (ILD), and under certain conditions, the laterolog (LL), and the long lateral when the ratio R_H/R_m is low or moderate] will read R_H . Because of the borehole effect, the short-spacing-electrode devices usually read values greater than R_H .¹⁰

Distribution of Fluids and Resistivities in Permeable Formations Invaded by Mud Filtrate. Inasmuch as the hydrostatic pressure of the mud is usually maintained greater than the natural pressure of the formations, mud filtrate (forced into the permeable beds) displaces the original formation fluids in the region close to the borehole. Solid materials from the mud deposited on the wall of the hole form a mudcake, which tends to impede and reduce further infiltration.

The thickness and the nature of the mudcake depend on the kind of mud and on the drilling conditions rather than on the formations. The thickness, h_{mc} , is usually between $\frac{1}{8}$ and 1 in. For water-based muds the mudcake resistivity, R_{mc} , is about equal to one or two times the mud resistivity, R_m . In some oil-emulsion muds, R_{mc} may be somewhat greater.

Fig. 49.4a represents a schematic cross section of an oil-bearing permeable bed penetrated by a borehole. Fig. 49.4b and 49.4c show the corresponding radial distribution of fluids in formation and resistivities.

As indicated in Fig. 49.4a, the zones of different resistivity may be divided into the drilling mud within the borehole (of resistivity R_m); the mudcake R_{mc} , the flushed zone R_{xo} ; a transition zone; in some cases an "annulus," R_{an} (present only in certain oil- or gas-bearing formations); and the uncontaminated zone (of resistivity R_t). The invaded zone (of "average" resistivity, R_i) includes the flushed zone and the transition zone.

Invaded Zone. This zone is behind and close to the wall of the hole; it is believed that most of the original interstitial fluids have been flushed out by the mud

Fig. 49.4—*a*. Horizontal section through a permeable oil-bearing bed ($S_w < 60\%$); *b*. radial distribution of fluids in formation (qualitative); *c*. radial distribution of resistivities.

filtrate. This flushed zone, of resistivity R_{xo} , is considered to extend, under usual conditions of invasion, at least 3 in. from the wall. Exceptions to this rule can occur.

If the bed is water bearing, the pores in the flushed zone are completely filled with the mud filtrate, and for clean formations R_{xo} is nearly equal to $F_R R_{mf}$; F_R being the formation factor and R_{mf} the mud-filtrate resistivity.

If the bed is oil bearing, the flushed zone contains some residual oil saturation, S_{or} . From Eq. 5, S_{xo} , the water saturation in the flushed zone is

$$S_{xo} = \left(\frac{F_R R_{mf}}{R_{xo}} \right)^{1/2}$$

or

$$R_{xo} = \frac{F_R R_{mf}}{S_{xo}^2}, \quad \dots \dots \dots (6)$$

where $S_{xo} = 1 - S_{or}$.

Beyond the region of maximum flushing, R_{xo} , there is a more or less extended transition region, the nature of which depends on the characteristics of the formation, the speed of invasion, and the hydrocarbon content. The invaded zone includes the flushed zone and the part of the transition zone invaded by filtrate. In the case of water-bearing sands and oil-bearing sands of high water saturation, the invaded zone extends up to the uncontaminated zone, R_f .

There can be no exact definition of the depth of the invaded zone, but it is convenient to introduce a factor d_i , called the "electrically equivalent diameter of invasion," corresponding to an average invaded zone of resistivity R_i , which has the same effect as the actual in-

vaded zone on measurements made in the borehole. The depth of invasion is variable. It depends on the plastering properties of the mud, pressure differences between the mud column and the formation, time elapsed since the formation was drilled, porosity of the formation, proportion and nature of the fluids (water, oil, gas) present in the pores, reaction of any interstitial clays with the mud filtrate, etc.

All other conditions being the same, the greater the porosity, the smaller the depth of invasion. With usual muds, d_i seldom exceeds $2d_h$ (d_h = hole diameter) in high-porosity sands, but it may exceed $5d_h$ and even $10d_h$ in low-porosity formations such as consolidated sandstones or limestones. In some cases, invasion can be extremely shallow in very permeable formations and in gas-bearing formations.

In very permeable beds, when there is an appreciable difference between the specific gravities of the mud filtrate and the salt-laden interstitial water, gravity-segregation effects may occur, with the fresher filtrate tending to accumulate at the top boundary of the bed, resulting in a decrease in the depth of invasion in the lower part of the bed.¹¹

In fissured formations, the permeability is quite often enormous because of the fissures—much greater than the permeability of the matrix material surrounding them. Suppose that a formation is composed of a porous but relatively impermeable material, broken by networks of roughly parallel fissures. Mud filtrate penetrates the fissures easily and deeply, driving out much of the original fluids (oil and formation water). On the other hand, the matrix itself may be penetrated hardly at all by the filtrate. Since the fissures constitute a small part of the total PV, only a very small portion of the total original fluids is displaced. As a result, R_{xo} is little different from R_f , and the ratio R_{xo}/R_{mf} is no longer representative of the formation factor.

Annulus. When the formation contains hydrocarbons, the process of invasion is complex. The distribution of fluids is then affected by the two-phase permeabilities, relative densities (gravities) and viscosities of the fluids, capillary forces, etc.

When the initial water saturation is low (less than about 50%), one important feature is the existence of an *annular region* just inside the uncontaminated zone, containing mainly formation water and some residual oil. This annulus is explained as follows. The mud filtrate penetrates the formation radially, sweeping the removable oil and formation water ahead of it. For large oil saturation, the relative permeability to oil is appreciably greater than that to water. Therefore, the oil moves faster, leaving a zone (the annulus) enriched in formation water behind it.

It seems likely that, because of the effects of diffusion, capillary pressure, gravity, etc., the existence of a well-defined annulus is a transitory phenomenon. Field log experience nevertheless seems to show that the annulus does very often exist at the time the logs are run. Computations have shown that the presence of the annulus has a practically negligible effect on the response of the devices with electrodes (normals, laterals, and laterolog). It may have an effect on the induction log, but this can be taken care of for practical purposes by means of appropriate interpretation charts.²

Uncontaminated Zone. For clean formations, from Eq. 5,

$$R_t = \frac{F_R R_w}{S_w^2} \dots \dots \dots (7)$$

In the usual case, R_{mf} is 10 to 25 times as large as R_w . Thus, comparing Eqs. 6 and 7 with usual values of S_w and S_{xo} , R_t , even in oil-bearing formations, is often less than R_{xo} , as represented in Fig. 49.4c.

Apparent Resistivity. Since any resistivity measurement is affected in some degree by the resistivities of all the media in the immediate vicinity of the sonde (i.e., mud, different parts of the formation that vary in resistivity, adjacent formations if the bed measured is thin), any given device records an apparent resistivity. Each resistivity device is calibrated so that when the sonde is in a homogeneous medium (or in some other condition appropriate to practice, specified for the particular device) the apparent resistivity reading is equal to the actual resistivity.

Requirements for and Types of Resistivity Devices. Inspection of basic relations in Eqs. 1, 2, 5, and 6 shows that a determination of S_w and ϕ requires a knowledge of R_t and R_{xo} (or R_i , in certain cases where R_{xo} is not easily determined). Thus, for the reservoir-evaluation problem, it is necessary to have resistivity-measuring devices with different depths of investigation to obtain values indicative of the resistivities of the invaded zone and the uncontaminated zone. The readings of the deep- and shallow-investigation curves may often be used to correct each other, through correction charts or departure curves, to obtain better values of R_t and R_i .

Another function of resistivity recording is to provide an accurate definition of bed boundaries, particularly of permeable beds. Finally, it is desirable that the readings not be influenced by the effect of the mud column or, in case of thin beds, by the adjacent formations.

These requirements are only partly satisfied with the "conventional" resistivity devices. The introduction of microdevices and focused devices has brought about an appreciable improvement.

Currently used resistivity devices may be classified in two categories.

1. Macrodevices, which derive their reading from about 10 to 100 cu ft of material around the sonde (useful for R_t and R_i evaluation), and include unfocused-electrode devices, focused-electrode devices, and induction logging devices.

2. Microdevices (also called wall-resistivity devices), which derive their readings from a few cubic inches of material behind or close to the wall of the hole. Since the electrodes are mounted on an insulating rubber pad pressed against the wall of the hole, measurements are affected only marginally by the mud column. Microdevices are of unfocused and focused types.

Resistivity devices that have electrodes may be used in holes filled with water or water-based drilling mud, which provides the electrical contact necessary between electrodes and formation. The induction log can also be used in empty holes or in holes filled with nonconductive oil-based mud. The various resistivity devices are described later.

Spontaneous Potential (SP) Log

The SP log is a record of the naturally occurring potentials in the mud at different depths in a borehole. The measurement is made in uncased holes containing water-based or oil-emulsion muds between an exploratory electrode on the sonde in the borehole and a stationary reference electrode at the surface.

Usually the SP curve (Fig. 49.2) consists of a more or less straight baseline (corresponding to the shales) having excursions or peaks to the left (opposite the permeable strata). The shapes and the amplitudes of the excursions may be different, according to the formations, but there is no definite correspondence between the magnitudes of the excursions and the values of permeability or porosity of the formation.

The principal uses of the SP curve are to (1) detect the permeable beds, (2) locate their boundaries (except when the formations are too resistive), (3) correlate such beds, and (4) obtain good values for R_w , the formation-water resistivity.

Origin of the SP. The character of the potentials measured in the mud results from ohmic drops produced by the flow of SP currents through the mud resistance. If the mud is extremely conductive, these ohmic drops may be insignificant, and the variations in the SP curve may be too small to be useful.*

The SP currents flow as a result of electromotive forces (EMF's) existing within the formations or at the boundaries between formations and mud. One phenomenon that could cause an EMF to appear across the mudcake opposite a permeable bed is *electrofiltration*. The mud filtrate, in being forced through the mudcake, would tend to produce an EMF, positive in the direction of flow. According to experiments,¹² the EMF across the mudcake may be quite sizable, but there is also an electrofiltration EMF generated across the adjacent shales. Thus, the net effect of electrofiltration in causing variations of SP is small and in most cases negligible for all practical purposes—a conclusion verified by field experience.**

Most important are the EMF's of electrochemical origin, which occur at the contacts between the drilling mud (or its filtrate) and the formation water, in the pores of the permeable beds, and across the adjacent shales.¹⁶ In a clean sand lying between shale beds, all penetrated by a borehole containing conductive (water-based) mud, the total electrochemical EMF, E_c , is produced in the chain (Fig. 49.5): Mud/mud filtrate/formation water/shale/mud. The EMF of the junction, mud/mud filtrate, is taken to be practically nil because, although the resistivities of the mud and its filtrate may differ, their electrochemical activities should be the same.

The part of the chain consisting of "formation water/shale/mud" gives rise to the shale-membrane EMF, E_M . The part "mud filtrate/formation water" gives rise to the liquid-junction EMF, E_J . For NaCl (monovalent-ion) solutions, at 75°F,

$$E_M = 59 \log_{10} \frac{a_w}{a_{mf}}$$

*In such a case the gamma ray log, which distinguishes shales from nonshale beds, is sometimes recorded as a substitute for the SP.

**Further information on the electrofiltration EMF, or streaming potential, may be found in Refs. 13 through 15.

Fig. 49.5—Schematic representation of electrochemical chain and SP current path at boundary between permeable bed and adjacent shale.

and

$$E_J = 12 \log_{10} \frac{a_w}{a_{mf}},$$

where a_w and a_{mf} are the chemical activities of the formation water and mud filtrate, respectively (at 75°F), and E_M and E_J are in millivolts. The total E_c is the sum of E_M and E_J :

$$E_c = K_c \log_{10} \frac{a_w}{a_{mf}}, \quad \dots \dots \dots (8)$$

where K_c is the electrochemical coefficient and is equal to 71 at 75°F.

Eq. 8 is general, provided that both formation water and mud filtrate are essentially NaCl solutions of any concentration. The values of K_c are directly proportional to the absolute temperature. Thus, at 150°F the coefficient K_c in Eq. 8 becomes 81 instead of 71, and at 300°F it becomes 101 (see Fig. 49.6).

From Eq. 8, in the usual case of a_w greater than a_{mf} , E_c is positive. However, if a_{mf} is greater than a_w , corresponding to mud more saline than formation water, then E_c is negative and the SP deflections corresponding to permeable beds are then reversed on the log.

Effect of Invasion on Generation of the EMF. In the explanation of the electrochemical potential, it has been assumed that no shale-type potential is created by the mudcake. In the normal case, mud filtrate bathes both sides of the mudcake and no shale-type potential can arise. In some formations, there is only a little filtrate behind the mudcake. Such small amount of filtrate will be contaminated easily by the formation water. In this case, one face of the mudcake is wetted by the filtrate in the hole, the other face by contaminated filtrate of different activity. This will give rise to a shale-type potential of the same polarity as the main shale potential, and the SP curve will be decreased. This explains the decreasing of the SP curve with time in very highly permeable beds.¹⁷ The filtrate is evacuated by gravity

Fig. 49.6— R_w determination from the SP. The inset chart of true R_w vs. R_{wv} applies to formation waters of average composition.

segregating forces and the formation fluids tend to come back toward the hole with time.

Conversely, an increase in SP with time is observed often in low-permeability water-bearing formations. Very little filtrate invades the formation in a freshly drilled hole and the filtrate is contaminated by the formation water. As the invasion proceeds, more and more filtrate goes into the formation and the mudcake is wetted on both faces by the mud filtrate. When the mudcake does not contribute any shale-type potential, the SP curve, recorded on the front of a thick permeable sand, is said to be fully developed.

Effect of Interstitial Shales on the SP. Increasing amounts of shale or clay in a permeable bed effectively result in a reduction of the SP curve. At the limit, for 100% shaliness, E_c becomes zero; that is, the "sand" is then all shale and indistinguishable from the surrounding shales.

The presence of oil in a shaly sand tends to enhance the effect of the shale. All other conditions being the same, the total E_c of a shaly sand will be smaller if oil bearing than if water bearing.

The effect of interstitial shale is also greater in low-porosity formations. In these cases, only a small amount of shale reduces the SP deflection appreciably. Conversely, the E_c of shaly water-bearing sands of high porosity remains practically equal to the E_c of a clean sand, as long as the shale content is reasonably low—i.e., does not exceed a few percent.

Geometric Effect Influencing the SP Curve

Circulation of the SP Current. The various EMF's add their effects to generate the SP currents, which follow the paths represented schematically in Fig. 49.7 (right) by solid lines. Each current line encircles the junction of mud, invaded zone, and uncontaminated zone. In the usual case where the formation waters are saltier than the mud, E_c is positive and the current circulates in the direction of the arrows. The potential of a point in the mud column opposite the sand is negative with respect to one opposite the shale.

Along its path, the SP current forces its way through a series of resistances, both in the ground and in the mud. Along a closed line of current flow, the total of the ohmic-potential drops is necessarily equal to the algebraic sum of the EMF's encountered. Moreover, the total potential drop is divided between the different formations and the mud in proportion to the resistance of the path through each respective medium.

Static SP (Clean Formations) and Pseudostatic SP (Shaly Formations). It is convenient to use an idealized representation in which the SP current is prevented from flowing by means of insulating plugs placed across hole and invaded zones, as shown in Fig. 49.7a (right). Under these conditions, a plot of the potential in the mud column would appear as the dashed cross-hatched curve on the left of Fig. 49.7a, with a maximum negative deflection opposite the permeable bed equal to the algebraic sum of all the EMF's of various origins. This is the maximum SP that could be measured. It is therefore convenient to use this theoretical value as a reference. In the case of a clean sand, it is called the static SP, E_{SSP} . If the sand is shaly, it is called the pseudostatic SP, E_{pSP} .

For given values of the activities of mud and formation water, the pseudostatic SP of a shaly sand is smaller than the static SP of a clean sand. The ratio E_{pSP}/E_{SSP} is called the reduction factor or ratio and is designated by the symbol α_{SP} .

The SP log records only that portion of the potential drop occurring in the mud. When the bed is sufficiently thick the amplitude of the SP deflection approaches the static SP (or E_{pSP} in case of shaly formations), because then the resistance offered to the current by the bed itself is negligible compared with the resistance of the path through the mud in the borehole.

Factors Influencing the Shape and Amplitude of SP Deflections. As seen in Fig. 49.7b, the current circulates in the hole not only opposite the permeable formation but also a short distance beyond its boundaries. As a result, although on the static SP diagram the boundaries of a permeable bed are indicated by sharp breaks, those on the actual SP curve show a more gradual change in potential. An analysis of the circulation of the current¹⁸ shows that, for uniform resistivity in the formations, the bed boundaries are located at the inflection points on the SP log. This fact provides a means of determining the thickness of a bed from the SP log.

Both the shape of the SP deflection and its relative amplitude (in fractional parts of the E_{SSP} or E_{pSP}) are influenced by four factors, which determine the conditions for the circulation of SP currents: (1) bed thickness, (2) resistivities of the bed, the adjacent formations, and the

Fig. 49.7—a. Static SP diagram (left) that would be observed in hole when current is prevented from flowing by means of insulating plugs (right); b. actual SP diagram (solid curve, left) and schematic representation of SP current distribution in and around permeable bed (right).

mud, (3) borehole diameter, and (4) depth of invasion. All other factors remaining the same, a change of the total EMF's affects the amplitude but does not modify the general shape of the SP log.

Influence of Mud Resistivity and Hole Diameter. The mud resistivity has a predominant influence on the SP curve. If the mud is of about the same degree of salinity as the formation water, electrochemical EMF's are small. If the mud is more saline than the formation water, the SP may be reversed (sand deflections toward the positive side of the log). Moreover, the lower the mud resistivity (compared with the formation resistivity) the broader the deflection above and below the permeable bed and, because the ohmic drops in the mud are decreased, the smaller the amplitude of the deflection.

An increase in hole diameter acts approximately like an increase in the ratio of formation resistivity to mud resistivity. It tends to round off the deflections on the SP log and reduce the amplitude of the deflections opposite thin beds. A decrease in hole diameter has the same effect as a decrease in the ratio of formation resistivity to mud resistivity.

The SP log would also be influenced by a lack of homogeneity of the mud—a change in salinity of the mud

Fig. 49.8—SP phenomena in highly resistive formations (schematic).

at a certain level would result in an SP baseline shift at that level. However, it has been found in practice that such changes in salinity are rare.

Effect of Invasion. Permeable beds in general are invaded by mud filtrate. Because the boundary between mud filtrate and interstitial water is somewhere inside the formation, a fraction of the SP current flows directly from the shale into the invaded zone, without penetrating the mud column. As a result, the presence of the invaded zone has an effect on the SP log similar to that of an increase in hole diameter.

SP in Soft Formations. Theory and field experience have shown that the amplitude of the SP deflection is practically equal to the static SP (of a clean sand) or to the pseudostatic SP (of a shaly sand) when the permeable beds are thick and the resistivities of the formations are not too great compared with that of the mud. Moreover, the SP curves define the boundaries of the bed with great accuracy. The amplitude of the deflection is less than the static SP or pseudostatic SP for thin beds, and the thinner the bed, the smaller the deflection.

On the other hand, when the resistivity of the formation, R_f , is considerably greater than that of the mud, R_m , the SP curves are rounded off, the boundaries are marked less accurately, and all other conditions being the same, the amplitude of the peak is less than when the ratio R_f/R_m is close to unity.

For the case of shaly sands, the SP curve may also be affected by the presence of oil. A change in the magnitude of the SP deflection occurs very often when passing an oil/water contact in a shaly sand. This change is not a positive criterion for the detection of oil because the same effect would be obtained if the salinity of the interstitial water were reduced or if the percentage of shale were increased.

SP in Hard Formations. Hard formations are highly resistive except for permeable beds, whether oil- or water-bearing, and shales, which are impervious. The SP currents generated by the different EMF's flow into the hole out of the shale sections and out of the hole into

the permeable sections. In between, they flow through the mud rather than through resistive sections close to the borehole, because of the large resistances the latter paths offer. However, within the formation at a distance from the borehole, where the paths through the resistive beds have larger cross sections and hence lower resistances, the SP currents can complete their circuits from permeable beds to shale. They cannot return to the mud through adjacent permeable beds because there they encounter EMF's opposing them.

Opposite a given resistive bed, the SP current in the mud column remains essentially constant along the borehole. This means that the potential drop per unit length of hole is also constant, thus giving a constant slope on the SP log as shown by the straight-line portions of the SP in Fig. 49.8. At the level of each conductive bed, some SP current will enter or leave the mud column, thus modifying the slope of the SP log. For instance, the slope of the SP log changes at the level of the permeable bed, P_2 , because part of the current leaves the hole and flows into the bed.¹⁸

As a general rule, in hard formations the permeable beds are characterized on the SP log by slope changes or curvatures that are convex toward the negative side of the log. Shales are characterized by curvatures that are convex toward the positive side of the log. Highly resistive beds correspond to essentially straight parts of the SP log.

Determination of Static SP (SSP). The SP deflection is measured with respect to the shale baseline, a reference line which can generally be traced along the extreme positive edges of the SP curve. Usually the shale line is straight and vertical.*

In any given well, since the mud salinity is constant and the interstitial waters may tend to be constant, there is often a definite tendency for the maximum SP deflections to be the same for the same types of permeable formations at comparable depths. Thus, it is usually possible to draw, parallel to the shale line, a sand line on the log along the maximum negative deflections of the clean sands of sufficient thickness.

It is very likely that, for all the beds where the SP peaks reach the sand line, (1) the formation-water resistivity is practically the same, (2) the beds are virtually free from shaly material, and (3) the amplitude of the deflection is equal to the SSP. For thin beds in cases where the SSP cannot be determined as above (or for a thin shaly sand), the SP reading from the log must be corrected by means of appropriate charts in order to obtain the E_{SSP} or E_{pSP} .²

Determination of R_w from SSP

Since the variations of electrofiltration potential from sand to shale can generally be neglected, the SSP is taken in practice as equal to the corresponding value of $-E_c$ as long as the SP is "fully developed."

It is convenient to replace Eq. 8 by

$$E_{SSP} = -K_c \log \frac{R_{mf}}{R_{we}}, \dots \dots \dots (9)$$

*Field experience has shown that in certain regions there may be shifts of the shale line. Sometimes these shifts are found systematically at the same places in the geological column and can be used as markers.

where R_{we} is an equivalent formation-water resistivity. The computation of R_{we} is given in the chart of Fig. 49.6, and R_w is derived from R_{we} by means of the auxiliary chart at the lower right of Fig. 49.6. The solid curves on this auxiliary chart correspond to highly saline formation waters, where the presence of salts different from NaCl is negligible in practice. They are derived from the known activity/resistivity relationships for pure NaCl solutions. The dashed curves correspond to formation waters of low salinity, where the presence of other salts (calcium and magnesium chlorides, sulfates, and bicarbonates) have an important bearing on the activity values. These curves are derived from empirical observations and cover formation waters of average composition.¹⁹ Note that, for intermediate salinities ($0.08 < R_w < 0.3$ at 75°F), the value of R_{we} is practically equal to R_w .

The mud filtrate is taken here as an NaCl solution, and this is generally done in practice, except for muds containing gypsum, CaCl_2 , or NaOH. In such cases, the determination of R_w from the SP curve requires the measurement of the activity of the mud. A field instrument is provided for this purpose.

Resistivity Logging Devices*

A general classification of the types of resistivity logging devices was given previously.

Electrical Survey (ES). During the first 25 years of logging practice, the standard ES (Fig. 49.2) usually included, in addition to the SP, three conventional (unfocused) resistivity curves; namely, a *short normal* curve (distance between electrodes A and M is 16 in.), a *long normal* (AM=64 in.) or a *short lateral* (distance between electrodes A and O is 6 to 9 ft), and a *standard lateral* (AO=18 ft, 8 in. in general), all recorded simultaneously. In some regions, such as the Permian basin (west Texas and New Mexico), the short-normal spacing was reduced to 10 in., and the limestone sonde was recorded instead of the long normal. The ES log is rarely run today, but it was the standard log for many decades.

Induction-Electrical Surveys (IES) (Figs. 49.9 and 49.10). The simultaneous recording of induction (conductivity and resistivity) curves, 16-in. normal, and SP curve, is a good combination for the logging of formations of low to moderate resistivities in fresh muds. Of late, the 16-in. normal has been replaced by a focused electrode system, and two induction logs of different investigations may also replace the single induction.

Focused Electrode Devices. In wells drilled with very saline mud, or in high resistivity formations, a laterolog or dual laterolog is used with a gamma ray tool. Fulltest benefit of these combinations usually is derived if a microresistivity survey is also run. Microresistivity surveys generally include a microcaliper curve (hole-diameter recording) (see Figs. 49.9 and 49.10). To avoid multiple runs, many of the above devices are combined with porosity logs—acoustic, density, and neutron logs. These porosity logs are discussed in other chapters.

*See Table 49.6 for the names of the various service companies' tools.

Conventional Resistivity Devices

During the first quarter century of well logging, the only electrical surveys available were the conventional resistivity logs plus the SP. Thousands of them were run each year in holes drilled all over the world. Since then, new logging methods have been developed to measure values much closer to R_{xo} and R_t , which are the values sought. Nevertheless, the conventional ES (consisting of SP, 16-in. normal, 64-in. normal, and 18-ft 8-in. lateral) still is being run in some parts of the world. For this reason, and also because new information can often be obtained by reinterpreting old ES logs, this chapter includes discussion on the principles and responses of the ES measurements.

Principles: Normal and Lateral Devices. In conventional resistivity logging a current of known intensity is sent between two electrodes, A and B (A on the sonde, B on the sonde or at the surface), and the resulting potential difference is measured between other electrodes M and N. The apparent resistivity is proportional to the measured potential difference.

For normal devices, the distance AM is small (1 to 6 ft) compared with MN, MB, and BN. In practice N or B may be placed in the hole at a large distance above A and M (Fig. 49.11). The voltage measured is practically the potential of M (because of current from A), referred to an infinitely distant point. The distance AM of a normal device is its *spacing*. The point of measurement is midway between A and M.

For lateral devices, measuring electrodes M and N are close to each other and located several feet below current electrode A. Current-return electrode B is at a great distance above A or at the surface. The voltage measured is approximately equal to the potential gradient at the point of measurement O, midway between M and N. The distance AO is the spacing of the lateral device. The two arrangements shown in Fig. 49.12 (in which current and measuring electrodes are interchanged) are equivalent as regards measured potentials (and resistivities).

Curve Shapes—Laboratory Results. Fig. 49.13 shows laboratory curves from a normal device for homogeneous resistive layers between adjacent beds of low resistivity. The curves are symmetrical with respect to the center planes of the layers. The same curves are recorded if M is above A instead of, as in the figure, A above M.

The upper part of Fig. 49.13 shows a resistive bed thicker than the spacing (bed thickness, h , is $6d_h$; spacing AM is $2d_h$; where d_h is the hole diameter). At the boundaries of the bed the curve tends to be rounded off owing to the influence of the borehole. Moreover, the indicated bed thickness (distance between the inflection points P and P') is less than the actual thickness. Normal curves tend to show resistive beds thinner than they actually are (and conductive beds thicker than they actually are) by an amount equal to the spacing AM. The error in picking the boundaries of thick resistive beds is small for short-spacing normals, which is one reason for the recording of a short normal.

As shown in the lower part of Fig. 49.13, for a resistive layer thinner than the spacing, the curve shows

Fig. 49.14—Laboratory curves for lateral sonde of spacing $AO = 11d$ through uninvaded beds more resistive than adjacent formations.

a depression opposite the layer with two symmetrical small peaks, c and d, on either side. The main disadvantage of the normal device is that beds thinner than the spacing, no matter how resistive they may be, appear on the log as being conductive.

Fig. 49.14 shows similar curves for a lateral. The lateral curves are markedly dissymmetrical, and their features are more complex. Again the transitions in the curves at the boundaries have been rounded off by the effect of the borehole. When the bed is thicker than the spacing, the upper boundary of the bed is not well defined on the lateral curve, and, as a whole, the bed appears as being displaced downward by a distance equal to the spacing AO .

In the lower part of Fig. 49.14 the lateral indicates a resistive layer thinner than the spacing by a sharp peak of relatively low apparent resistivity. Below the layer is a low-resistivity "blind zone," followed by a "reflection peak" at a distance AO below the bottom boundary of the layer. The blind zone is recorded when the resistive streak is located between the current electrode and the measuring electrodes.

The lateral is useful for the location of thin, highly resistive streaks, although interpretation may be difficult if several resistive streaks are close together. A lower streak located in the blind zone of an upper resistive streak may be missed, and the reflection peaks may be mistaken for actual resistive streaks in the formation. For a resistive layer of thickness approximately equal to the spacing (*critical thickness*), the lateral is almost completely flattened.

Similar generalizations are possible for lateral curves recorded for beds more conductive than the surrounding formations. Whether the layer is thick or thin, the shape of the curve is dissymmetrical and the anomalies are spread downward, outside the bottom boundaries. The apparent increase of bed thickness is roughly equal to AO .

Normals and Laterals in Hard Formations. Fig.

Fig. 49.15—Responses of normals and laterals in hard formations (qualitative).

49.15 shows schematically the behavior of the normals and laterals in thick, highly resistive formations containing porous or shaly (that is, more conductive) zones. In a highly resistive formation most of the current from electrode A flows up or down the borehole, dividing in inverse proportion to the resistances of the two paths, which are determined mostly by the resistance of the mud column in the hole between the current electrode and the nearest conductive beds. At the conductive beds, depending on their thickness and conductivity, the current has low-resistance paths from the hole. The lopsided appearance of the normal and lateral curves is explainable in terms of the unequal division of current flowing up and down the hole.

The normal, for example, has M and N above the current electrode. The voltage measured is the ohmic potential drop in the hole resulting from current flowing in the mud between M and N. When the device is near the bottom of a resistive bed, most of the current flows down to the conductive bed just below, and there is little potential drop between M and N because the current up is small. When the device has moved farther up in the bed, the current down decreases because the resistance of that path has increased. Also, since the resistance of the upward path has decreased, the current up increases. Therefore, the potential drop between M and N increases as the device moves upward until electrode N reaches the next conductive bed, where the upward current is diverted from the hole. Above that level the normal reading decreases.

The explanation of the shape of the lateral curve is similar. The direction of the lopsidedness for either device depends on whether the measuring electrodes are above or below the current electrode. The depressions read on the curves opposite the conductive beds are smooth and, in the case of the lateral, much broadened and displaced downward. Accurate determinations of bed boundaries from the curves are practically impossible.

Fig. 49.16—Limestone sonde (schematic).

Limestone Sonde. Four current electrodes (A, A', B, and B'), connected as shown in Fig. 49.16 by insulated wires of negligible resistance, are symmetrically arranged so that $AB = A'B'$. A measuring electrode, M, is placed in the middle of the device. Depths are measured from electrode M. In practice $AM = A'M = 30$ or 35 in., and $AB = A'B' = 4$ or 5 in. The device is therefore a symmetrical double lateral.

Opposite a thick, highly resistive layer (upper part of Fig. 49.17) practically all the flow of current is confined to the spaces between A and B and between A' and B'. No current flows from B or B', up or down the hole away from the device. Hence, from Ohm's law, B and B' are at zero potential. Similarly M is at the same potential as A and A'.

The potential of M is, therefore, equal to the potential drop in the mud, because of the flow of current, between A and B (or A' or B'). As long as all the electrodes of the devices are opposite the resistive formation this potential difference is dependent only on hole size and mud resistivity; if these are constant, a constant apparent resistivity is recorded.

If the device is located just above a conductive streak (as in the lower part of Fig. 49.17), the streak is effectively a low resistance connecting adjacent portions of the device to points at zero potential. Part of the current now flows in the paths indicated by the arrows, and the potential of electrode M is correspondingly decreased. The conductive streak is indicated on the log by a relatively sharp, symmetrical depression.

The limestone sonde gives clearer and simpler logs in hard formations, but measurements with the limestone sonde are strongly affected by the mud column. When the formations are much more resistive than the mud, the readings are appreciably lower than the formation resistivities.

Application of Conventional Resistivity Logs. The three devices that are generally recorded in the conventional electrical log (16-in. normal, 64-in. normal, and 18-ft, 8-in. lateral) were designed to provide the most complete information with a system of nonfocused macrodevices.

Fig. 49.17—Principle of limestone sonde (schematic).

The short normal is well adapted for bed definition, boundary determination, and correlation of formations of low or moderate resistivities (sand-shale series). The lateral generally shows sharp peaks at the level of thin resistive beds, but the definition of these beds is often obscured by blind zones and spurious peaks.

The precision of the normal and lateral curves for bed definition is limited in hard formations and is quite poor when salty muds are used. Somewhat better resolution is obtained with the limestone sonde. In all cases, formation delineation is more detailed and accurate with the IL and focused devices (LL) and with the microdevices. In hard formations the 16-in. normal and the limestone sonde can provide an approximation to the value of R_i and hence an approach for formation factor evaluation. The capabilities of the conventional tools for the determination of R_i are discussed later in this chapter.

Induction Logging

The IL was first developed to measure formation resistivity in boreholes containing oil-based muds.²⁰ Electrode devices do not work in these nonconductive muds, and attempts to use wall-scratcher electrodes proved unsatisfactory. Experience soon demonstrated that the induction tools had many advantages over the conventional ES for logging wells drilled with water-based muds.²¹

Induction logging devices are focused to minimize the influence of the borehole and of the surrounding formations. They are designed for deep investigation and reduction of the influence of the invaded zone.

Principle

Practical induction sondes include a system of several transmitter and receiver coils. However, the principle can be understood by considering a sonde with only one transmitter coil and one receiver coil (Fig. 49.18).

High-frequency AC of constant intensity is sent through the transmitter coil. The alternating magnetic field thus created induces secondary currents in the formations. These currents flow in circular ground-loop paths coaxial with the transmitter coil. These ground-loop currents, in turn, create magnetic fields that induce

signals in the receiver coil. The induced receiver signals are essentially proportional to the conductivity of the formations. Any signal produced by direct coupling of transmitter and receiver coils is balanced out by the measuring circuits.

The IL operates to advantage when the borehole fluid is an insulator—even air or gas. But when properly designed the tool also will work very well when the borehole contains conductive mud, provided that the mud is not too salty, the formations are not too resistive, and the borehole diameter is not too large.

Equipment

Four types of induction equipment are now in use.

1. **The 6FF40 IES** tool includes a six-coil induction device of 40-in. normal spacing, a 16-in. normal, and an SP electrode. The induction array provides the greatest lateral depth of investigation presently available with induction tools.

2. **The 6FF28 IES** is a small-diameter (2½ in.) tool for use in slim holes. It is a scaled-down version of the 6FF40, having a 28-in. coil spacing, and incorporates a standard 16-in. normal and an SP.

3. **The Dual Induction-Laterolog 8 (DIL™) or Spherically Focused Log (SFL)** system uses a deep-reading induction device (ID, similar to the 6FF40), a medium induction device (IM), an LL8 (or an SFL), and an SP electrode. The IM device has vertical resolution similar to that of the 6FF40 tool but about half the depth of investigation. It is much more affected by large hole diameters and/or salty muds. The DIL log, with its three focused resistivity readings of different depths of investigation, is superior to the IES log for determination of R_t and R_{xo} in extreme ranges of invasion depths and in cases of annulus.

4. **The ISF/Sonic** combination incorporates an ID measurement similar to that from the 6FF40 tool, the new ISF log, an SP curve that may be electronically corrected for noise, a borehole compensated (BHC) sonic log, and an optional gamma ray curve. Of late, the BHC sonic tool can be replaced in this tool string by a combination neutron/density device.

Log Presentation and Scales

The SP and/or gamma ray curve are recorded in Track 1 for all tools; they can be recorded simultaneously with ISF/sonic equipment. A gamma ray curve may also be run with 6FF40 or DIL equipment.

Fig. 49.19 illustrates the standard IES presentation. The induction conductivity curve is sometimes recorded over both Tracks 2 and 3. The linear scale is in millimhos per meter (mΩ/m), increasing to the left. In Track 2 both the 16-in. normal and the reciprocated induction curves are recorded on the conventional linear resistivity scale.

The DIL introduced the logarithmic grid for resistivity presentations. The current form is the "log-linear" grid shown in Fig. 49.20. In this, the resistivity curves on the detail log (5 in./100 ft) have a split 4-decade logarithmic scale. On the correlation log (1 or 2 in./100 ft), the scale is linear. This presentation offers several advantages over the other alternatives. The detail log has good readability in low resistivities, a wide range without backup traces, and the ease of reading resistivity ratios

Fig. 49.18—Induction-logging equipment (schematic).

Fig. 49.19—Induction-electrical log presentation.

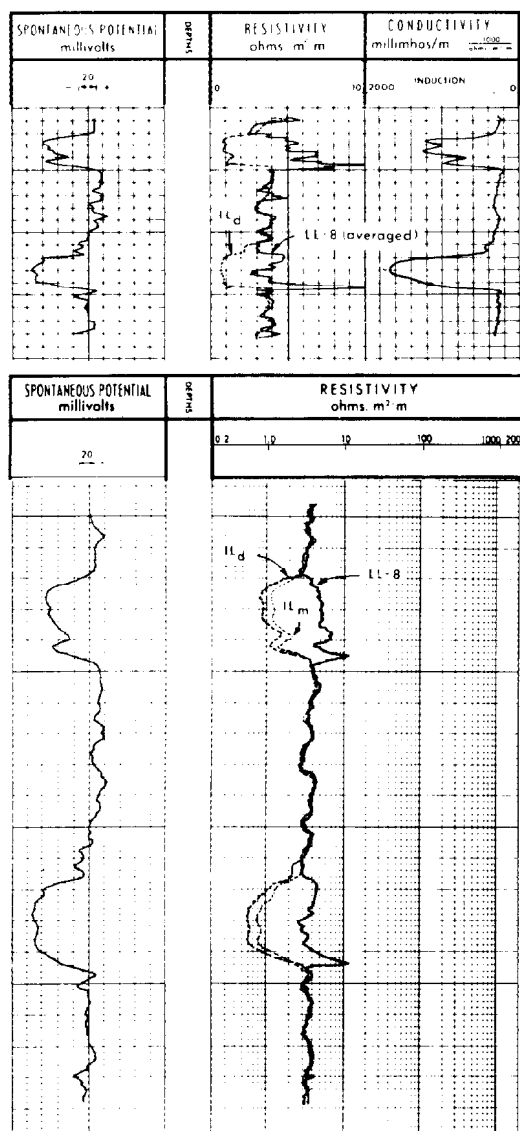

Fig. 49.20—Dual Induction Laterolog 8 presentation.

directly from the logarithmic scale. The linear scale is more easily correlated with earlier logs. This format has gained acceptance as the standard for resistivity logs.

The ISF log in combination with the sonic log requires a modification of this grid usage because Track 3 is needed for the sonic Δt curve. The grid selected is shown in Fig. 49.21.

Skin Effect

In very conductive formations the induced secondary currents are large, and their magnetic fields are important. The magnetic fields of their ground loops induce additional EMF's in other ground loops. This interaction between the loops causes a reduction of the conductivity signal recorded by the induction log. This signal reduction is known as "skin effect."

Induction logs usually are automatically corrected for skin effect during recording. The correction is based on the magnitude of the uncorrected tool response treated as

Fig. 49.21—ISF/sonic presentation.

if it were from a homogeneous medium. A secondary skin-effect correction may be required when the media surrounding the sonde are not of uniform conductivity. Such corrections are incorporated in various interpretation charts.

Geometrical Factor

When conductivities are not high, skin effect may be neglected, and the response of induction logs can be described in terms of conductivities and "geometrical factors" of the volumes surrounding the tool. The geometrical factor, G , of a volume having a specific geometrical orientation with the sonde is simply the fraction of the total signal that would originate with that volume in an infinite homogeneous medium. For computation of geometrical factor to be practical, it is necessary to assume that the volumes conform to symmetry of revolution about the sonde.

The magnitude of the signal in conductivity units is the product of the geometrical factor and the conductivity of the material, and the total signal sensed by the tool is the

Fig. 49.22—Geometrical factor. Dashed curve includes skin effect under conditions shown, for the ILd device.

sum of these products for all volumes within range (which extends to infinity, but can be circumscribed to practical limits). Since the G 's add up to unity by definition, this can be stated:

$$C_{IL} = C_1 G_1 + C_2 G_2 + C_3 G_3 + \dots + C_N G_N, \dots (10)$$

where C and G refer to the zones of differing conductivity and N is the total number of such zones.

The chief significance of this concept is the fact that a volume of space defined only by its geometry relative to the sonde has a fixed and computable geometrical factor. This permits the construction of mathematically sound correction charts to account for the effects of borehole mud, the invaded zone, and adjacent beds on the R_t measurement, providing symmetry of revolution exists.² These charts incorporate the secondary skin effect correction mentioned above.

Invasion Effects

Fig. 49.4 illustrates an invaded formation. It includes volumes having several conductivities, C_m , C_{xo} , C_i , and C_t (corresponding to R_m , R_{xo} , R_i , and R_t). The total conductivity signal, C_T , received from this zone by the induction tool is

$$C_T = C_m G_m + C_{xo} G_{xo} + C_i G_i + C_t G_t, \dots (11)$$

If the zone were infinitely thick, this would be the only signal received, and $C_T = C_{IL}$. If the tool is a 6FF40, the hole size moderate, and the mud relatively fresh, the borehole signal is negligible, and the C_{xo} and C_i zones can be merged into one for this example.

If a moderate diameter of invasion, say 65 in., is assumed, Fig. 49.22 reveals that the geometrical factor of all material within the 65-in. diameter is 0.2. If R_{xo} is taken equal to $4 R_t$, then $C_{xo} = C_t/4$, and the induction tool response is

$$\begin{aligned} C_{IL} &= C_{xo} G_{xo} + C_t G_t, \\ &= (C_t/4) (0.2) + C_t (0.8), \\ &= 0.85 C_t. \end{aligned}$$

In the same conditions, but using salty mud so that $R_{xo} = R_t/4$, the response is

$$\begin{aligned} C_{IL} &= 4 C_t (0.2) + C_t (0.8), \\ &= 1.6 C_t, \end{aligned}$$

which illustrates the "conductivity-seeking" characteristic of the induction devices, and shows why they must be used with discretion in salt-mud environments. As a rule of thumb, R_t should be less than about $2.5 R_{xo}$ and d_i (diameter of invaded zone) no greater than 100 in. for satisfactory R_t determination from 6FF40-type induction logs.

Annulus

In oil-bearing formations of low S_w and high permeability, an annulus of low resistivity, R_{an} , may exist between the flushed zone, R_{xo} , and the virgin formation. When R_{xo} is greater than R_t , R_{an} is less than R_t , and the effects of the two on the induction log tend to cancel. However, the high conductivity of the annulus has more effect in medium invasion ranges ($2d_h < d_i < 4$ or $5d_h$), and it may cause a single ID to read resistivities lower than either R_{xo} or R_t . The DIL 8 tool is often capable of detecting the presence of annuli, since in these circumstances the IM measurement reads lower than either the LL8 or the ID values.

Thin Bed Corrections

The skin-effect correction accomplished automatically in the induction tools assumes infinitely thick beds. Skin effect in thin beds may require additional corrections, and these are provided in Ref. 2.

Fig. 49.23—Schematic of focusing-electrode devices.

Borehole Corrections

Conductivity signals from the mud can be evaluated using geometrical factors. Chart Rcor-4 (Ref. 2) gives corrections for the various induction tools and standoffs. On the basis of bit size the nominal borehole signal is sometimes removed from the recorded log. When the hole signal is significant, log headings should always be consulted to ascertain whether this was done. This precaution applies most frequently to the IM measurement of the DIL tool.

For hole diameters in the range of 7 to 13 in. there is an uncertainty of about ± 0.0003 on the geometrical factor of the borehole for the 6FF40 sonde. This results from several factors, including diameter and shape of the borehole, mudcake thickness, standoff, and sonde tilt. To preclude the possibility of cumulative errors exceeding 20% of the 6FF40 reading, the tool should not be used where the resistivity to be measured is greater than about $500 R_m$.

Very Resistive Formations

There is an uncertainty of about $\pm 2 \text{ m}\Omega/\text{m}$ on the zero of the present induction sondes (6FF40, ID, and IM), and consequently the resistivity error may be great as conductivity approaches zero. To preclude an error of more than 20%, the formation conductivity should be greater than $10 \text{ m}\Omega/\text{m}$ (i.e., the resistivity less than $100 \Omega \cdot \text{m}$). This error can sometimes be practically eliminated by downhole calibration techniques if suitable formations are present.

Calibration

Primary calibration is performed by placing a test loop around the sonde. The conductive loop has a resistance, which has been adjusted to produce a certain conductivity signal in the sonde. An additional calibration procedure has a signal produced internally in the sonde to adjust the control-panel sensitivity for proper galvanometer deflections. The "zero errors" of the electronics in the equipment are also checked and balanced out. "Calibrate tails," usually attached to the log, serve as a record of the calibration tests made before and after the logging run.

In some regions it is possible to check the calibration of the IL by observing that the conductivity reading op-

posite an impervious formation of exceedingly high resistivity (such as anhydrite) represents the sum of all spurious signals. If the hole diameter is known, it is then possible to correct the IL reading so that the range of uncertainty is reduced and greater accuracy is obtained in formations of practical interest.

Summary

1. The IL can be used most effectively in holes filled with moderately conductive drilling muds, nonconductive muds, and in empty holes.
2. Vertical focusing is good, making possible reliable evaluation of beds down to about 5 ft thick with 6FF40, ID, and IM devices, and down to about $3\frac{1}{2}$ ft thick with 6FF28 tools.
3. The deep induction logs (ILD) are only moderately affected by invasion in relatively fresh muds, and good R_t determinations are possible where R_t is less than about $2.5 R_{xo}$ and d_i is less than 100 in.
4. The three curves of the DIL give more precise knowledge of invasion profiles and hence better R_t values in the cases of deep invasion or annulus.
5. The log-linear presentation of the DIL and other IL's meets most log requirements better than alternative displays.

Focused-Electrode Logs

The responses of conventional ES can be greatly affected by the borehole and adjacent formations. These influences are minimized by a family of resistivity tools that use focusing currents to control the path taken by the measure current. These currents are supplied from special electrodes on the sondes.

Equipment

The focused-electrode tools include the Laterologs (LL) and SFL's. These tools are much superior to the ES devices for large R_t/R_m values (salt muds and/or highly resistive formations) and for large resistivity contrasts with adjacent beds (R_t/R_s or R_s/R_t). They are much better for resolution of thin to moderately thick beds. Focusing-electrode systems are available with deep, medium, and shallow depths of investigation.

Devices using this principle have as quantitative applications the determination of R_t and of R_{xo} . The R_t tools are Laterolog 7 (LL7), Laterolog 3 (LL3), and

Fig. 49.24—Response of Laterolog 7 and ES opposite a thin, resistive, noninvaded bed, with very-salty mud (laboratory determination).

LLD of the deep dual laterolog. The medium-to-shallow-reading devices, all integral with combination tools, are Laterolog 8 (LL8) of the DIL, LLS of the shallow dual laterolog, and the SFL of the ISF/sonic combination.

Laterolog 7. This device²² comprises a center electrode A_0 , and three pairs of electrodes: M_1 and M_2 ; M'_1 and M'_2 ; and A_1 and A_2 (Fig. 49.23). The electrodes of each pair are symmetrically located with respect to A_0 and are connected to each other by a short-circuiting wire.

A constant current I_0 is sent through electrode A_0 . Through bucking electrodes A_1 and A_2 , an adjustable current is developed; the bucking current intensity is adjusted automatically so that the two pairs of monitoring electrodes, M_1 and M_2 and M'_1 and M'_2 , are brought to the same potential. The potential drop is measured between one of the monitoring electrodes and an electrode at the surface (i.e., at infinity). With a constant I_0 current, this potential varies directly with formation resistivity.

Since the potential difference between the M_1 - M_2 pair and the M'_1 - M'_2 pair is maintained at zero, no current from A_0 is flowing in the hole between M_1 and M'_1 or between M_2 and M'_2 . Therefore, the current from A_0 must penetrate horizontally into the formations.

Fig. 49.23 shows the distribution of current lines when the sonde is in a homogeneous medium; the "sheet" of I_0 current, indicated by the hatched area, retains a fairly constant thickness up to a distance from the borehole somewhat greater than the total length $A_1 A_2$ of the sonde. Experiments have shown that the sheet of I_0 current retains substantially the same shape opposite thin resistive beds. The thickness of the I_0 current sheet is 32 in. (distance $O_1 O_2$ on Fig. 49.23), and the length $A_1 A_2$ of the sonde is 80 in.

Fig. 49.24 compares the curves obtained experimen-

tally opposite a thin resistive bed using the conventional devices (16- and 64-in. normals and 18-ft, 8-in. lateral) with the corresponding LL7 recording. The conventional devices give poor results; the LL7, in spite of difficult conditions (R_T/R_m is 5,000), shows the bed very clearly and reads close to R_T . An SP curve may be recorded on depth simultaneously with the LL7.

Laterolog 3

Like LL7, LL3 also uses currents from bucking electrodes to focus the measuring current into a horizontal sheet penetrating into the formation. However, as seen in Fig. 49.23, large electrodes are used. Symmetrically placed, on either side of the central A_0 electrode, are two very long (about 5-ft) electrodes, A_1 and A_2 , which are shorted to each other. A current, I_0 , flows from the A_0 electrode whose potential is fixed. From A_1 and A_2 flows a bucking current, which is automatically adjusted to maintain A_1 and A_2 at the potential of A_0 . All electrodes of the sonde are thus held at the same constant potential. The magnitude of the I_0 current is then proportional to formation conductivity.

The I_0 current sheet is constrained to the shaded, approximately disk-shaped area in Fig. 49.23. The thickness, $O_1 O_2$, of the I_0 current sheet is usually about 12 in., much thinner than for LL7. As a result, LL3 has a better vertical resolution and shows more detail than LL7. Furthermore, the influences of the borehole and of the invaded zone are slightly less.

The simultaneous recording of an SP curve is possible, but the SP has to be displaced in depth, usually by about 25 ft, because of the large mass of metal in the sonde. However, a gamma ray curve is normally run simultaneously with the LL3 for lithology definition, since the SP has very little character in the salt muds where the LL is used. There is also available a simultaneous LL3-neutron/gamma ray combination tool.

Fig. 49.25—Schematic of the dual laterolog.

Guard-Electrode Device. In the guard-electrode system, the surveying current flows into the adjacent formations from a measuring electrode disposed between relatively long upper and lower guard electrodes from which current also flows. The guard electrodes tend to confine the current from the measuring electrode to a generally horizontal path. The measuring and guard electrodes are connected through a very low impedance, as necessary to measure the surveying current supplied to the measuring electrode.

A resistivity value is obtained by recording the ratio of the voltage of an electrode in the assembly (referred to a distant point) to the current emitted from the measuring electrode. The guard-electrode device is used mostly in hard-rock territories for detailed bed definition, correlation, and as a help in reservoir evaluation. For the determination of R_t , it is preferable that R_{mf}/R_w be small (less than 4), as in the case of salty muds.

Laterolog 8. The shallow-investigation LL8 device is recorded with small electrodes on the DIL sonde. It is similar in principle to LL7 device except for its shorter spacings. The thickness of the I_0 current sheet is 14 in., and the distance between the two bucking electrodes is somewhat less than 40 in. The current-return electrode is located a relatively short distance from A_0 . With this configuration, the LL8 tool gives sharp vertical detail, and the readings are more influenced by the borehole and the invaded zone² than are those for LL7 and LL3. The LL8 data are recorded with the DIL on a split 4-decade logarithmic scale.

Dual Laterolog. Since the measure current of an LL has to traverse mud and invaded zone to reach the undisturbed formation, the measurement is necessarily a combination of effects. With only one resistivity measurement, the invasion profile and R_{xo} had to be known or

Fig. 49.26—Radial pseudogeometrical factors, fresh muds (solid) and salty muds (dashed).

estimated in order to calculate R_t . The need for a second measurement at a different depth of investigation resulted in the dual laterolog/gamma ray tools (Fig. 49.25).

One version of the tool records the two laterologs sequentially; another does it simultaneously and has added a shallow MICROSF (MSFL) for R_{xo} information. Both can record a gamma ray curve on depth, simultaneously with the resistivity curves. An SP can also be run.

By use of effectively longer bucking electrodes and a longer spacing, the LLD (deep laterolog) has been given a deeper investigation than either LL7 or LL3 devices. The LLS (shallow laterolog) uses the same electrodes in a different manner (Fig. 49.25 right) to achieve a current beam equal in thickness to that of LLD, 24 in., but having a much shallower penetration. The LLS depth of investigation lies between those of the LL7 and LL8 devices (Fig. 49.26).

Spherically Focused Log. The SFL log is part of the ISF/sonic combination, and it was developed as an improvement over both the 16-in. normal and the LL8 as a short-spacing companion to the deep induction log.

Normal resistivity devices rely on the concept of equal intensity of current radiation in all directions, as would happen in a homogeneous isotropic medium. When the current distribution is distorted from the spherical model, as by the presence of a borehole, the readings must be corrected by departure curves. The SFL device uses focusing currents to enforce an approximately spherical

Fig. 49.27—Laterolog recorded on hybrid scale.

shape on the equipotential surfaces over a wide range of wellbore variables. The borehole effect is virtually eliminated where $d_h \leq 10$ in., yet most of the response is from the invaded zone in all but extreme conditions.

Scales. The linear resistivity scales originally used for LL data were poorly adapted to record the wide range of measurements characteristic of these tools. Although linear scales are still used occasionally, compressed scales of either the hybrid or logarithmic type have supplanted the linear for quantitative work.

The hybrid scale, first used on the LL3 log, presented linear resistivity on the first half of the grid track and linear conductivity on the last half. Thus, one galvanometer could record all resistivities from zero to infinity. (See Fig. 49.27.)

The logarithmic scale was used first with the dual induction tool, and it has also been adapted for the LL and the SFL devices (Fig. 49.28). It combines readability and detail in low resistivities with a wide range of values, and it also offers the advantage of graphic (quick-look) interpretations.

Influence of Wellbore Variables

These logging devices can be significantly affected by the borehole mud, the invaded zone, and adjacent beds. Charts Rcor-1 and Rcor-2 of Ref. 2 provide needed corrections. Where only one measurement is available, some knowledge or assumption of depth of invasion must be used for deriving R_t . Readings must be corrected for borehole effect before the shoulder-bed charts are entered. (See Figs. 49.29 and 49.9.) These figures

Fig. 49.28—Laterolog over same interval as Fig. 49.22, recorded on logarithmic scale.

Fig. 49.29—Shoulder-bed corrections, LL3 (top) and LL7 (bottom).

give R_c/R_a as a function of bed thickness, R_c being the corrected resistivity and R_a the apparent resistivity corrected for borehole effect.

Pseudogeometrical Factors

Geometrical factor may be defined as that fraction of the total signal that would originate from a volume having a specific geometrical orientation with the sonde in an infinite homogeneous medium.

The only well-logging devices for which this concept is sound are the induction tools, because only with these is the measuring geometry independent of variations in R_{xo}/R_t . However, it is useful to construct charts based on "pseudogeometrical factors" for other resistivity devices, for purposes of comparative evaluation. Such a chart is shown in Fig. 49.26 in which the integrated pseudogeometrical factors of progressively larger cylinders are plotted vs. the diameters of the cylinders. The apparent resistivity, R_a , measured in a thick bed is given approximately by

$$R_a = R_{xo} G_{pi} + R_t (1 - G_{pi}), \quad \dots \dots \dots (12)$$

where G_{pi} is the pseudogeometrical factor. It must be emphasized that a pseudogeometrical factor relating to an electrode-type resistivity device is applicable in only one set of conditions, and therefore charts of this type are not valid as general-purpose invaded-zone correction charts. The most useful feature of the Fig. 49.26 chart is its graphic comparison of the relative contribution of invaded zones to the responses of the various tools.

The Delaware Effect

If both B and N electrodes are placed downhole as in Fig. 49.10, LL data may exhibit "Delaware effect"* (or "gradient") in sections located just below thick nonconductive beds such as anhydrite. It appears as abnormally high resistivity for 80 ft or so below the resistive bed. The LL3 is the only field tool now using this arrangement.

Fig. 49.10 illustrates the effect and its causes. As B enters the thick anhydrite, the current flow is confined to the borehole, and if the bed is thick enough (several hundred feet) practically all the current will flow in that part of the hole below B. Then when N enters the bed, it can no longer remain near zero potential as intended. It is exposed to an increasing negative potential as it rises farther from the bed boundary. This potential appears at the surface as an increase in the resistivity measurement.

LL7 and LLD devices normally use surface electrodes for current return, so they are not subject to Delaware effect. However, a small anti-Delaware effect has been observed, which produces resistivities that are too low just below the resistive beds.

Conclusions

Resistivity devices with the focusing electrode principle meet certain logging requirements better than other types now available. These requirements are (1) to take measurements leading to determination of R_t in conditions for which the induction tools are not well suited—i.e., R_t values in excess of 100 Ω -m and/or mud resistivities of the same order or lower than those of the

formation waters—and (2) to provide correlation and R_{xo} determinations in conjunction with deeper-reading R_t devices.

Microresistivity Devices

Microresistivity devices are used to measure R_{xo} (resistivity of the flushed zone) and to delineate permeable beds by detecting the presence of mudcake. In the discussion that follows, the microlog (ML) will be treated in considerable detail, not because of its relative importance—the microlaterolog (MLL), the proximity log (PL), and the MSFL are superior tools for obtaining R_{xo} —but because its principle is fundamental, and it is still the best of the three microresistivity devices for delineating permeable-bed boundaries, hence for making "sand counts."

Measurements of R_{xo} are important for several reasons. When invasion is moderate to deep, knowledge of the R_{xo} value makes possible more accurate determinations of true resistivity and hence of saturation. Also, some methods for computing saturation are entered with the ratio R_{xo}/R_t . Also, in clean formations, a value of F may be computed from R_{xo} and R_{mf} , if S_{xo} is known or estimated. From F , a value for porosity may be found.

To measure R_{xo} a shallow-investigation tool is desirable, since the R_{xo} zone may sometimes extend only a few inches beyond the hole wall. Also, the reading should preferably not be affected by the borehole.

A sidewall-pad tool is indicated. The pad, carrying short-spacing electrode devices, is pressed against the mudcake, thus reducing the short-circuiting effect of the mud. Currents from the electrodes on the pad must pass through the mudcake to reach the R_{xo} zone.

Microresistivity readings are more or less affected by mudcake, depending on its resistivity, R_{mc} , and thickness, h_{mc} . Moreover, mudcakes can be anisotropic, with mudcake resistivity parallel to the borehole wall less than that across the mudcake. Mudcake anisotropy increases the mudcake effect on microresistivity readings, so that the effective, or electrical, mudcake thickness is greater than that indicated by a caliper. The microresistivity tools incorporate two-arm calipers, which show the size and condition of the borehole.

Equipment

Present equipment includes a combination tool with two pads mounted on opposite sides. One is the ML pad, and the other may be for either the MLL or the PL, as required by mudcake conditions. The measurements are recorded simultaneously. The MSFL is a combination tool, which can be run with either formation density or dual laterolog equipment.

Log Presentation

The microresistivity logs are scaled, of course, in resistivity units. When recorded by itself, the ML data are usually recorded over Tracks 2 and 3 on a linear resistivity scale. The microcaliper data are in Track 1. The MML or PL is recorded on a four-decade logarithmic scale on the right of the depth track (Fig. 49.30). The caliper is recorded in Track 1. When the ML data are also recorded, they are in Track 1 on a linear scale. The MSFL data are also recorded on the

* So-called because it was first observed in the Delaware sand of the Delaware basin (west Texas). This sand underlies a very thick anhydrite bed.

logarithmic grid. When run with the dual laterolog, it is presented on the same film as the LL curves. With the Compensated Formation Density (FDC™) log, it must be presented on a separate film, since the FDC log uses a linear grid; the two logs are normally recorded simultaneously.

Microlog

With the microlog tool,²³ two short-spacing devices with different depths of investigation provide resistivity measurements of a very small volume of mudcake and formation immediately adjoining the borehole. They readily detect the presence of any mudcake, indicating invaded (hence permeable) formations.

Principle. Arms and springs press a rubber pad against the hole wall. In the face of the pad are inserted three small electrodes in line, spaced 1 in. apart. With these electrodes a 1- \times 1-in. microinverse, $R_{1 \times 1}$, and a 2-in. micronormal, R_2 , are recorded simultaneously.

As drilling mud filters into the permeable formations, mud solids accumulate on the hole wall, forming a mudcake. The resistivity of the mudcake is about equal to, or slightly greater than, the resistivity of the mud. Mudcake resistivity is usually considerably smaller than the resistivity of the invaded zone near the borehole.

The 2-in. micronormal has a greater depth of investigation than the 1- \times 1-in. microinverse. It is therefore less influenced by the mudcake and reads a higher resistivity, producing "positive" curve separation. In the presence of the low-resistivity mudcake, both devices will measure moderate resistivities, usually ranging from about 2 to 10 times R_m .

Interpretation. Positive separation in a permeable zone is illustrated in Fig. 49.30, at Level A. The caliper shows evidence of mudcake. However, quantitative inferences of permeability are not possible from the ML data. When no mudcake exists, for whatever reason, the ML data may yield useful information as to borehole condition or lithology, but the log is not quantitatively interpretable.

Under favorable circumstances, R_{xo} values can be derived from the ML by use of Fig. 49.31. R_{mc} values for this purpose can be measured directly or estimated from Ref. 2, and h_{mc} is obtained from the caliper. Limitations of the method are (1) the ratio R_{xo}/R_{mc} must be lower than about 15 (porosity more than 15%), (2) h_{mc} must be no greater than $\frac{1}{2}$ in., and (3) depth of invasion has to be over about 4 in., otherwise the ML readings are affected by R_f . Eqs. 6 or 14 permit the porosity derivation from the ML measurements. For this, the value of S_{xo} must be reasonably well known.

Mud Log

The ML sonde is lowered into the hole with arms closed. Except in holes smaller than 8 in., the measuring pad will randomly face away from the wall part of the time, and its reading then will be determined mostly by the mud. A recording of these readings, conveniently made going down, serves as a "mud log," on which the lowest resistivities correspond to the upper limit of the in-situ value of R_m . This log has several potential applications, including crosschecking the surface R_m measurement, detecting mud-system changes, and identifying downhole water flows.

Fig. 49.30—Presentation of proximity log-microlog.

Fig. 49.31—Interpretation chart for 8-in.-hole series C microlog for which adjacent electrodes are 1 in. apart. $R_{2 \text{ in.}}$ designates reading of 2-in. micronormal ($AM_2 = 2$ in.) and $R_{1 \times 1 \text{ in.}}$ is 1- by 1-in. microinverse ($AM_1 = 1$ in., $M_1, M_2 = 1$ in.). Type I hydraulic pad, noninsulated sonde.

Fig. 49.32—Microlaterolog pad showing electrodes (left) and schematic current lines (right).

Microlaterolog (MLL)

On ML (Fig. 49.31) for values of R_{xo}/R_{mc} greater than about 15, the curves for constant values of R_{xo}/R_{mc} are crowded; as a result, the accuracy of the determination of R_{xo} from the ML is poor in this region. With the MLL method, it is possible to determine R_{xo} accurately for higher values of R_{xo}/R_{mc} , provided, however, that the mudcake thickness does not exceed $\frac{3}{8}$ in.

Principle. The MLL pad is shown in Fig. 49.32.²⁴ A small electrode, A₀, and three concentric circular electrodes are embedded in a rubber pad applied against the hole wall. A constant current, I₀, is emitted through electrode A₀. Through the outer electrode, A₁, is sent a current automatically adjusted so that the potential difference between the two monitoring electrodes is maintained essentially equal to zero. The I₀ current flowing past the M₁ electrode cannot reach M₂ and is forced to flow in a beam into the formations. The current lines are shown on the figure. The I₀ current near the pad forms a narrow beam, which opens up rapidly at a few inches from the face of the pad. The MLL reading is influenced mostly by the formation within this narrow beam.

Fig. 49.33 compares qualitatively the current-line distributions of the MLL and the ML when the corresponding pad is applied against a permeable formation. The greater the value of R_{xo}/R_{mc} the greater the tendency for the microlog I₀ current to escape through the mudcake to reach the mud in the borehole. Consequently, for high R_{xo}/R_{mc} values, the readings of the ML respond very little to variations of R_{xo} . On the contrary, all the MLL I₀ current flows into the formation and the MLL reading will depend mostly on the value of R_{xo} .

Response. Laboratory tests have shown that the virgin formation has practically no influence on the MLL readings if the invasion depth is more than 3 or 4 in. The influence of mudcake is negligible up to $h_{mc} = \frac{3}{8}$ in. but increases rapidly with greater thicknesses. Chart Rxo-2 in Ref. 2 gives appropriate corrections; however, if mudcakes thicker than $\frac{3}{8}$ in. are anticipated, the PL is preferred for R_{xo} determination.

Fig. 49.33—Comparative distribution of current lines of Microlaterolog and Microlog.

Proximity Log (PL)

Principle. The proximity tool is similar in principle to the MLL tool. The electrodes are mounted on a somewhat wider pad, which is applied to the wall of the borehole; the system is automatically focused by monitoring electrodes.

Response. Pad and electrode design are such that isotropic mudcakes up to $\frac{3}{8}$ in. have very little effect on the measurements (see Chart Rxo-2 in Ref. 2). If the invasion is shallow, the reading of the proximity device is influenced by R_t . The resistivity measured can be expressed as

$$R_{PL} = G_{pi} R_{xo} + (1 - G_{pi}) R_t, \quad \dots \dots \dots (13)$$

where G_{pi} is the pseudogeometrical factor of the invaded zone. The value of G_{pi} as a function of invasion diameter d_i is given in Fig. 49.34; this chart gives only an approximate value of G_{pi} , which in fact also depends to some extent on the diameter of the borehole and on the ratio R_{xo}/R_t .

If d_i is greater than 40 in., G_{pi} is very close to 1 and, accordingly, R_{PL} will differ little from R_{xo} . If d_i is less than 40 in., R_{PL} is somewhere between R_{xo} and R_t , usually much closer to R_{xo} than to R_t . R_{PL} can be fairly close to R_t only if the invasion is very shallow (of course when R_{xo} and R_t are nearly equal, the value of R_{PL} will depend very little on d_i).

MICROSFL (MSFL)

This is a pad-mounted SFL device. It embodies two distinct advantages over other microresistivity devices: (1) it is compatible with other logging tools, specifically the FDC and the simultaneous dual laterolog (SDL), which eliminates the need for a separate logging run to obtain R_{xo} information, and (2) it responds to shallow R_{xo} zones in the presence of mudcake. The MSFL gives good R_{xo} resolution in thick-mudcake conditions, but

does not require as great an invasion depth as does the PL. This characteristic makes it useful in a wider range of conditions than either the PL or the MLL. The effect of mudcake on the MSFL data is shown in Ref. 2.

Principle. Spherical focusing is the shaping of the equipotential surfaces produced by the resistivity device to approximately spherical form. The focusing is accomplished by auxiliary electrodes, as in the MLL and PL; but, instead of being forced into a narrow beam, the measure current is merely prevented from following the borehole mud or mudcake paths. A careful selection of electrode spacings achieves an optimal compromise between too much and too little depth of investigation.

Conclusions

The ML permits a very accurate delineation of permeable beds in all types of formations. It can also provide satisfactory R_{xo} and porosity determinations under favorable conditions, which are (1) $R_{xo}/R_{mc} \leq 15$, (2) $h_{mc} \leq \frac{1}{2}$ in., and (3) depth of invasion greater than about 4 in.

The focused microresistivity tools can provide good R_{xo} values under a much wider range of conditions. The MLL is limited chiefly by mudcake thickness, but is well adapted to salt-base muds. When h_{mc} exceeds $\frac{3}{8}$ in., the PL or the MSFL log is preferable.

Uses and Interpretation of Well Logs

Bed Detection and Definition

Formations encountered in uncased boreholes may be detected and their boundaries defined by a number of different logs. The SP and short-investigation curves are most commonly used. For great detail, the microdevices are superior—ML in fresh muds and MLL in very salty muds. A substitute for the SP in salt muds is the gamma ray log, which distinguishes shales from nonshale beds. Also, the sonic and density logs could be used in all types of formations, with any type of mud.

In holes filled with nonconductive muds, or in empty holes, the induction, radiation, temperature, sonic (not applicable in empty holes), and perhaps section-gauge logs can provide useful information. Sometimes conventional devices with wall scratchers, for contact with the formation, may be run.

Porous and Permeable Beds—Sand Count. Porous and permeable beds are of primary interest since they are the potential oil and gas reservoirs. A sand-count determination of the total effective thickness of a permeable section, excluding shale streaks and other impermeable zones, can be derived from electrical logs.

Fresh Muds. The SP and microresistivity devices are the principle curves for locating and defining permeable beds. The SP has a good resolving power in formations of low and moderate resistivity. In very resistive formations it can still detect shales and permeable beds, but it cannot define their boundaries accurately. In most types of formations the ML is best for establishing the detailed location of the boundaries of permeable beds.

The microcaliper helps in the location of permeable beds because it can usually detect the mudcakes, particularly if the adjacent formations are approximately at bit size. Shales, on the other hand, generally tend to cave

Fig. 49.34—Pseudogeometrical factors, MLL and PL.

or erode more than the permeable or hard impervious beds. Very often, and mostly in sand-shale series, the difference between the readings of a short-investigation and a long-investigation device is a clear indication of the presence of a permeable bed.

Salt Muds. The combination of very salty mud with moderate-to-high formation resistivity adversely affects the conventional (nonfocused) devices and the SP curve. Also, mudcakes are thin; as a consequence, the microcaliper (or also the section gauge) is not of great help for the detection of permeable sections but detects clearly the caved shales. In conjunction with the LL and MLL the gamma ray log distinguishes between shales and nonshales, and the neutron, sonic log, and density log provide indications of porosity.

Correlation

The process of correlating two (or more) logs in different wells depends essentially on the similarity in shapes or outlines of the curves (Fig. 49.35). In some regions such correlations may be easily made for wells miles apart; in other cases (where serious faulting, lenticular deposits, or unconformities are present) it may be difficult to correlate logs from wells only a few hundred feet apart. The knowledge of formation dip from dipmeter determinations assists in correlation.

Correlations are facilitated when the curves show characteristic "markers" such as a well-known chalk or shale section. Thin resistive beds such as lignites or evaporites frequently furnish valuable correlation points. For long-range correlation, the devices that investigate large volumes of formation are best. However, when the

Fig. 49.35—Example of long-distance correlation.

pay zones are known in a field, they can be correlated in great detail from well to well by comparing the ML or MLL; thus, the geometry of the reservoir can be obtained.

Investigation of Porosity

Evaluation of formation porosity from electrical logs is based on determination of the formation factor, F_R , which is related to porosity, ϕ , by Eq. 2. F_R can be found from the value of R_{xo} as determined from the ML or MLL with Eq. 6 rewritten as

$$F_R = \frac{R_{xo}}{R_{mf}} (S_{xo})^2, \quad (14)$$

where $S_{xo} = 1 - S_{or}$.

To determine R_{xo} from microresistivity measurements, it is necessary that invasion be deep enough that the measurements are not affected by the formation resistivities beyond the flushed zone. An exceedingly great mudcake thickness may also limit the accuracy of the R_{xo} determination. For reliable porosity interpretation from ML data the porosity should be greater than about 12 to 15%.

In an oil-bearing sand, the residual oil saturation (ROS) must be surmised for use in Eq. 14. Taking a value of 20% for the ROS would not usually entail too great an error in most cases, at least in formations with granular porosity and containing light oils. Greater ROS's are frequent, however, chiefly in the cases of highly viscous oil. Gas-bearing formations also seem to display high residual gas saturations in the flushed zone if the permeability is high. This is because of segregation effects resulting from a combination of gravity and capillary forces. Because of these residual saturations, the ML may show water contacts.

To check the results of the microresistivity devices, or to replace them in case they are not available, F_R may be determined as equal to R_0/R_w , R_0 being the true resistivity of the formation at a level where it is 100% water bearing. Extrapolation of a value of F_R determined at a water-bearing level to the oil-bearing section within the same formation implies that the lithological

characteristics are approximately constant, which is not always the case, however.

Still another approach often used in hard formations is based on the value of R_i , the average resistivity of the invaded zone estimated from the readings of the limestone sonde or the short normal.^{25,26} This procedure has proved valuable in many cases.

Other Tools for Obtaining Porosity. The sonic log, the neutron log, and the density log are increasing in importance as auxiliaries to the electrical logs for improved porosity determination.* In addition, with the present sample taker, reliable determination of formation factor and porosity are often possible from sidewall cores.

Investigation of Fluid Content

Quite often good qualitative judgments about a formation as a potential producing zone can be had by direct visual inspection of the log. Basically such judgments usually depend on (1) identification of a permeable formation by means of the SP, mudcake indications on microcaliper, positive separation on ML, indication of invasion by separation between shallow- and deep-investigation macroresistivity curves, etc., and (2) indication by the deep-investigation resistivity devices that R_i in the permeable formation is appreciably larger than the resistivity, R_0 , that the formation would be expected to have if water bearing.

When it can be assumed that there is no abrupt change in the salinity of the formation waters, the radius of invasion, etc., qualitative evaluations of saturation may be made by comparing a porosity log with a resistivity log over a large enough section of formations. Such a method, in which the neutron log was the source of the porosity data, was proposed several years ago.²⁷ Also, the possibility of accurate measurements of porosity with the sonic and density logs has prompted similar qualitative interpretation procedures.²⁸

When invasion is not too deep, so that the deep-investigation resistivity devices read fairly close to R_i , the following procedures are applicable.

1. Sonic** transit time may be plotted vs. a deep IL resistivity (in case of fresh muds) or vs. the LLD resistivity (in case of salty muds).²⁹ By a proper choice of scales, lines of constant resistivity index, I_R , become straight lines on the chart, as in Fig. 49.36. The line of 100% water saturation ($I_R = 1$) is constructed as the line bounding the leftmost plotted points and passing through the point corresponding to infinite resistivity and zero sonic log porosity. Lines for other values of I_R may then be constructed. It is possible to distinguish between oil- or gas-bearing and water-bearing zones by the relative positions of the plotted points. For a zone to be oil- or gas-productive the plotted point should fall appreciably to the right of and below the line of 100% saturation. This method is useful even if the formation-water resistivity is not initially well known.

2. By use of porosity derived from the sonic or neutron log and the resistivity from the deep-investigation log, apparent values of the formation-water resistivity

*The short-interval sonic velocity log (sonic log) is discussed in Chap. 50. The neutron log is discussed in Chap. 51.

**With some precautions, density or neutron data may be employed in place of sonic data in a similar crossplot technique.

$R_{wa} = R_t / F_R$ may be computed (using Eqs. 2 or 3 to obtain F_R). When tabulated in terms of depth, those apparent values that stand definitely above the average trend indicate the presence of hydrocarbon saturation. This procedure is rapid and applicable in shaly sands. It is also applicable when formation-water salinity varies appreciably with depth, provided that the variation is gradual and continuous.

3. The readings of a short-investigation resistivity log should give indications of the variations in the formation factor (and porosity). Accordingly, hydrocarbon saturation can also be qualitatively determined by examining the ratios of the readings of a short-investigation device (such as a short normal, LLS, or PL) to those of the deep induction log (ILD) or LLD. The two sets of readings may be used to locate points on a graphic plot, as described previously, or to construct a continuous curve of the ratio vs. depth. In either case the comparison is facilitated if the logs have been recorded on a logarithmic sensitivity scale.

The following procedure is helpful when, because of deep invasion, the value of the true resistivity is in doubt. The porosity from the sonic log is compared with the porosity computed from a shallow-investigation resistivity log (such as short normal, limestone sonde, LLS or PL). The latter porosity is affected by any residual oil saturation, whereas the sonic log porosity is not. Zones where the two porosities differ should accordingly indicate potentially productive formations.

Also, in hard formations (where permeability is generally low) a resistivity gradient (corresponding to a saturation gradient) is observed on the logs between the zone of lowest water saturation and the level of 100% water saturation. The existence of this gradient is the basis of a method for the delineation of intervals saturated with hydrocarbons.³⁰

Quantitative Interpretation*

Quantitative determinations of the hydrocarbon saturation from electrical logs are essentially determinations of the water saturation, S_w , in the uncontaminated zone. Recalling Eq. 5

$$S_w = \left(\frac{R_0}{R_t} \right)^{1/2} = \left(\frac{F_R R_w}{R_t} \right)^{1/2}$$

The evaluation of R_t is a major step in the determination. Evaluation of F_R is equivalent to an evaluation of porosity, as already discussed. R_0 may be determined in a 100% water-saturated section of the same sand or in a lithologically similar sand.

Some interpretation procedures do not require explicit evaluation of R_t and F_R . Along with a knowledge of the SSP, or equivalently the ratio R_{mf}/R_w , they are based on the ratios of readings taken with deep- and shallow-investigation devices [e.g., R_{xo}/R_t method, induction-electrical log (IEL) interpretation, Rocky Mountain method]. A special approach is applied in case of shaly formations.

Fig. 49.36—Qualitative method for differentiating water-bearing and oil- or gas-bearing zones by plotting deep-investigation resistivity values against sonic-log transit times. The ordinate scale is proportional to $(1/R)^{1/2}$.

Determination of R_t . Conventional resistivity logs can provide for the value of R_t only for thick beds, since the readings in general cannot be reasonably corrected for the effect of adjacent formations. The long lateral, because of its large radius of investigation, is practically unaffected by the mud column and the invaded zone and gives a good approximation of R_t when the beds are reasonably uniform over a thickness of at least 30 ft. Such favorable conditions are seldom met in practice.

The long-normal reading usually requires a correction for the borehole effect. This correction is sufficiently accurate in fresh mud. The reading is close to R_t when the bed thickness is at least 10 to 15 ft and invasion is shallow. The effect of deep invasion can be accounted for, to some extent, by means of departure curves.^{31,32} Correction for invasion requires the help of other devices with shorter radii of investigation (ML and/or short normal), which provide values of the invaded-zone resistivity.

The advantage of the ILD and the LLD is that under usual conditions of application their readings are practically unaffected by the mud column or by the adjacent formations for bed thicknesses greater than about 5 to 6 ft.

The ILD, with the present technique, is appropriate for logging in fresh mud. Its accuracy is excellent for formations reading up to 50 Ω-m and reasonable up to 200 Ω-m. Above that figure the accuracy is not so good. The ILD gives R_t when the invasion diameter does not exceed 25 to 40 in. and can be corrected for deep invasion. The auxiliary readings are the ML and/or the short normal, or better, the LL8 or SFL, particularly in case of consolidated formations.

*Only computations that can be made by hand will be studied here. Latest interpretation techniques are made by computers and are explained under The Digital Age.

The LL is the essential tool for the logging of hard formations in salty mud. It gives R_t for shallow invasion (d_i less than 15 to 25 in.). Correction for invasion is made with the help of the MLL or MSFL. The most efficient way to correct for invasion and thus obtain R_t is the use of a three-log combination: (1) DIL or dual induction/SFL in fresh muds and in soft and intermediate formations and (2) dual laterolog/ R_{xo} in hard formations or salty muds. The so-called "butterfly or tornado charts" in Ref. 2 provide a simple procedure to obtain R_t .

Maximum Producing Oil Index

If the porosity, ϕ , of a formation is uniform and intergranular, the quantities $S_{xo}\phi$ and $S_w\phi$ represent the amounts of water per unit of bulk volume present in the pores of the flushed and uncontaminated zones, respectively. The difference $Y = (S_{xo} - S_w)\phi$ is the amount of oil per bulk volume displaced by the mud filtrate. Y is called "maximum producible oil index" because it approximates the maximum amount of oil per bulk volume producible with water drive. Y is given approximately by the equation²⁹

$$Y = \left(\frac{R_{mf}}{R_{xo}} \right)^{1/2} - \left(\frac{R_w}{R_t} \right)^{1/2} \quad (15)$$

Evaluation of Y by this equation does not require a direct knowledge of porosity, ϕ , formation saturation, S_w , or flushed-zone saturation, S_{xo} (or ROS).

Ratio Methods

It is impossible, in the space available, to present all log-interpretation techniques or to present all charts and tabulations made up thereof. For the practicing log interpreter most of the charts needed are included in Ref. 2.

The R_{xo}/R_t Method. For clean formations, saturations can be computed from the empirical relationship found by combinations Eqs. 5 and 6,

$$S_w = S_{xo} \left(\frac{R_{xo}}{R_t} \cdot \frac{R_w}{R_{mf}} \right)^{1/2} \quad (16)$$

Any method which gives correct values for R_{xo} , R_t , R_{mf} , and R_w may be used to determine S_w , provided S_{xo} is known or can be reasonably surmised.

The chart of Fig. 49.37 provides a convenient way for solving Eq. 16. The ratio R_{mf}/R_w is entered in abscissas (upper scale) and the ratio R_{xo}/R_t in ordinates. From the point so plotted, an oblique line is extended up to its intersection with the edge of the chart; from this intersection, a horizontal line is drawn which gives the values of S_w for different values of S_{xo} .

The value of S_w found directly by interpolation between the two nearby oblique lines is based on the assumption that S_{xo} , on the average, is related to S_w through the empirical equation $S_{xo} = \sqrt[3]{S_w}$. Within the limits where $R_w \approx R_{we}$ (i.e., R_w between 0.08 and 0.3 Ω -m at 75°F), the E_{SSP} can be entered, instead of R_{mf}/R_w , using the lower grid.

Microlog Shaly-Sand Method. The amplitudes of both the SP deflection and the resistivities are reduced by the presence of interstitial shale in a formation. In some ex-

SATURATION DETERMINATION

Fig. 49.37—Interpretation chart for R_{xo}/R_t and shaly-sand methods. (Working lines illustrate example of Fig. 49.38).

treme cases shaly oil sands are hardly differentiated from the adjacent shales on the logs. Furthermore, the ML does not show much separation between the curves. Interpretations in shaly sands, therefore, are generally made under comparatively unfavorable conditions. The practical method of interpretation described hereafter is quite approximate and is applicable only when the amount of shaliness is not too great.*

The practical method of interpretation in shaly formations³³ is based on the observations made on field logs that in 100% water-saturated shaly sands the PSP (pseudostatic SP) is given by

$$E_{PSP} = -K_c \log \frac{R_{xo}}{R_0} \quad (17)$$

For an interlaminated sand-shale formation containing oil and/or gas, the PSP can be expressed by the equation

$$E_{PSP} = -K_c \log \frac{R_{xo}}{R_t} - 2\alpha_{SP} K_c \log \frac{S_{xo}}{S_w} \quad (18)$$

where α_{SP} is the SP reduction factor and is defined as E_{PSP}/E_{SSP} . For clean sands, $\alpha_{SP} = 1$ and Eq. 18 reduces to Eq. 17 as a special case.

According to Eq. 18 the determination of S_w in a shaly sand requires the knowledge of R_{xo} , S_{xo} , R_t , E_{PSP} , and E_{SSP} . The E_{SSP} can be determined from clean sands reasonably close to the shaly formations considered. The E_{PSP} is given by the deflection of the SP curve at the level of the bed, after correction for bed thickness, if necessary. The value of $S_{xo} = 1 - S_{or}$ again must be surmised.

The solution of the equation for S_w is given by Fig. 49.37, which applies to both clean and shaly formations. For a shaly sand, the PSP and R_{xo}/R_t are first entered in abscissa and ordinate, respectively. This gives us the ap-

*Some other shaly-sand references are Refs. 8 and 9.

Fig. 49.38—Shaly-sand example: induction-electrical survey and microlog-microcaliper survey in well on Louisiana Gulf Coast. $R_m = 1.45$, $R_{mf} = 1.2$, and $R_{mc} = 1.3$ at BHT (140°F). $d = 8\frac{3}{4}$ in.

parent saturation. To find the true saturation, a line is drawn through the origin (circled), and the point representing the apparent saturation; and this line is extended until it intercepts the E_{SSP} or the corresponding value of R_{mf}/R_w . The saturation at this point is treated in the same manner as in the R_{xo}/R_t method above.

If the E_{SSP} is not known and R_w is unobtainable, it is not possible to determine the water saturation, S_w . Nevertheless, plotting the ratio R_{xo}/R_t vs. PSP on Fig. 49.37 will show whether or not the sand falls on the 100% water-saturation line. If it falls some distance below this line, there is a chance for production.

Note that in sand-shale laminations the value of S_w is the water saturation of the sand itself. In sands containing disseminated shale, it is the water bound by the quartz grains and does not include the water held by the colloids.

Example Problem 1. Fig. 49.38 shows the IEL and the ML over a portion of a well in Jefferson Davis Parish, LA. The shaly sand from 8,046 to 8,054 ft will

be interpreted. The mud resistivity at formation temperature of 140°F is 1.45 Ω -m, $R_{mc} = 1.3$ Ω -m, and $R_{mf} = 1.2$ Ω -m at 140°F. Bit size is 8 $\frac{3}{4}$ in.

From the IEL, the E_{PSP} is -55 mV. The E_{SSP} (sand at 7,830 to 7,850 ft) is -130 mV. Thus α_{SP} is 0.42. The short-normal resistivity R_{16} is 2.2 Ω -m, and the induction-log resistivity R_{IL} is 1.9 Ω -m. Invasion is known to be quite shallow, as further substantiated by the readings of the microlog. Therefore R_{IL} may be taken as equal to R_t .

As shown by the positive separation on the ML, three distinct porous intervals, A, B, and C, appear between 8,046 and 8,054 ft. The values of R_{xo} and h_{mc} for each interval are found by use of Fig. 49.31. Thus, for Interval A R_{xo} is 4.0, for Interval B it is 5.6, and for Interval C it is 6.8. The average R_{xo} is 5.5, and for all three intervals the mudcake thickness is $\frac{1}{2}$ in. Note that the microcaliper indicates a hole diameter of 7 $\frac{3}{4}$ in., exactly 1 in. smaller than bit size, corresponding to a $\frac{1}{2}$ -in. mudcake, thus verifying the h_{mc} values from Fig. 49.31.

Fig. 49.39—40-in. induction log, 16-in. normal interpretation chart. (Working lines illustrate example of Fig. 49.40.)

All necessary data are now at hand:

$$\begin{aligned} R_{xo} &= 5.5 \Omega\text{-m} \\ R_t (=R_{IL}) &= 1.9 \Omega\text{-m} \\ E_{PSP} &= -55 \text{ mV} \\ E_{SSP} &= -130 \text{ mV} \\ \alpha_{SP} &= 0.42 \\ K_c &= (\text{for the SP}) \text{ at } 140^\circ\text{F} \text{ is close to } 79 \\ R_{xo}/R_t &= 2.9, \text{ and} \\ R_{xo}/R_{mf} &= 4.6 \end{aligned}$$

Fig. 49.37 is entered with $R_{xo}/R_t = 2.9$ and $PSP = -55$ at $K_c = 79$, locating a point on the chart. Then a line is drawn through this point from the origin and extended until it intersects the vertical line erected at $E_{SSP} = -130$ mV for $K_c = 79$. This intersection gives a value of S_w equal to 43%, assuming that S_{or} is 15%, which is reasonable. The sand was perforated from 8,046 to 8,050 ft and made 75 BOPD and 280,000 cu ft/D gas through a 7/64-in. choke.

IEL Interpretation Method. A chart for practical interpretation of fluid saturation from the readings of the IEL combination is shown in Fig. 49.39, Ref. 2. The conditions limiting valid use of the chart are: (1) the invasion diameter d_i must be between $2d_h$ and $10d_h$ (d_h is the hole diameter), (2) R_{xo} must be greater than R_t , which is generally fulfilled if R_{mf}/R_w is greater than three to five, as for fresh muds and saline formation waters, and (3) the beds must be fairly homogeneous—i.e., the short-

normal reading must not be perturbed by the presence of resistive streaks.

The chart incorporates approximate compensation for the presence of an annulus, assuming equal viscosities for the oil and water and an S_{or} in the flushed zone of 15 to 30%. To use the chart the value of the ratio $R_{16''}/R_{1L}$ (resistivity from 16-in. normal divided by the IL resistivity), corrected, if necessary, for effect of borehole and adjacent formations, is plotted either vs. the SSP (lower grid) entered opposite the appropriate formation temperature or vs. R_{mf}/R_w (upper scale).

Points falling within the shaded area correspond to water-bearing sands. Points falling below the shaded area correspond to oil saturation. Approximate saturation scales are provided for d_i values of $3d_h$ and $5d_h$. The dashed lines represent lines of equal saturation on the chart. The critical saturation corresponds to $S_w = 60\%$ in soft formations and 50% in consolidated sandstones. These may not be the correct critical saturations for many limestones.

For shaly formations a construction like that used in the shaly-sand method can be used in Fig. 49.39. Although not rigorously correct, this procedure should give acceptable results if the shaliness is not too great.

Since it is not always known beforehand whether the interpretation chart (Fig. 49.39) is within its limits of applicability, it is useful to employ the value of porosity or formation factor, when known from independent sources, to check the results by means of Eq. 5. Details of this "porosity balance" check are given in Ref. 34.

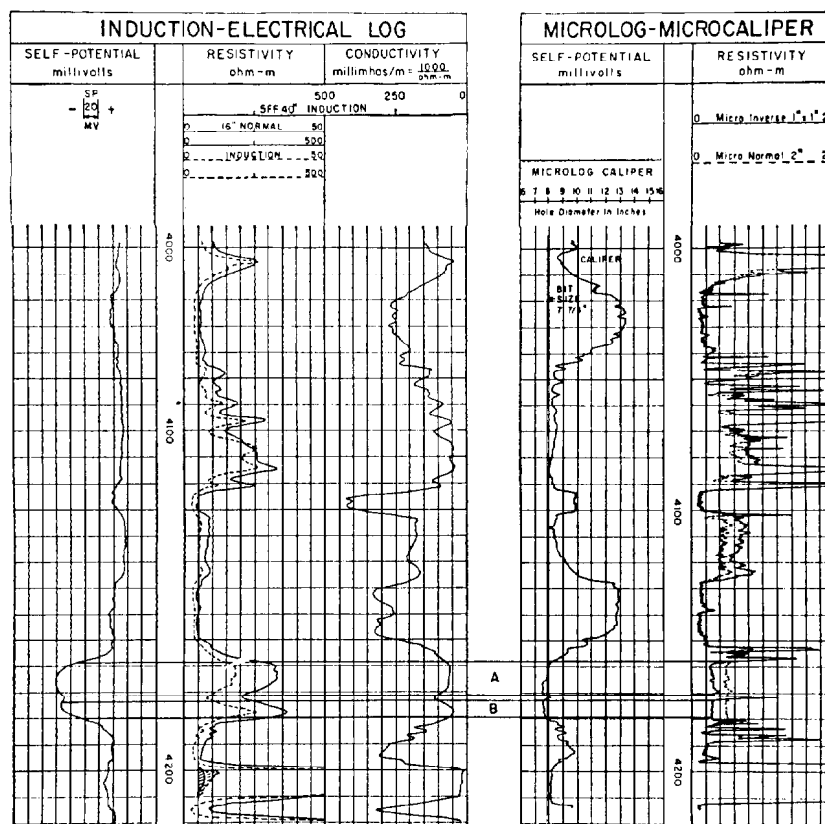

Fig. 49.40—Induction-electrical log and microlog-microcaliper log on a well in Young County, TX. $R_m = 0.95$ and $R_{mf} = 0.61$ at BHT (117°F). $d = 7\frac{7}{8}$ in.

Example Problem 2. Fig. 49.40 shows part of the induction-electrical log and ML on a well in Young County, TX. The sand at the bottom of the figure is divided into two parts, A and B, by a thin, hard streak, as shown on the ML. A and B will be interpreted separately. Necessary well data are $R_m = 0.95$ and $R_{mf} = 0.61$, at BHT of 117°F ; hole diameter, d_h , is $7\frac{7}{8}$ in.

Interval A. From the induction-electrical log, $R_{IL} = 17.5 \Omega\text{-m}$, $R_{16} = 32.5 \Omega\text{-m}$, $\text{SP} = -95 \text{ mV}$, and BHT is 117°F . Applying Fig. 49.39, the ratio $R_{16}/R_{IL} = 32.5/17.5 = 1.85$. The SP is -95 mV , so the point is fixed on the chart, giving an average S_w of about 30%.

Interval B. Here the $R_{IL} = 26.0 \Omega\text{-m}$ and $R_{16} = 37.0 \Omega\text{-m}$. $R_{16}/R_{IL} = 37.0/26.0 = 1.42$. The SP is -90 mV at 117°F . This fixes a point on Fig. 49.39, which gives a value of S_w of about 25%. Drillstem tests on the two intervals showed that the sand contained gas and distillate, with a higher flowing pressure over Interval B.

Rocky Mountain Method. The Rocky Mountain method²⁵ was developed for the interpretation of conventional electrical logs to yield values of S_w and ϕ in invaded, clean, hard formations when they are sufficiently thick and homogeneous. It is necessary that the invasion be such that the average resistivities recorded by the short normal and the lateral (when corrected for borehole effect) approximate the average values of R_i and R_t , respectively. For this to be true, the short-

normal readings should be at least 10 times the mud resistivity. Only average values, over thick intervals, can be obtained with this method.

$$R_i = \frac{F R_{wi}}{S_i^2}, \quad \dots \dots \dots (19)$$

where:

1. R_{wi} is the resistivity of the water found in the invaded zone. It is usually made up of filtrate and interstitial (connate) water mixed in such proportion that

$$\frac{1}{R_{wi}} = \frac{f_w}{R_w} + \frac{(1-f_w)}{R_{mf}}, \quad \dots \dots \dots (20)$$

where f_w is the fraction of interstitial (connate) water in the total mixture (usually 5 to 10%).

2. S_i is the water saturation in the invaded zone. It has been found by experience that $S_i^2 \approx S_w$; so $R_i = F R_{wi} / S_w$. Inasmuch as $R_t = F R_w / S_w^2$, we obtain $S_w = (R_i / R_t) / (R_{wi} / R_w)$.

Since $R_w / R_{wi} = f_w + (1-f_w) R_w / R_{mf}$, it follows that R_{wi} / R_w is a function of the SP value. The upper part of Fig. 49.41 gives a graphical solution of the equation for S_w . The SP is entered in ordinate and the ratio R_i / R_t on oblique lines. The intersection gives the abscissa S_w .

The lower part of the chart is used to obtain the porosity by using the water saturation, S_w , just found, with the

Fig. 49.41—Interpretation chart for Rocky Mountain method.

value of R_t/R_w . The intersection falls on or between oblique lines that are graduated into porosity values, according to the Humble formula, Eq. 2. This method should not be used in salt muds.

Electromagnetic Propagation Tool

Principle. The EPT[™] (electromagnetic propagation tool³⁵) measures the travel time and attenuation rate of an electromagnetic wave through the formation near the borehole. In addition, a caliper and a ML can also be recorded. The tool can be combined with the gamma ray, neutron, or density instruments.

The propagation time of water differs sharply from those of gas, oil, or matrix rock and is, moreover, little affected by the salinity of the water. This tool permits the evaluation of water saturation that is relatively independent of water resistivity (salinity) and, in fact, is most accurate in the fresher waters.

Dielectric permittivity is one of the main factors determining electromagnetic propagation in a material. Dielectric permittivity of any medium is proportional to the electric dipole moment per unit volume. The electric

dipole moment is made up of one or more effects: electronic, ionic, interfacial, and dipolar. Since each of these dominates over a certain range of the electromagnetic spectrum, they can be separated experimentally.

The electronic contribution results from the displacement of electron clouds, and is the only one that operates at optical frequencies. The ionic and interfacial contributions come from displacement and movement of ions, hence are confined to low frequencies. The dipolar contribution is from permanent electric dipoles, which orient themselves in the direction of an applied electric field. With the exception of water, there are very few materials abundantly found in nature that have permanent electric dipoles. A borehole dielectric measurement in the 10^9 -Hz frequency region, where the dipole polarization of water dominates, should lead to a measurement of water content that is independent of salinity.

Table 49.3 gives laboratory-measured values of propagation time and dielectric permittivity (relative to air) of typical reservoir materials.

Tool. The tools now in the field carry two transmitters and two receivers on a wall-contact pad, configured as shown in Figs. 49.42 and 49.43. These transmitters and receivers must be antennas to operate as they do in the microwave frequency range. The tool uses a differential measurement based on the signals detected by near and far receivers, similar in principle to the widely used method of measuring Δt with a two-receiver sonic tool. In a similar manner, the two receivers produce cancellation of any effects caused by mudcake or variations in signal coupling (so long as both receivers are affected equally).

To reduce any error caused by sonde tilt, the EPT uses an antenna configuration similar to the transducer array used in a borehole-compensated sonic tool. Transmitting antennas are placed above and below the receiver pair and are pulsed alternately. Simple geometric considerations show that if these two transmission modes are averaged, the first-order effects of pad tilt will be eliminated.

The basic principle of the tool involves a surface or lateral electromagnetic wave launched along the surface of a conducting pad. In the absence of mudcake, the electromagnetic wave would move along the pad face past two receiving antennas, but in the normal borehole case with mudcake present, propagation takes place on the surface between mudcake and formation. The phase shift and attenuation per unit distance along the surface of the pad are proportional to ϵ and C (as shown in theory) for a plane wave.

It has been demonstrated both theoretically and experimentally that for mud cakes up to $\frac{3}{8}$ in. the travel time measured by the EPT is essentially the same as the travel time in the invaded zone without any mud cake. Above such thickness the measurement deteriorates rapidly until the tool responds only to the mud. Limited experience with air- and oil-based mud-filled tools indicates that even very thin layers of these fluids between the pad and the formation cause the tool to respond only to the fluid and not the formation. This is because of the short travel time of these fluids. The tool contains a 1.1-GHz microwave transceiver. The transmitter is capable of generating more than 2 W of output power

TABLE 49.3—ELECTROMAGNETIC PROPAGATION VALUES

	Relative Dielectric Permittivity, ϵ	Loss-Free Propagation Time, t_{po}
Gas or air	1.0	3.3
Oil	2.2	4.9
Water	56–80	25–30
Quartz	4.7	7.2
Limestone	7.5	9.1
Dolomite	6.9	8.7
Anhydrite	6.5	8.4

while the receiver can process a 0.3 pico watt (pW) signal. This allows accurate measurements in formations when R_{ad} approaches $0.3 \Omega\text{-m}$.

Assuming a plane wave varying sinusoidally in time, the electric field, E , at the second receiver is given by

$$E = E_0 e^{-\gamma L + j\omega t} \quad (21)$$

where E_0 is the electric field at the first receiver; L is the distance between the two receivers; j is the vectorial operator $\sqrt{-1}$; ω is the angular frequency; t is the time of travel of the waves over a distance L in the formation; and γ is the complex propagation factor given by

$$\gamma = \alpha + j\beta \quad (22)$$

where α is the attenuation factor (coefficient) in neper/m, and β is the phase factor in rad/m.

For a "lossless" formation,* $\alpha = 0$. From Eq. 21, the phase velocity v_{po} is given by

$$v_{po} = \frac{L}{t} = \frac{\omega}{\gamma_d} = \frac{1}{t_{pd}} \quad (23)$$

where the subscript o indicates loss-free conditions and t_{pd} is the loss-free propagation time of a given medium in ns/m.

From Maxwell's equations, it can be shown that

$$\gamma_d = j\omega\sqrt{\mu\epsilon} = j\omega t_{po} \quad (24)$$

where μ is the magnetic permeability (H/m). Since most formations of interest are nonmagnetic, μ of the formation is the same as that of free space ($\mu_0 = 4\pi \times 10^{-7}$ H/m), and ϵ is the dielectric permittivity (F/m). When the formation is lossy, γ and α are complex.

*Formation with no electromagnetic energy losses

Fig. 49.42—Schematic of EPT antenna pad, showing principle of 2-receiver measurement of transit time.

Fig. 49.43—The EPT antenna pad.

Squaring Eq. 22 and Eq. 24 and equating the real and imaginary terms, we have

$$\omega^2 \mu_o \epsilon = \beta^2 - \alpha^2, \quad \dots \quad (25)$$

and

$$\omega \mu_o C = 2\alpha\beta, \quad \dots \quad (26)$$

where C is the equivalent conductivity (Ω/m) of the losses in the formation. Dividing Eq. 25 by ω^2 ,

$$\mu_o \epsilon = \frac{\beta^2}{\omega^2} - \frac{\alpha^2}{\omega^2}. \quad \dots \quad (27)$$

From Eq. 24, $\phi_o \epsilon = t_{po}^2$. Since $\beta/\omega = t_{pl}$ is the travel time in the lossy medium,

$$t_{po}^2 = t_{pl}^2 - \frac{\alpha^2}{\omega^2} \cdot * \quad \dots \quad (28)$$

Remembering that α is the attenuation factor, Eq. 28 implies that the actual propagation time in a conductive formation is longer than that of a corresponding loss-free formation. If the propagation wave is not a plane wave, suitable spreading-loss corrections to the measured attenuation (A_{log}) are made before Eq. 28 is applied. Thus the corrected attenuation $A_c = A_{log} - G_{sl}$ (dB/m) where G_{sl} is the geometrical spreading loss and A_{log} the recorded attenuation in dB/m. G_{sl} is about 50 dB/m in air or $G_{sl} = 45.0 + 1.3t_{pl} + 0.18t_{pl}^2$. Here t_{pl} is the recorded travel time in ns/m.

Interpretation. The range of travel time encountered in the borehole in common reservoir rock varies from 6.3 ns/m for a 40-pu sandstone filled with hydrocarbons to 17.2 ns/m for a 40-pu water-filled limestone. In terms of phase shift, this corresponds to angles between 100 and 270° when computed over a 4-cm receiver spacing.

The EPT log responds primarily to the bulk volume of water in the formation. Since the tool has a relatively shallow depth of investigation—about 1 to 6 in. depending on the conductivity—it normally responds to the flushed zone of an invaded section.

Eq. 28 can be transformed into

$$t_{po} = \left(t_{pl}^2 - \frac{A_c}{3604} \right)^{1/2} \quad \dots \quad (29)$$

The apparent water-filled porosity (ϕ_{EPT}) can be derived in a way similar to the derivation of the porosity from sonic Δt . Thus

$$\phi_{EPT} = \frac{t_{po} - t_{pm}}{t_{pwo} - t_{pm}} \quad \dots \quad (30)$$

t_{pwo} , the loss-free propagation time of water, varies with the temperature and slightly with pressure and can be obtained as

$$t_{pwo} = 20 \left(\frac{710 - T/3}{444 + T/3} \right),$$

where T is the temperature, °F. Knowledge of water salinity is not required to obtain t_{pwo} .

* α in neper/m and A_{log} is dB/m. Since 1 neper = 8.686 dB, $A_{log} = 8.686\alpha$.

The loss-free propagation time of matrix, t_{pm} , is indicated on Table 49.2. The nature of the matrix can be determined by the knowledge of the apparent matrix density and interpolating between lithology density values. The water saturation S_{xo} is given by

$$t_{po} = S_{xo} \phi t_{pwo} + (1 - S_{xo}) \phi t_{ph} + (1 - \phi) t_{pm} \quad \dots \quad (31)$$

or

$$S_{xo} = \frac{t_{po} - t_{pm} + \phi(t_{pm} - t_{ph})}{\phi(t_{pwo} - t_{ph})}, \quad \dots \quad (32)$$

where t_{ph} is the propagation time for hydrocarbon and ϕ is the porosity of the formation. Since t_{pm} and t_{ph} are fairly close, we can estimate S_{xo} roughly as

$$S_{xo} = \frac{\phi_{EPT}}{\phi} \quad \dots \quad (33)$$

Example Problem 3. Fig. 49.44 is an example of the log presentation currently in use. Track 1 contains a conventional caliper curve, taken from the motion of the backup pad, and the attenuation curve, scaled in dB/m. Tracks 2 and 3 are given to the principal measurement, travel time (t_{pl}), in ns/m. Track 3 also presents the signal levels from the two receivers. The chief use of these curves is to monitor the primary signal detection at the receivers, which provides an indication of the relative reliability of the log parameters at any level.

A self-evident and very real advantage may be inferred from the 4-cm spacing between receivers; the tool has excellent vertical resolution. The log of Fig. 49.44 actually looks overactive in spots, but its repeatability testifies that the recording is valid. In fact, the data recorded by the tool are too detailed for direct merging with other logs by means of computer. Averaging (smoothing) subroutines are thus required preliminaries for programs using EPT data.

Example Problem 4. Fig. 49.45 shows an ISF log and the porosity computed from density, neutron, and EPT logs. Zone A is obviously gas bearing, as evidenced by the neutron porosity reading much less than the density. The EPT porosity is a little higher than the neutron porosity and much less than the density porosity, confirming the presence of hydrocarbons.

Zone B exhibits a different porosity profile. Once again the neutron porosity is less than the density porosity, indicating the presence of some light hydrocarbons, but now the EPT porosity is less than both neutron and density porosities. Since the total porosity from neutron and density logs is roughly

$$\phi = \frac{\phi_N + \phi_D}{2},$$

and the hydrocarbon volume is

$$\phi_{HC} = \phi - \phi_{EPT},$$

the volume of hydrocarbons affecting the three porosity tools is about the same for Zones A and B as determined from the EPT data. However, there is a much stronger light hydrocarbon effect on the neutron and density logs in Zone A. Thus, it would be expected that Zone B contains more condensate or oil than Zone A.

Fig. 49.44—An unaveraged EPT log shows fine detail. Repeat sections (faint curves) of the attenuation and t_{pl} curves show excellent repeatability.

Fig. 49.45—ISF and EPT/CNL/FDC logs.

Zone C appears to contain some residual hydrocarbons, since the EPT porosity is often slightly less than the neutron and density porosities. There is a little more hydrocarbon in the shalier bottom part of Zone C than in the cleaner top portion.

The very top of Zone D contains oil since the EPT measurement is much lower than the neutron and density porosities, which read about the same. Water-bearing zones are identified when the EPT porosity is about the same or higher than the neutron and density porosity. Thus, Zone E is clearly water bearing, as is the bottom of Zones B and D.

Machine programs are available to give complete quantitative interpretation of all these logs. This is especially important in the study of tar sands or crude oils where the hydrocarbon is not flushed by the mud filtrate and where S_{xo} is very near S_w . These studies are also of great interest to provide values of residual oil saturations.

The Digital Age

Before 1960, all logs were recorded in analog form on film or paper. Magnetic tape recording was introduced in 1960 to record dipmeter. Shortly thereafter, various other logs were also recorded on tape, thus permitting the use of computers for various purposes. Before long, computers were made an intrinsic part of the recording systems on the logging trucks. This has revolutionized the capacity for data acquisition at the wellsite. At the same time, many computer-processed products have become available in real time or only a short time after logging is completed at the wellsite.

TABLE 49.4—WELLSITE ANALYSIS AVAILABLE IN REAL TIME

Generic Name	Derivation	Log Input Required	Presentation	Schlumberger	Gearhart	Dresser	Welex
R_{wa}	Assumes all formations contain 100% water. Computes apparent R_w . $R_{wa} = R_t/F$	Simultaneous resistivity and porosity. Usually sonic and induction	Single curve in Track 1 on logarithmic scale.	R_{wa}	R_{wa}	R_{wa}	R_{wa}
R_{xo}/R_t	Uses deep resistivity and shallow focused resistivity to estimate R_{xo}/R_t ratio.	Simultaneous deep resistivity and shallow focused resistivity	Single curve in Track 1 compatibly scaled as a pseudo SP curve.	R_{xo}/R_t	R_{xo}/R_t	R_{xo}/R_t	R_{xo}/R_t
"F" overlay or " R_o " overlay	Derives F from a porosity curve that is played onto logarithmic resistivity as R_o .	Deep resistivity and porosity	Single dashed curve in Tracks 2 and 3 on logarithmic scale.	R_o	R_o	"F" Curve	"F" Curve
Compatible porosity scales	Any combination of porosity logs with same lithology assumptions to compute porosity.	Simultaneous porosity logs	Coded curves in Tracks 2 and 3 with gamma ray and caliper in Track 1.	Compatible porosity scales	Compatible porosity scales	Compatible porosity scales	Compatible porosity scales
Hole volume	Uses caliper logs to compute hole volume for cement calculation.	Caliper curve—preferably 2 curves at 90° such as 4-arm dipmeter	Pips or tic marks in depth column at every 10 cu ft and 100 cu ft.	Borehole volume	Borehole volume	Borehole volume	Borehole volume
Fracture locating log	Uses differences in adjacent pad readings from 4-arm dipmeter to infer fractures.	4-arm dipmeter	Adjacent pad readings are superimposed and any separation is coded.	Fracture identification log	Fracture detector log	Fracture location log	Dipmeter fracture log

TABLE 49.5—WELLSITE ANALYSIS AVAILABLE IN REPLAY* TIME

Generic Name	Derivation	Log Input Required	Presentation	Schlumberger	Gearhart	Dresser	Welex
Merged and depth shifted data	Replays all logs, shifts depths and makes simple calculations such as R_{wa} , R_{xo} , R_{xo}/R_t , compatible porosity scales or cross plot porosities.	Any logs run on tape.	Usually 3 to 5 tracks. Varies by service company, displays only log data.	Cyberlook Pass 1	Cross-plot (X-plot)	Prolog	Computer Van
Wellsite evaluation log	Uses all logs to provide a first order computer analysis.	Resistivity and porosity	Usually 3 or 4 tracks. Has reservoir data derived from log data.	Cyberlook	Well evaluation log	Prolog	CAL
Formation dip computations	Computes formation dip from 4-arm dipmeter	4-arm dipmeter	Formation dip, hole deviation, calipers.	Cyberdip	FED DDL	Pro-Dip	
True vertical depth log	Computes TVD of any point from dipmeter orientation data	Continuous dipmeter plus any log to be converted to TVD	Replay of any log on TVD scale	TVD	TVD	TVD	

*All logs available in real time are also available in replay time if recorded on magnetic tape

Without any doubt, the digital age is responsible for the creation of new equipment deemed impossible before. Many interpretation techniques and studies today could not be made without the use of computers. Finally, electronic transmission of log data is a present reality, facilitating exchange between wells and offices, towns and continents. An overview of this vast field is necessary.

Magnetic Tapes

API-recommended standard format permits logging service company tapes to be read by most computers. More exhaustive treatment of the subject is available directly from the service companies. Quality control of the magnetic tape is ensured in real time in integrated logging systems having on-board computers.

Computed Log Products

Log analysis performed by a computer is available to the log user at three different levels.

1. Real-time "quick-look" products, summarized in Table 49.4, run at the same time the log is being run. Many of these curves, such as R_{wa} and F curves, are recorded on the standard logs and are often placed in the SP or resistivity tracks.

2. Wellsite log analysis products, summarized in Table 49.5, are generally available at the wellsite in replay time. Wellsite analysis is made after the logging is completed. The process involves playing back taped logs and using an appropriate log analysis program, such as a shaly-sand analysis or a dipmeter computation.

3. Computing center products are provided well after the logging is finished (days or weeks later) and are generally more comprehensive than either of the wellsite products. In general, these computations fall into three categories: shaly-sand analysis, complex lithology study, and dipmeter processing. The most-used products are summarized in Table 49.6. Other, less frequently used products such as tar sand analysis or mechanical properties are not included; details on these may be obtained directly from the service company.

TABLE 49.6—LOG ANALYSIS AVAILABLE FROM COMPANY COMPUTING CENTERS

Generic Name	Derivation	Log Input Required	Presentation	Schlumberger	Gearhart	Dresser	Welex
Advanced sandstone analysis	Uses most sophisticated analytical and statistical methods to correct and compute logs in sandstones and shaly sandstones.	Resistivity, density, neutron, gamma ray with sonic desirable	Usually 4 tracks presentation of lithology, saturation, porosity and bulk volume.	SARABAND VOLAN	Comsand "F" Pairs	EPILOG Sandstone Analysis	CAL
Advanced carbonate analysis	Uses most sophisticated analytical and statistical methods to correct and compute logs in carbonate and lithologically complex reservoirs	Resistivity, density, neutron, gamma ray with sonic and microresistivity desirable	Usually 4 tracks presentation of lithology, saturation, porosity, and bulk volume.	CORIBAND GLOBAL	Comlith Frax	EPILOG Complex Reservoir Analysis	CAL
Advance dipmeter computations	Uses most advanced correlation logic to compute dips followed by a statistical sorting to retain the most reliable data.	4-arm dipmeter	Arrow plot with caliper, correlation curve and hole deviation. Also available: azimuth frequency, modified Schmidt plots, histograms, and listings.	CLUSTER (structural) and GEODIP (stratigraphic)	NEXUS	Dresser computed dipmeter	Diplog analysis

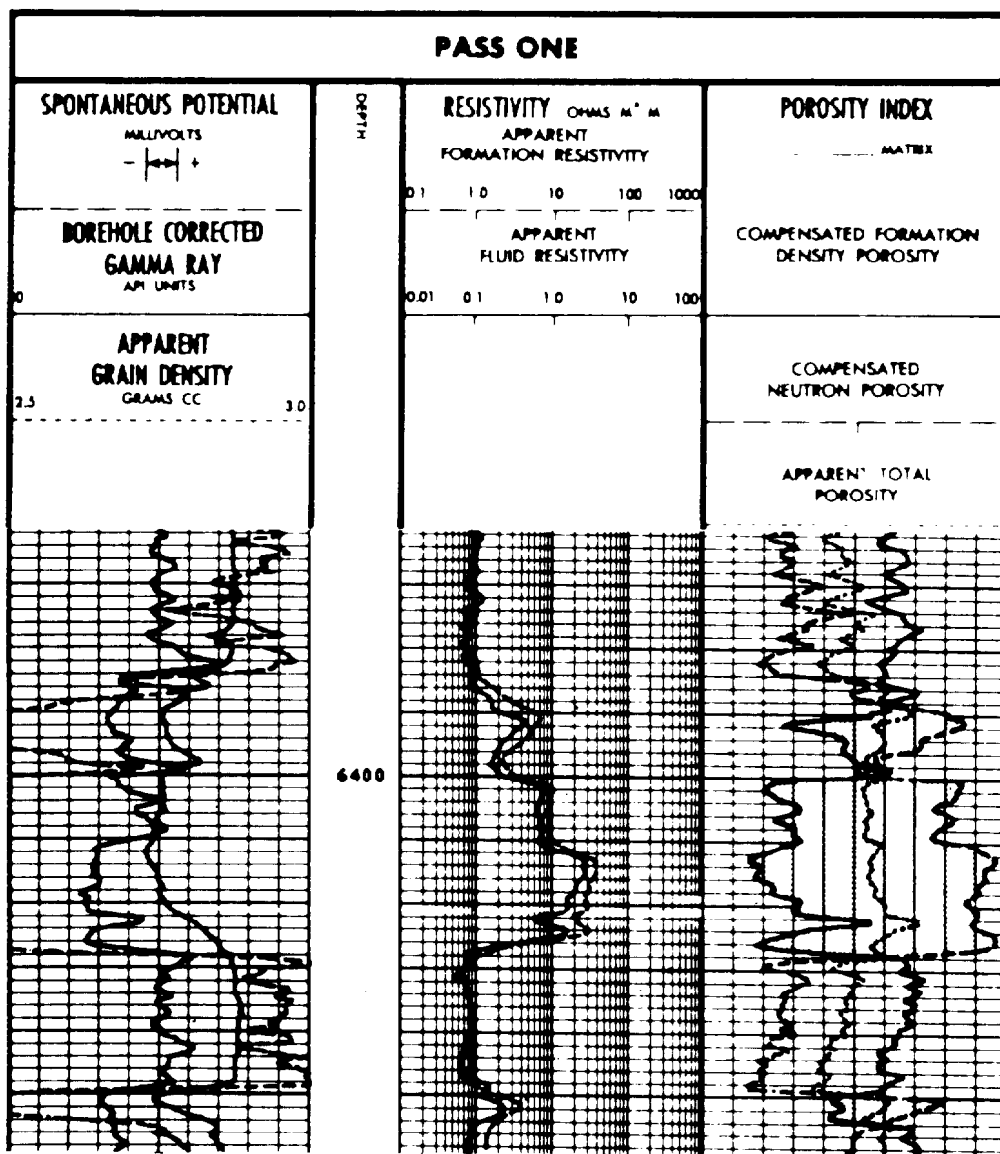

Fig. 49.46—CYBERLOOK Pass One log.

An example of wellsite log analysis is the CYBERLOOK™ program,³⁶ which requires as a minimum suite of logs a deep investigation resistivity, CNL™-FDC™ (compensated neutron/density logs), a gamma ray, or SP curve. The CYBERLOOK computation is based on the dual-water model and is normally made in two passes.

On the Pass One log (Fig. 49.46), the SP curve is on Track 1 with the gamma ray. On Track 2, in four cycles, are found the R_t curve, the R_{wa} (computed from R_t), and the porosity given by the CNL. Track 3 shows the porosity given by the density, ϕ_D , the porosity given by the neutron, ϕ_N , and a crossplot porosity computed from ϕ_D and ϕ_N .

On Pass Two log (Fig. 49.47), the Track 1 gives the shale index, which is the minimum shale index of several shale indicators obtained from the SP curve, the gamma ray, and the maximum and minimum neutron readings. Track 2 shows R_t as a dashed curve and R_0 as a solid

curve. The left half of Track 3 has the water saturation and the right half has the porosity and bulk volume free water. A differential caliper is presented as a dotted curve with bit size in the middle of Track 3. A gas flag appears in the depth track when a large hydrocarbon correction was necessary to obtain the porosity from neutron/density logs.

VOLAN™ is an example of a complex analysis program (Fig. 49.48). It is based on the dual-water model, as is the CYBERLOOK program mentioned previously, but the computations are far more refined and the results more accurate. For a detailed study of the dual-water model, see Refs. 37 and 38. The dual water model simply says that in a shaly sand, its equivalent formation water conductivity is dependent on the relative amount of "bound" water and "free" water.

The conductivity of the bound water is found by the use of the nearby shale resistivity and the total porosity given by the average of CNL. In a like manner, the free

Fig. 49.47—CYBERLOOK Pass Two log.

water conductivity is found by use of the resistivity of the clean water sand and its total porosity. In a shaly water sand, the equivalent water conductivity is found in the same way by using the resistivity of the shaly water sand and its total porosity. Knowing the bound and free water conductivities, it is easy to compute their fractions of the total porosity that are necessary to obtain the same equivalent water conductivity of the shaly water sand.

The fractions of bound and free water can be related to the relative deflections of the gamma ray or SP curve, etc., thus permitting the use of such calibrations when analyzing hydrocarbon saturated zones. The analysis is done by using a dispersed-clay-type equation.

Nomenclature

a_{mf} = chemical activity of mud filtrate
 a_w = chemical activity of formation water

A_c = corrected attenuation of a formation
 A_{log} = recorded attenuation of a formation
 C = equivalent conductivity of losses in the formation
 C_{IL} = conductivity as given by induction log
 C_T = total conductivity signal
 C_i = conductivity of invaded zone
 C_m = conductivity of mud
 C_t = true conductivity of formation
 C_{xo} = conductivity of flushed zone
 E = electric field
 E_c = total electrochemical EMF
 E_j = liquid-junction EMF
 E_M = shale-membrane EMF
 E_{PSP} = pseudostatic SP
 E_{SSP} = static SP

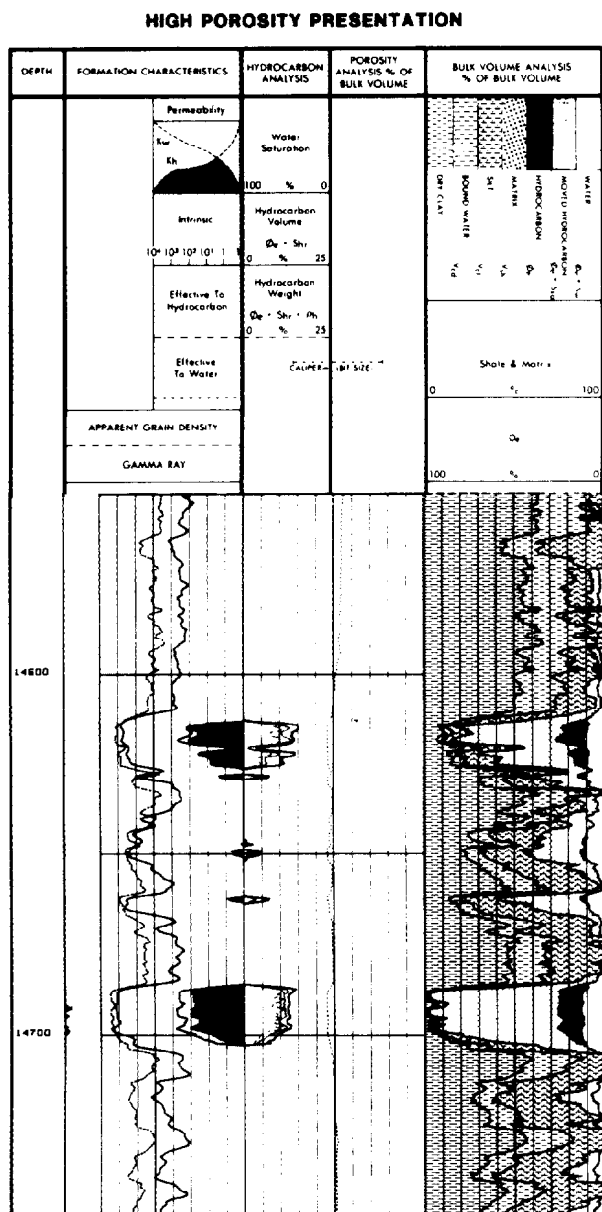

Fig. 49.48—High-porosity presentation.

- E_0 = electric field at the first receiver
 F_R = formation resistivity factor
 F_{R_w} = resistivity factor of formation water
 $F_{R_{wi}}$ = resistivity factor of water in invaded zone
 f_w = fraction of interstitial (connate) water in the total mixture
 G_i = geometrical factor of invaded zone
 G_m = geometrical factor of mud
 G_{pi} = pseudogeometrical factor of the invaded zone
 G_{sl} = geometrical spreading loss
 G_t = geometrical factor, true formation
 G_{xo} = geometrical factor of flushed zone
 I_R = resistivity index
 j = vectorial operator $\sqrt{-1}$

- K_c = electrochemical coefficient
 m = cementation exponent or factor
 n = saturation exponent
 R_a = apparent resistivity
 R_{an} = annulus resistivity
 R_c = corrected resistivity
 R_{IL} = induction-log resistivity
 R_{PL} = proximity-log resistivity
 R_i = resistivity of invaded zone
 R_{mc} = resistivity of mudcake
 R_{mf} = resistivity of mud filtrate
 R_t = true formation resistivity
 R_w = formation-water resistivity
 R_{we} = equivalent formation-water resistivity
 R_{wi} = resistivity of the water found in the invaded zone
 R_{xo} = resistivity of flushed zone
 R_0 = resistivity of a clean (nonshaly) formation saturated with 100% water
 $R_{1 \times 1}$ = resistivity of 1- \times 1-in. microinverse
 R_2 = resistivity of 2-in. micronormal
 R_{16} = short-normal resistivity
 S_i = water saturation in the invaded zone
 S_{or} = residual oil saturation
 S_w = formation water saturation
 S_{xo} = water saturation in the flushed zone
 t_{ph} = propagation time for hydrocarbon
 t_{pl} = travel time in the lossy medium
 t_{pm} = loss-free propagation time of matrix
 t_{po} = loss-free propagation time
 t_{pwo} = loss-free propagation time of water
 Y = maximum producible oil index
 α_{SP} = SP reduction factor
 γ = complex propagation factor
 ϵ = relative dielectric permittivity
 μ = magnetic permeability
 ϕ_D = density porosity
 ϕ_{EPT} = electromagnetic propagation tool porosity
 ϕ_{HC} = hydrocarbon porosity
 ϕ_N = neutron porosity

Chapter 50

Nuclear Logging Techniques

Darwin V. Ellis, Schlumberger-Doll Research *

Introduction

In this chapter, the use of nuclear radiation in wireline logging will be presented. To avoid repetition, the reader is referred to Chap. 49 for a basic introduction to the principles of wireline logging in terms of the operation and general types of devices used in the area of electrical logging; Chap. 51 discusses the third major area—acoustic well logging.

To introduce the general subject of nuclear logging, it is appropriate to provide a motivation for the use of nuclear measurement techniques in well logging. This can be done best by constructing a list of petrophysical parameters of interest in the evaluation of hydrocarbon-bearing formations. In the most straightforward application, the purpose of well logging is to provide measurements that can be related to the volume fraction and type of hydrocarbon present in porous formations. In the case of openhole logging (as distinguished from measurements made in a production well with steel casing), there are four principal parameters of interest: (1) presence of hydrocarbons, (2) porosity, ϕ , (3) water saturation, S_w , and (4) permeability, k . To this list, additional parameters or descriptors can be added: (5) lithology, (6) clay identification, and (7) pore fluid identification. For cased-hole logging the same list of petrophysical parameters of interest may hold, but with perhaps more emphasis on fluid identification.

Relationship of Petrophysical Parameters and Physical Parameters

These petrophysical parameters of interest are derived normally from a number of measurements provided by logging services. For the moment, we will concentrate on some bulk physical parameters associated with them that may be amenable to measurement through the use of nuclear techniques.

Presence of Hydrocarbons. An obvious method for the detection of hydrocarbons is based on their chemical compositions. Since there is no oxygen in most hydrocarbons, the ratio of the atomic concentration of carbon to oxygen for a hydrocarbon is significantly different from the ratio for most sedimentary rocks and formation fluids. Thus, a measurement of the ratio of the number of carbon atoms to oxygen atoms (C/O) contained in a formation would indicate directly the presence of hydrocarbons when no carbon is present in the matrix. This is to be contrasted with the method of electrical measurements, where detection of hydrocarbons is based on the contrast of conductivities between saline water and hydrocarbon in a porous medium.

Porosity. The porosity or nonmatrix portion of a rock sample can be determined from a measurement of its bulk density. The fundamental equation that relates the bulk density, ρ_b , to the solid matrix, which has a density ρ_{ma} , and the porosity or volume fraction, ϕ , which contains a fluid of density ρ_f , is

$$\rho_b = \phi \rho_f + (1 - \phi) \rho_{ma} \quad \dots \dots \dots (1)$$

From this relationship, the porosity, ϕ , can be determined from a measurement of bulk density, assuming that the matrix density and fluid density are known. These will be known with any precision only if the fluid type and properties and the lithology are known. In practical terms, the density range of fluids is between 0.8 and 1.2 g/cm³ (although calcium chloride solutions may reach 1.4 g/cm³), and most matrix densities are between 2.60 and 2.96 g/cm³.

Another means of detection and quantification of porosity is based on the fact that the formation porosity is filled with liquid or gas, all of which contain disproportionate amounts of hydrogen. This hydrogen may be

*Author of the original chapter on this topic in the 1962 edition was John L.P. Campbell.

associated with the brackish formation water or with the hydrocarbons. Thus, detection of hydrogen is a means of inferring porosity in an otherwise solid rock matrix.

Hydrocarbon Saturation. The determination of hydrocarbon saturation can proceed once the porosity of a formation has been determined. It can be done (1) by the direct measurement of C/O and comparison to the value expected for fully oil- and water-saturated cases, or (2) by a more indirect measurement of the effective salinity of the formation in question.

Permeability. There is no clear-cut physical parameter amenable to nuclear measurements that will predict formation permeability accurately. However, there is one measurement technique—nuclear magnetic resonance—that can be related to permeability; it is discussed in Chap. 53.

Lithology, Clay Types, and Fluid Identification. These parameters have been grouped together because of a common approach for their determination, which is basically some aspect of their chemical composition.

There are two principal interests in identifying the lithology. One is for a reasonable matrix density to be assigned to a formation so that porosity can be extracted from the density measurement. The other is to provide identification of formations for use in well-to-well correlation. Since the neutron properties of rocks are somewhat dependent on the type of lithology, it is possible to determine the three principal lithological matrices by comparison of the gamma ray attenuation and neutron-slowing-down properties of the medium. Well-to-well correlation often is done most simply by comparison of the natural radioactivity of the formations.

However, a more direct approach for the identification of the lithology (i.e., sandstone, limestone, or dolomite) is not based on the density but rather on the unique chemical composition of each of these matrices. One method of identifying the lithology would be to make a chemical identification of the various elements associated with the matrix. Another slightly more refined approach to the determination of the lithology depends on another bulk property of the material: its average atomic number. The average atomic number of the formation, which reflects to some extent the lithological composition, can be obtained by measuring the low-energy gamma ray absorption properties of the material.

Identification and quantification of clays are much more difficult, since the chemical compositions of clays are so varied. Hence, the chemical composition of clays is a key to their detection. A measurement of the presence of elements such as Al, Si, Fe, and K must be counted as a means to their identification. An earlier technique, which measured the total natural gamma ray activity of earth formations, was based on the fact that the naturally occurring radioactive daughter products (subsequent products of radioactive decay of an element) of uranium, thorium, and potassium were associated with clay minerals. Sometimes, however, one or more of these elements (U, Th, K) is present in a formation containing no clay. Examples of this include the case of potassium feldspar in the rock matrix or uranium dissolved in the formation water.

A third property of clays is the great abundance of hydrogen associated with the clay mineral structure. Thus, detection of the presence of hydrogen is another means of clay identification.

Pore fluid identification is based on indirect measurements and inferences. The presence of gas in the formation pores will have a significant impact on the bulk density for reasonable porosities as well as on the neutron-slowing-down properties. The distinction between oil and water again is measured most directly by the atomic C/O density ratio or based on the thermal neutron absorption properties of the water phase, which generally contains chlorides.

Fig. 50.1 summarizes the relationships between petrophysical descriptors and physical parameters, which can be determined quantitatively through the use of nuclear radiation and measurement techniques. A third column has been added to indicate the additional information necessary to interpret the suggested bulk property measured to obtain the desired petrophysical descriptor.

Physical Parameters and Nuclear Radiation

Before presenting the basic nuclear phenomena necessary to describe the operation of most of the common nuclear logging devices, we need to link, in general terms, the physical parameters discussed previously to the types of general nuclear techniques that will be described later in more detail. To be specific, it should be pointed out that the types of nuclear radiation used in well logging are gamma radiation and neutrons. These two types of penetrating radiation are the only ones that are able to traverse the pressure housings of the logging tools and the formation of interest and still return a measurable signal. It is for this reason that α and β radiation are of no particular interest for exploring formation characteristics; their penetration ranges are much too small to be of any practical use.

In the preceding section, it is clear that many of the proposed parameters to be measured are, in fact, no more than the chemical composition of the earth formation. Instead of the obvious but time-consuming and expensive chemical analysis of formation samples, a technique of gamma ray spectroscopy can be used. This is based on the fact that the nucleus of any atom, after having been put into an excited state by a previous nuclear reaction, can emit gamma rays of characteristic energies, which uniquely identify the atom in question. Gamma ray spectroscopy refers to the detection and identification of these characteristic gamma rays.

Another use of gamma rays is in conjunction with the measurement of bulk density. The bulk density of a material has a significant influence on the scattering and transmission of gamma rays through it. At very low energies, the transmission of gamma rays is influenced additionally by the chemical composition. This additional absorption is related to the atomic number, Z , of the absorber.

The interest in using neutrons in well logging techniques comes from several properties of their interaction with matter. First, the transmission and moderation of neutrons are influenced by the bulk properties of the medium and, in particular, by the amount of hydrogen present. The scattering of neutrons by hydrogen is very

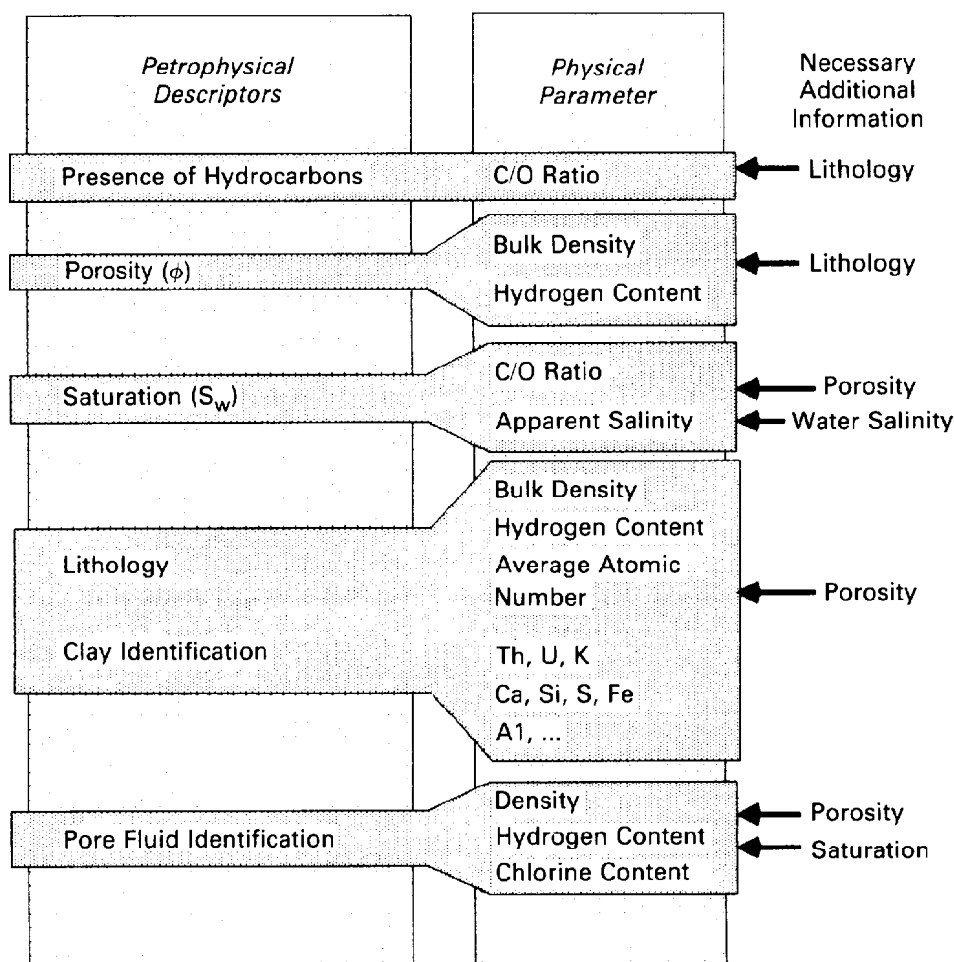

Fig. 50.1—Relationship between petrophysical descriptors and measurable physical parameters.

efficient in reducing the neutron energy. Second, interaction of high-energy neutrons with certain nuclei can excite characteristic gamma rays for subsequent elemental identification by gamma ray spectroscopy. At very low energies, neutrons can be absorbed, thereby reducing the flux, and as a byproduct, another set of characteristic gamma rays may be emitted. Some of these capture gamma rays are emitted after some delay and are referred to as activation gamma rays. So there are two types of measurements that can be based on the use of neutrons: the scattering or slowing-down properties of formations and neutron production of gamma rays (either by absorption or inelastic high-energy reactions with elements) of characteristic energies for use in spectroscopic identification. Fig. 50.2 illustrates the types of nuclear measurement techniques that can be used to measure physical parameters related to the relevant petrophysical descriptors sought.

Nuclear Physics for Logging Applications

Nuclear Radiation

Nuclear radiation refers to the transport of energy by a nuclear particle. In the earliest investigation of radioactive materials, three types of radiation were identified

and named, quite unimaginatively, α , β , and γ radiation. It subsequently was discovered that α radiation consisted of fast-moving He particles stripped of their electrons and that β radiation consisted of energetic electrons. The gamma rays were found to be packets of electromagnetic radiation, also referred to as photons.

The discovery of this radiation then provoked its quantification, namely the measurement of the amount of energy transported. The unit chosen is known as the electron-volt (eV), which is equal to the kinetic energy acquired by an electron accelerated through an electric potential of 1 V. For the types of radiation discussed in the following sections, the range of energies is between fractions of an eV and millions of electrons volts (MeV). Another convenient multiple for discussing gamma ray energies is the kiloelectron volt (keV).

Since α and β radiation consist of energetic charged particles, their interaction with matter is primarily ionization. That is, they interact with the electrons of material by losing energy rapidly during their passage and transferring it to electrons. In most materials their range is rather limited and is a function of the material properties (Z , the atomic charge or number of electrons per atom, and its density) and the energy of the particle. They consequently have not been of any practical impor-

Fig. 50.2—Nuclear measurement techniques linked to measurable physical parameters of petrophysical interest.

tance for well logging applications. Gamma rays, on the other hand, are extremely penetrating radiation, which makes them of great importance for well logging applications.

Radioactive decay of certain naturally occurring substances such as radium was responsible for the developments mentioned and needs further discussion. Radioactive decay is a time-varying property of nuclei whereby a transition from one nuclear energy state to another lower one is made spontaneously. The result is that the excess energy is shed by the nucleus by one or more of the types of radiation previously mentioned. The basic experimental fact of radioactivity is that the probability of any one nucleus decaying, within an interval of time dt , is proportional to dt —i.e., it is independent of external influences, including the decay of another nucleus. This probability is proportional only to the time interval of observation. So for a *single* radioactive atom the probability $P(dt)$ of decaying in the interval of time dt is expressed as

$$P(dt) = \lambda dt, \quad (2)$$

where λ is the decay constant. For a *collection* of N_p particles, the number decaying, dN , is just

$$dN = -\lambda dt N_p, \quad (3)$$

resulting in the expression for radioactive decay, namely

$$\frac{dN}{N_p} = -\lambda dt \rightarrow N_p = N_i e^{-\lambda t}, \quad (4)$$

where N_p now is the number of particles remaining at time t , of the initial number of particles N_i . The constant of proportionality, λ , is related to the better-known parameter, the half-life, $t_{1/2}$, by

$$t_{1/2} = \frac{0.693}{\lambda}. \quad (5)$$

No physical quantity can ever be measured exactly, but in the case of nuclear processes where the number of events observed is small, randomness is important. The practical complication of this statistical process of nuclear decay is that only the bulk or average properties can be predicted with any certainty. We can talk only about the measurement of a group of particles together and the distribution of the measured value about some mean.

To understand one important property of nuclear radiation, it is necessary to digress a moment for a quick review of the binomial distribution, which was discovered in the 18th century by Bernoulli. It describes the probability, P_x , that an event that has a probability P of occurring will occur x times when the observation is repeated z times. The probability thus specified was identified with the binomial expansion of $(P+q)^z$, where

$$q = 1 - P, \dots\dots\dots (6)$$

so that the general term of the expansion is

$$P_x = \frac{z!}{x!(z-x)!} P^x (1-P)^{z-x}, \dots\dots\dots (7)$$

which gives the probability of x occurrences in z trials.

This expression can be applied to radioactive decay, in which P_x represents the probability of having x nuclei decay in time dt when there are z atoms present. For this case, generally the probability P is very small but the number of particles observed (z) is very large so that Eq. 7 simplifies to

$$P_x = \mu^x \frac{e^{-\mu}}{x!}, \dots\dots\dots (8)$$

which is known as the Poisson distribution. It gives the probability of observing x decays in a given time where an average of $\bar{\mu}$ decays is to be expected. Fig. 50.3 shows the general form of the Poisson distribution with the maximum probability at the mean value, which was taken as 100 for this example. The curve resembles the usual bell-shaped distribution curve with a width specified by a parameter σ , the standard deviation.

The practical importance of this discussion is that the appropriate σ for the Poisson distribution that characterizes the statistics of counting random nuclear events is not an independent parameter (as is the case for most measurements) but is related to the mean value $\bar{\mu}$ by

$$\sigma = \sqrt{\bar{\mu}}, \dots\dots\dots (9)$$

This means that if N_r counts from a radiation detector are expected per time interval, then, in repeated observations, about 32% of the measurements will deviate beyond the value of $N_r \pm \sqrt{N_r}$. This is a quantitative description of the statistics associated with all nuclear logging techniques.

Fig. 50.3—The Poisson distribution for the case of mean value ($\bar{\mu}$) of 100. The probability, P_x , is shown for values of x around the expected mean value.

There have been a number of clever techniques for dealing with the statistical fluctuations inherent in nuclear counting rates. Probably best known is the R-C circuit, which has a time constant associated with it and permits the recording of a continuous moving average. There are now more modern digital signal processing techniques (such as Kalman filtering) to provide more refined filtered counting rates or outputs derived from statistically varying counting rates. However, the only sure approach to reduce the fluctuations is to increase the average number measured, either by using higher-output sources, more efficient counters, or longer counting times per sample.

Particle Reactions. There are certain nuclear particle interactions of interest to well logging. To discuss these as necessary in the following sections, a few mathematical definitions are presented here to help the mechanisms of the reactions.

As in radioactive decay, the process of nuclear reactions is also statistical in nature. The question of interest is how readily these reactions will take place. Fig. 50.4 shows the idealization of the nuclear reaction process. A beam of radiation (it may be gamma rays or neutrons) of an intensity Ψ_i is seen to enter the slab of material. The intensity of the radiation, Ψ_i , is called the flux and has units of numbers of particles per unit surface area per unit time.

The slab of material is characterized by N_p , the number of particles per unit volume with which the flux of radiation may interact. The experimental fact observed is that after passing through a slab of material of thickness δh , a certain fraction of the incident particles have undergone interactions, and that number is proportional to the thickness and the number of target nuclei and the incident flux. This is expressed mathematically as

$$\delta \Psi = \sigma \Psi N_p \delta h, \dots\dots\dots (10)$$

Fig. 50.4—Idealized view of nuclear radiation interacting with matter showing the reduction in flux traversing a thickness of material characterized by the number of interacting particles per cubic centimeter.

where the constant of proportionality, σ , is called the cross section of the interaction. The units of this microscopic cross section σ are area/interacting target nucleus. Cross section is used because in a classical sense it is the apparent area each target nucleus presents to the incoming beam. In effect, it collects all the nuclear interaction details into one useful number. The practical unit is called the "barn" and is equal to 10^{-24} cm^2 . The macroscopic cross section, Σ , is the product of σ and N_p and has the dimension of area/particle times particles/volume or inverse length. In practical terms, Σ can be calculated easily because N_p is related to Avogadro's number, N_A , and the material density, ρ_b , by

$$N_p = \frac{N_A}{M} \rho_b, \quad (11)$$

where M is the molecular weight of the target for a single particle per molecule.

In general, the cross sections for most reactions must be determined experimentally and are often available in graphical or tabular form. The quantity $\sigma \Psi N_p$ in Eq. 10 has dimensions of $(\text{cm}^3 \cdot \text{sec})^{-1}$ and has the interpretation of the reaction rate per unit volume resulting from the incident flux.

Nuclear Reactions. To discuss the second type of radiation of great importance to well logging applications—neutrons, which are not the result of naturally occurring radioactive decay schemes—a brief discussion of artificial or induced radioactivity is given here.

The classic reaction that inspired the discovery of the neutron was the bombardment of beryllium by alpha particles and can be written as

This forms the basis for the cheapest, easiest, and most reliable method for neutron production. The physical explanations of this reaction are beyond the scope of interest of the present work and may be found in Refs. 1 and 2. The practical construction of a neutron source consists of finding a naturally occurring α emitter and mixing it with an appropriate light element having a large $(\alpha, n)^*$ cross section. Some possibilities for α emitters are Pu, Ra, Am, and Po. Three target elements are Be, B, and Li. The actual spectrum (energy distribution) of emitted neutrons is quite complicated and depends somewhat on the geometric details of the α emitter and target; but generally speaking, the peak of the neutron distribution is around 4 MeV.

Another method of exploiting particle-induced reactions is by use of charged particle accelerators. In one realization currently used in well logging, deuterium and tritium ions are accelerated toward a target impregnated with the hydrogen isotopes deuterium (D) and tritium (T). The reaction is written as

The cross section for this reaction has a maximum at about 100 keV of D projectile energy, which dictates the accelerating voltages in such a device.

Despite the engineering difficulties of constructing such a device, the advantages for logging are many. One is the relative high energy of the produced neutrons. They are emitted at 14.1 MeV (not 17.6 MeV, because some of the energy of this reaction is given up to the alpha particle). These high-energy neutrons are useful for producing other interesting nuclear reactions in the formation, as discussed later. The other advantage is that a source of this type can be controlled—i.e., switched off and on at will. This provides a degree of safety unparalleled for radioactive sources as well as opening the door to measurements involving timing as a means of determining some interesting nuclear properties of the formation.

Now that we have covered the two types of nuclear radiations currently used in logging devices, let us examine how gamma rays and neutrons interact with matter and define some macroscopic properties of matter that can be used to characterize this behavior.

Fundamentals of Gamma Ray Interactions

For the purposes of our discussion there are three types of gamma ray interactions that are of interest: the photoelectric effect, Compton scattering, and pair production. The type of interaction a gamma ray will undergo depends on the properties of the material and the energy of the gamma ray. The ordering of these three interactions reflects the transition of the dominant process as the gamma ray energy increases.

The photoelectric effect concerns the interaction of a gamma ray with an atomic electron in the material. In this process the incident gamma ray disappears and transfers its energy to the bound electron. Depending on

*This shorthand (α, n) indicates a reaction of an α particle with an unspecified nucleus, n , resulting in the production of a neutron and another unspecified nucleus.

the energy of the incident gamma ray, generally the electron is freed from its nucleus and begins collisions with the adjacent material. Normally the ejected electron is replaced by another electron with the accompanying emission of a characteristic fluorescence X-ray with an energy dependent on the atomic number of the material and generally below 100 keV.

The cross section for the photoelectric effect, σ_{pe} , varies strongly with energy, falling off as nearly the cube of the gamma ray energy (E_{GR}). It is also highly dependent on the atomic number (Z) of the absorbing medium. In the energy range of 40 to 80 keV, the cross section per atom of atomic number Z is given by

$$\sigma_{pe} \propto \frac{Z^{4.6}}{E_{GR}^{3.15}} \quad (14)$$

For most earth formations the photoelectric effect becomes the dominant process for gamma ray energies below about 100 keV.

The photoelectric effect is an important process in understanding one of the conventional gamma ray detection devices and a well logging tool³ that is sensitive to the lithology of the scattering formation. The tool in question makes a measurement of the photoelectric absorption factor, F_{pe} , which is proportional to the photoelectric cross section per electron.

Since this quantity is very sensitive to the average atomic number of the medium, Z , it can be used to obtain a direct measurement of the lithology of the scattering medium. This is because the principal rock matrices (sandstone, limestone, and dolomite) have considerably different photoelectric absorption characteristics and the pore fluids play only a minor role because of their low Z 's.

The Compton scattering process involves the interaction of a gamma ray and an electron. It is a process in which only part of the gamma ray energy is imparted to the electron and the energy of the gamma ray, consequently, is reduced. Unlike the photoelectric effect, the probability for Compton scattering changes relatively slowly with energy.

To see the bulk effect of Compton scattering in a material consisting of nuclei of atomic mass A and atomic number Z , one can use the linear absorption coefficient, which is just the Compton cross section, σ_{Co} , multiplied by the number of electrons per cubic centimeter:

$$\Sigma_{Co} = \sigma_{Co} \frac{N_A}{A} \rho_b Z. \quad (15)$$

The final Z factor in this equation takes into account that there are Z electrons per atom. Consequently, the attenuation of gamma rays resulting from Compton scattering will be some function of the bulk density (ρ_b) and the ratio of $Z/A \approx 1/2$ for most elements of interest is the basis for the determination of bulk density from gamma ray scattering devices.

The third and final gamma ray interaction is that of pair production. It, like the photoelectric process, is one of absorption rather than scattering. In this case the gam-

Fig. 50.5—Regions of dominance of the three major gamma ray interactions in terms of the gamma ray energy, E_{GR} , and the atomic number, Z , of the target material. The two lines separating the three regions indicate where the two adjacent interactions occur with equal probability.

ma ray interacts with the electric field of the nucleus, and if the gamma ray energy is above the threshold energy of 1.022 MeV, it disappears and an electron/positron pair is formed. The subsequent annihilation of the positron (positively charged electron) results in the emission of two gamma rays of 511 keV each. The cross section of this process is somewhat energy-dependent and is zero below the required threshold energy of 1.022 MeV. In addition, it also depends on the charge of the nucleus.

To establish the regions of dominance of the three types of interactions, refer to Fig. 50.5. It shows, as a function of gamma ray energy and atomic number of the absorber, the regions in which the probabilities of the various processes are equal. The regions of dominance are quite clear.

From the earlier definition of cross section, the fundamental law of gamma ray attenuation can be stated as

$$\Psi = \Psi_i e^{-n\sigma h}, \quad (16)$$

where Ψ_i is the flux incident on a scatterer of thickness h , n is the number of scatterers per unit volume, and σ is the cross section for scattering per scatterer.

In the case of gamma-gamma density devices, the source of gamma rays is chosen to have an energy for which the primary interaction is Compton scattering. In this case the scatterers are electrons and σ refers to the Compton cross section per electron. This results in the following expression for the attenuation of the source energy gamma rays:

$$\Psi = \Psi_i e^{-\rho_b (Z/A) N_A \sigma h}, \quad (17)$$

where h , in this case, is very nearly the source-to-detector spacing.

It is convenient to define the electron density index as

$$\rho_e = 2 \frac{Z}{A} \rho_b, \quad (18)$$

Fig. 50.6—The mass absorption coefficient for gamma ray interactions in aluminum.

so that the attenuation of the gamma rays is seen to be proportional to the spacing, h , between source and detector and the electron density index, which in turn can be related to the bulk density if the properties (specifically Z/A) of the scattering material are known. For most sedimentary rocks the ratio of Z/A is nearly $1/2$ so that ρ_e is very nearly equal to ρ_b .

Another unit for measuring the gamma ray attenuation properties of a material is the mass absorption coefficient, K_a ,* which regroups the constants in Eq. 17—i.e.,

$$K_a = \frac{Z}{A} N_A \sigma, \dots \dots \dots (19)$$

so that the gamma ray attenuation equation can be written as

$$\Psi = \Psi_i e^{-K_a \rho_b x}, \dots \dots \dots (20)$$

The convenience of the mass absorption coefficient for Compton scattering is that it is remarkably similar for all materials since $Z/A \approx 1/2$ and the density dependence has been eliminated. Fig. 50.6 shows the mass attenuation coefficients (in cm^2/g) for aluminum. This element, with a density of 2.7 g/cm^3 and atomic number of 13, is quite typical of earth formations. The average atomic number ranges from 11 to 16 between quartz and limestone, while the grain densities are between 2.65 and 2.71 g/cm^3 .

Fundamentals of Neutron Interactions

As in the case of gamma rays, the interaction of neutrons with materials can be categorized by the types of interactions with the appropriate cross sections that describe

*The symbol used in physics for mass absorption coefficient is μ .

Fig. 50.7—The relationship between neutron energy and speed for the three broad classifications of neutron energies.

each one. The reactions of neutrons with matter are much more varied and complex than those of the gamma rays. For simplification we will confine ourselves to four principal types of interactions of neutrons with matter.

Fig. 50.7 defines in broad terms the energy range of interest for neutrons. For logging applications it can be seen that the energy range of interest is over about 9 decades: from source neutrons of 5 to 15 MeV in the broad fast neutron range above 10 eV, to epithermal neutrons in the range of 0.2 to 10 eV and thermal neutrons, which are distributed around 0.025 eV at room temperature.

To have an idea of the time scale for later discussions of the thermalization process, it is useful to note the relationship between neutron energy and its associated velocity. To evaluate the velocity of a neutron, we can use (at low energies) the classical relationship between kinetic energy, E_k , velocity, v , and mass, m ,

$$E_k = \frac{1}{2}mv^2, \dots \dots \dots (21)$$

so that the velocity, v , is given by

$$v = \sqrt{\frac{2E_k}{m}}, \dots \dots \dots (22)$$

If this expression for velocity is evaluated for thermal energies (0.025 eV), the result is 2200 m/s or 0.22 cm/μs. Thus, the velocity at any energy E (in eV) is given by

$$v = 0.22 \sqrt{\frac{E}{0.025}}, \dots \dots \dots (23)$$

where v is the velocity, cm/ μ s. Therefore, the speed of an epithermal neutron of 2.5 eV is 2.2 cm/ μ s, and for a near-source energy neutron of 2.5 MeV the velocity is 2200 cm/ μ s. These velocities are also noted on Fig. 50.7.

Of the four principal types of interactions, the first two generally are referred to as moderating interactions, or interactions in which the energy (or speed) of the neutron is reduced. One of these is known as elastic scattering and the other, inelastic scattering. Classical mechanics (elastic billiard ball analysis) can describe the moderating power of the struck nucleus. The energy of the neutron is reduced more efficiently as the mass of the struck nucleus approaches the mass of the neutron. Thus, hydrogen and other low-atomic-mass elements are quite efficient in reducing fast-neutron energy. Fig. 50.8 illustrates, for elastic neutron scattering with several elements, the range of reduction in neutron energy available for a single collision. It is seen that for the most common earth formation elements the maximum energy reduction per collision for the heavy elements is about 10 to 25%. However, for the case of hydrogen it is seen that the entire neutron energy can be lost in a single collision.

In the case of inelastic scattering, a portion of the energy of the incident neutron goes into exciting the target nucleus. This reduces the energy of the incident neutron and, in addition, the target nucleus usually will produce a characteristic gamma ray upon de-excitation. This type of reaction always has a threshold energy (below which it will not happen) associated with it and is exploited in the measurement of the C/O ratio in earth formations.

The second general category of neutron interactions is known as absorptive interactions. The two general types are radiative capture and reactions in general. In radiative capture, unlike the moderating interactions considered above, the neutron (usually near thermal energies) is absorbed by the target nucleus and then disappears, and subsequent characteristic gamma rays are produced. The general category of neutron reactions is quite broad; it will be sufficient to say that the interaction of neutrons with other nuclei can provoke the emission of other particles such as alphas, protons, β 's, or even several subsequent neutrons. All these reactions, although common, have a very small probability for happening relative to the other interactions of interest to us and usually occur over a restricted and high-energy range.

To show the complexity of the cross sections for neutron interactions see Fig. 50.9, which schematically indicates the variations with energy. The top figure refers to the total cross section as a function of neutron energy, E_N , and the four following figures indicate how this can be decomposed. The first line (n,n) refers to elastic scattering, which is shown to be rather constant with energy except for some resonances at low energies. The next line shows inelastic interactions (n,n') showing some characteristic threshold below which this reaction is not possible; the fourth line is one of the many particle reactions possible (n,α); and the final line (although there could be others) is the radiative capture (n,γ), which is seen to increase in probability at low energies.

Despite these complexities, there are some gross properties that can be assigned to materials on the basis of

Fig. 50.8—The range of energy reduction possible for neutron elastic scattering with several important elements for formation evaluation. E_0 is the energy before scattering, and E is the energy after scattering. Hydrogen is seen to provide the greatest possible energy reduction for a single collision.

Fig. 50.9—A schematic illustration of the components involved for the total neutron cross section as a function of energy. The characteristics of four specific cross sections are shown.

Fig. 50.10—The mean free path of fast neutrons in water and water-filled limestone at several porosities as a function of energy.

their neutron cross sections. The first is the macroscopic cross section, which is defined as the product of the cross section in question times the number of atoms per cubic centimeter, N_p —i.e.,

$$\Sigma_i = N_p \sigma_i = \frac{N_A \rho_b}{A} \sigma_i \quad (24)$$

The dimensions of the macroscopic cross section Σ_i are inverse centimeters and the interpretation is that its reciprocal is the mean-free-path length in centimeters between interactions of Type i . Frequently in logging, use is made of the macroscopic absorption cross section at thermal energies. The units of this (so-called capture units, c.u.) are just 1,000 times the Σ_i defined previously, where σ_i refers to the thermal absorption cross section, which is dominant at thermal energies for most elements. Fig. 50.10 shows the total mean free path in limestone of 0, 20, 40, and 100 porosity units (PU) as a function of energy for fast neutrons. At the energy of chemical source emission (2 to 4 MeV), it is seen that there is very little porosity dependence. It is only as the neutrons are slowed down that the mean free path becomes strongly porosity-dependent.

As mentioned earlier, in the case of elastic scattering, low-mass nuclei are more efficient in reducing the energy of the scattered neutron. As can be inferred from Fig. 50.8, the result of a collision can be considered, on average, as a percentage decrease of the neutron energy. This

usually is expressed as the average logarithmic energy decrement, ξ :

$$\bar{\xi} = \overline{\ln(E_i) - \ln(E)} = -\overline{\ln(E/E_i)} \quad (25)$$

It can be shown from classic mechanics that the average log energy decrement is simply related to the atomic mass, A , of the struck nucleus by

$$\bar{\xi} \approx \frac{2}{A+2/3} \quad (26)$$

for large values of atomic mass A . The average log energy decrement allows an estimation of the average number of collisions, n , to reduce the neutron from an initial energy E_i to some lower energy E from the following reasoning. If the sequence $E_1, E_2 \dots E_n$ represents the average energy after each collision, then we can write

$$\ln\left(\frac{E_i}{E_n}\right) = \ln\left(\frac{E_i}{E_1} \frac{E_1}{E_2} \dots \frac{E_{n-1}}{E_n}\right) \quad (27)$$

$$= \ln\left(\frac{E_i}{E_1}\right)^n = n \ln\left(\frac{E_i}{E_1}\right) \quad (28)$$

$$= n\bar{\xi} \quad (29)$$

TABLE 50.1—NEUTRON SLOWING-DOWN PARAMETERS

Moderator	ξ	\bar{n}^*
H	1.0	14.5

20-PU limestone	0.514	29.7
0-PU limestone	0.115	132

*Average number of collisions from 4.2 MeV to 1 eV.

Thus, the average number of collisions is given by

$$\bar{n} = \frac{1}{\xi} \ln \left(\frac{E_i}{E_n} \right) \dots \dots \dots (30)$$

The constant ξ can be computed for a mixture of elements by weighting the value of each ξ_i for element i with the appropriate total scattering cross section σ_i . Table 50.1 shows some typical values for the average logarithmic energy decrement and the number of collisions necessary to reduce source energy neutrons (4.2 MeV) to 1 eV.

There are two more parameters that help to characterize neutron interactions with bulk material. One parameter is known as the slowing-down length, L_s , and the other as the diffusion length, L_d . L_s can be described as roughly proportional to the average distance a neutron (in an infinite homogeneous medium) travels from its emission at high energy until it arrives at the lower edge of the epithermal energy region. This distance can be calculated⁴ with a detailed knowledge of the cross sections of the constituent elements. Fig. 50.11 shows the variation of L_s as a function of water-filled porosity for limestone, sandstone, and dolomite.

L_d can be thought of as the distance a thermal energy neutron travels between the point at which it became thermal until its final capture. This distance is given by

$$L_d = \sqrt{D/\Sigma}, \dots \dots \dots (31)$$

where D is the thermal diffusion coefficient and Σ is the macroscopic thermal absorption cross section of the material. The diffusion coefficient, D , also can be calculated from the knowledge of the cross sections of the material and is shown in Fig. 50.12 as a function of porosity for the three principle matrices.

Since thermal neutrons will be affected strongly by the presence of thermal absorbers, it is interesting to look at an abbreviated list of elements that frequently are found in formations that have large macroscopic thermal absorption cross sections. This is found in Table 50.2, where the units are capture cross section (c.u.) per gram of material. Of particular interest is chlorine, the implication being that salt water will have some measurable effect on the thermal neutron population as well as iron and boron, which frequently are associated with clays.

Fig. 50.11—The calculated slowing-down length, L_s , as a function of water-filled porosity for three rock matrices: sandstone, limestone and dolomite.

Fig. 50.12—The calculated thermal diffusion coefficient, D , as a function of water-filled porosity for three rock matrices: sandstone, limestone, and dolomite.

Fig. 50.13—Components of a gas-discharge radiation detector.

Fig. 50.14—Schematic of the steps involved in gamma ray detection by the production of a measurable electrical signal in a photomultiplier coupled to an NaI crystal.

Another auxiliary parameter, the migration length (L_m), has been defined as

$$L_m^2 = L_s^2 + L_d^2 \quad (32)$$

It can be viewed as a distance that represents the combination of the path traveled during the slowing-down phase (L_s) and the distance traveled in the thermal phase before being captured (L_d). The use of this parameter provides a convenient way of predicting the response of a thermal neutron porosity device, which is discussed in more detail in a later section.

Nuclear Radiation Detectors

Gamma Ray Detectors. The devices for the detection of gamma rays involve the exploitation of one or more of the three processes of gamma ray interactions with matter described earlier. Three general types of gamma ray detectors in current use will be described next. The first variety, the ionized-gas counter, is a direct descendant of the earliest efforts in nuclear radiation detection. The second and most common present-day gamma ray detector used in well logging applications is the scintillation detector. The third type of device, the solid-state detector, is just beginning to be used in logging applications.

The common form of the ionized-gas or gas-discharge counter consists of a metal cylinder with an axial wire passing through it (Fig. 50.13) and insulated from it. The cylinder is filled with a gas that is normally nonconduc-

tive, and some moderate (several hundreds of volts) electrical potential is maintained between the central wire and the cylinder. The detection process is initiated by the formation of some ionized gas molecules. These freed electrons are accelerated by the radial electric field and in successive collisions produce additional free electrons, which finally results in a measurable charge collection on the central wire.

For gamma rays to be detected with such a device, the gas somehow must be ionized initially. Since the gas density is moderate, even at rather high pressure available in commercial tubes, and the atomic number of useful gases is relatively low, there is little possibility of the gamma rays interacting directly with the gas. The main detection mechanism is photoelectric absorption or recoil electron ejection from Compton scattering in the metal shield. For the gamma rays absorbed near the inner radius of the cylinder, there is some probability of the ejected electron escaping into the gas and providing the initial ionization. This also is illustrated in Fig. 50.13.

It should be evident from the foregoing discussion that the detection efficiency of such detectors is not high. It can be improved somewhat by the incorporation of conductive high-atomic-number gamma absorbers, such as silver, as an inner lining of the cylinder. Although they can be operated in a proportional mode, the energy resolution of these detectors is not of great practical use. The most positive aspects of gas-discharge counters are their simplicity, ruggedness, and reliability for functioning in the hostile environment of well logging. Because of their poor efficiency and inapplicability to spectroscopic gamma ray detection, they are being replaced rapidly by a newer generation of scintillation detectors.

A more common type of gamma ray detector uses a scintillation crystal. Once again, the active detector element is sensitive to ionizing radiation, such as energetic electrons. When these particles travel within the crystal lattice, they impart their energy to a cascade of secondary electrons, which finally are trapped by impurity atoms. As the electrons are trapped, visible or near-visible light is emitted. The light flashes are then detected by a photomultiplier tube optically coupled to the crystal and transformed into an electrical pulse. This is indicated schematically in Fig. 50.14. The output pulse height can be related to the total energy deposited in the crystal by the initial high-energy electron. The great advantage of such a detection scheme is the possibility of performing gamma ray spectroscopy—that is, to detect the actual energy of the incident gamma ray, which, in some cases, will identify uniquely the source of the emitted gamma ray, as in the case of induced gamma ray logging.

However, a scintillation detector is a detector of gamma rays only to the extent that an electron is produced in the crystal through one or more of the three basic gam-

TABLE 50.2—MACROSCOPIC THERMAL ABSORPTION CROSS SECTIONS

gamma ray interaction mechanisms: photoelectric absorption, Compton scattering, and pair production. Thus, the gamma ray detection efficiency of a scintillator will depend on its size, density, and average atomic number (for photoelectric absorption). A scintillator in common use is a crystal of sodium iodide doped with a thallium impurity, NaI (Tl), which has good gamma ray absorption properties and a fairly rapid scintillation decay time (~ 0.23 μsec) to allow for high-counting-rate spectroscopy.

The use of such a device for gamma ray spectroscopy implies that the output light pulse is proportional to the incident gamma ray energy; however, this is possible only for the case of total absorption of the gamma ray. Some of the difficulties that can complicate the detected spectrum are shown in Fig. 50.15, for the case of a tool designed to look for the unique gamma rays emitted by inelastic neutron reactions with carbon and oxygen. The figure illustrates what might happen to an inelastic carbon gamma ray that is produced at the site marked (IS) with an initial energy of 4.44 MeV. It first makes a Compton scattering in the borehole fluid (CS) and loses 90 keV of energy before traversing the tool housing and entering the NaI detector with an energy of 4.05 MeV. At the point marked (PP) it suffers a pair-production interaction, producing one electron and one positron with energies of 2.00 and 1.03 MeV, respectively, the missing 1.02 MeV having gone into the creation of the electron/positron pair. Both particles impart their energy to the scintillation process indicated by the dashed lines. When the positron has given up all its kinetic energy, it annihilates with an electron to produce two gamma rays, each of 0.51 MeV energy. One of the gamma rays undergoes Compton scattering at (CS), and the reduced-energy gamma ray (0.41 MeV) is finally absorbed photoelectrically within the crystal at point (Ph.A). The other 0.51-MeV gamma ray is shown escaping the crystal, to the right, and being absorbed in the tool housing without contributing to the total energy transferred to the crystal. The energy recorded by the crystal for the event depicted is 3.54 MeV ($4.05 \text{ MeV} - 1.02 \text{ MeV pair-production} + 0.511 \text{ MeV annihilation}$) instead of the 4.44 MeV that we would like to be measuring.

Thus, the degradation of the structure of the incident gamma ray spectrum is seen to be inherent in the physics of the many processes involved in the detection. Only if the gamma ray is absorbed totally by the detector is the light output of the scintillator proportional to the incident gamma ray energy. This would be the case for the photoelectric absorption, for example. Fig. 50.16 shows the energy deposited in this case as the single line to the right marked E_γ .

If only a Compton interaction occurs, then a fraction of the energy will be registered. The possible range of energy deposition in this case follows the distribution shown in Fig. 50.16 from zero to the Compton edge, which corresponds to the maximum energy being transferred from the gamma ray to the electron. Additionally, if the gamma ray is of sufficiently high energy there may be a pair-production reaction, and if one or more of the 511-keV photons escapes the detector without interaction, the so-called first and second escape peaks will be produced in the detected spectrum. Fig. 50.17 indicates the additional distortion introduced by this process.

In addition to the distortions in the measured spectrum produced by the possible interactions within the detector,

Fig. 50.15—Illustration of the possible sources of gamma ray energy degradation in an NaI detector system.

Fig. 50.16—Idealized response from a scintillation detector to mono-energetic gamma rays of energy E_γ , showing the photo-peak and the Compton tail.

Fig. 50.17—Idealized spectrum distortion in a scintillator caused by pair-production. The highest energy peak corresponds to photoelectric absorption or the full energy of the incident monoenergetic gamma ray, and the two lower energy escape peaks correspond to escape from the crystal of one or two of the annihilation gamma rays of 511 keV.

a dominant perturbation to the measurement is the detector resolution. This refers to the broadening of the line spectra, as can be observed clearly in Fig. 50.17. The width of the observed gamma ray lines is, in the case of an NaI detector, primarily a function of the gamma ray energy, the size of the crystal, and the optical coupling between the crystal and photomultiplier, as well as the characteristics of the photomultiplier. One of the major drawbacks of the scintillation detectors is their poor energy resolution. The reason is that detection in this type of device requires a number of inefficient steps, the result being that the energy required to produce one information carrier (a photo-electron in the photo-multiplier) is about 1,000 eV. Thus, the number of carriers for a typical radiation detection is rather small; the statistical fluctuations on such a small number place an inherent limitation on the energy resolution.

The use of semiconductor materials as radiation detectors can produce many more information carriers per detected event and, thus, can achieve a very-high-energy resolution. In a solid-state device such as the germanium detector, the semiconductor properties are used to transfer the charged-particle energy into a usable electrical pulse in a much more direct manner. When a gamma ray interacts with the detector, charged particles are produced. These, in turn, transfer energy to electrons bound (by only 0.7 eV for Ge) in the crystal lattice, enabling many of them to become free. Each free electron leaves a positive hole in the electron structure of the crystal. Under a strong electrical field applied to the detector crystal, the free electrons and holes migrate quickly to the electrodes and create an electrical impulse.

The excellent resolution arises because the band gap is so small. About 3.5×10^5 electrons are freed by the detection of a 1-MeV gamma ray to contribute to the resulting pulse with no intervening inefficient steps. The

result is sharp energy resolution. Another result is that the detector must be operated at extremely low temperatures. This is because at room temperatures the electrons have sufficient energy to cross the 0.7-eV band gap and camouflage those freed by gamma ray interactions. Although the gamma ray spectra obtained with Ge detectors are superb, their overall counting rates are less than those obtained by NaI detectors. Application of solid-state detectors is limited to devices concerned with precise spectroscopic elemental definition or in-situ chemical analysis.

Neutron Detectors. Neutrons are detected through nuclear reactions in which energetic charged particles are produced. Thus, most neutron detectors consist of a target material for this conversion coupled with a conventional detector, such as a proportional counter or scintillator, to achieve the measurement. Since the cross section for neutron interactions in most materials is a strong function of neutron energy, different techniques have been developed for different energy regions. For well logging applications, at present, it is the detection of thermal and epithermal neutrons that is of interest. The detection schemes considered in this section are appropriate for these low-energy neutrons.

The determination of useful nuclear reactions for neutron detectors involves satisfying several criteria: the cross section for reaction must be very large, the target nuclide should be of high isotopic abundance, and the energy liberated in the reaction following the neutron capture should be high for subsequent ease of detection by conventional means. Three target nuclei have been found generally to satisfy these conditions: ^{10}B , ^6Li , and ^3He . In the case of the first two targets, the (n, α) reaction is used, and for ^3He it is the (n, p) reaction.

The boron reaction is exploited widely in the form of BF_3 in a proportional tube. In this case the boron trifluoride serves as the target and as the proportional tube gas. For this application the gas is enriched in ^{10}B , to attain a high detection efficiency. Another approach is to use boron as the inner coating of a proportional counter, which may use some other proportional gas more suitable than BF_3 for applications involving fast timing, for example.

Since a suitable lithium compound gas does not exist, the lithium reaction is not exploited in a proportional counter. However, lithium scintillators, similar to those of sodium iodide for gamma ray detection, are available. Because of the large amount of energy released by the (n, α) reaction, neutrons are registered at an energy of about 4.1 MeV, which provides a means of discriminating against the gamma rays, which also will be detected readily by the LiI crystal.

The most common neutron detector in well logging, however, is based on the ^3He (n, p) reaction. In this case ^3He is used as the target and proportional gas in a counter. It is preferred to BF_3 because it has a higher cross section than the boron reaction and the gas pressure can be made much higher without degradation of its proportional operation. The overall simplicity of a proportional tube is preferred to the additional complications associated with a scintillator.

For the three reactions discussed, the cross sections vary inversely with the square root of the neutron energy so that the detection efficiency for neutrons will vary in the same manner. The detectors using these reactions, then,

are basically thermal neutron detectors. For some logging applications, it is desirable to measure the epithermal neutron flux while being insensitive to thermal neutrons. This can be achieved by making a minor modification to any of the three types of detectors previously mentioned. It consists of using an exterior thermal-neutron-absorbing material with a large cross section, such as cadmium, to shield the detector. Thermal neutrons will be absorbed in the shield, but the reaction particles, whose range is small (on the order of tenths of millimeters), will not reach the counter. The higher-energy neutrons that manage to penetrate the shield will be detected by the thermal neutron detector with somewhat reduced efficiency.

Nuclear Radiation Logging Devices

The logging devices discussed in the following section fall under two general categories: those that measure natural radiation fields and those that produce radiation fields and measure some aspect of their interaction with the formation. The first group contains tools that measure the natural gamma ray activity of earth formations resulting from the spontaneous decay of radioactive materials. The second category can be broken down into the type of radiation used—gamma rays or neutrons. The latter may be subdivided further into the use of chemical or steady-state neutron sources or pulsed particle accelerator-based sources described earlier.

Rather than trace the historical development, which has been well documented by Segesman,⁵ only the most recent logging devices will be discussed. Both neutron porosity and gamma-gamma density devices have undergone substantial evolution since their respective introductions as commercial services. The earliest devices invariably used a single detector. As the use of these types of measurements grew, more emphasis was put on improving the quantitative nature of the measurements and a better appreciation of environmental effects was gained. This led to the development of borehole-compensated devices generally using a second detector at a lesser spacing from the source that, because of its larger sensitivity to environmental effects, provides a correction to be applied to the principal detector.

Gamma Ray Devices

There are two series of naturally occurring radioactive isotopes that occur in significant quantities in sedimentary rocks: the uranium and thorium series. The only other significant naturally occurring radioisotope is that of potassium (⁴⁰K). Clay minerals that are formed during the decomposition of igneous rocks in general have a very high cation exchange capacity. Because of this property they are able to retain trace amounts of radioactive minerals that originally may have been components of the feldspars and micas that go into the production of clay minerals. This process generally results in a higher concentration of radioactive elements in shales than in sandstones or carbonate rocks not produced by weathering. However, some radioactivity can be associated with carbonate rock and sandstones because of transport of radioactive minerals in solution in the formation waters.

The principal use of the gamma ray log is to distinguish between the shales and the nonshales. Historically, the first gamma ray devices measured only the total gamma

Fig. 50.18—Theoretical gamma ray emission spectra from the three naturally occurring radioactive products.

ray flux emanating from the formation. However, it is now known that different types of shale have different total gamma ray activity because of the Th, U, and K concentrations. Fig. 50.18 shows the various gamma ray line emissions associated with each. This indicates that by determining the intensity of the particular gamma ray energies it is possible to identify the quantity of each radioactive emitter in the formation. With the development of improved spectroscopic-quality gamma ray detectors, it became natural to refine the gamma ray measurement into a measurement of the actual concentrations of the three components.

The measurement element for recent gamma ray or spectral gamma ray logging devices is the NaI detector. The gamma ray devices measure the total number of gamma rays above some practical lower limit (on the order of 100 keV). This total counting rate will be (1) a function of the distribution and quantity of radioactive material in the formation and (2) influenced by the size and efficiency of the detector used. For this reason some calibration standards have been established by the API, and all total-intensity gamma ray logs are recorded in API units.

The definition of the API unit of radioactivity comes from the artificially radioactive formation constructed at the U. of Houston facility. A formation containing approximately 4% K, 24 ppm Th, and 12 ppm U was constructed and defined to be 200 API units. The details of this calibration facility can be found in Ref. 6.

Spectral gamma ray devices basically use the same type of detection system as the total gamma ray devices, but instead of one broad energy region for detection, the gamma rays are analyzed into several different energy bins.

Fig. 50.19—Geometry for the gamma ray flux at a point from uniformly distributed sources in an infinite medium.

This allows for the determination (after comparing to normalized standard formations where the concentrations of K, U, and Th are known) of the concentrations of these elements present in the measured formation. These log output quantities usually are expressed as a percent by weight of the total material.

It is of interest to note that the gamma ray intensity from a uniformly distributed source (whose concentration is maintained at a constant value when expressed in weight percent of the medium in which it is embedded) is independent of the formation density, even though the attenuation is a direct function of the formation density. This can be seen from the following argument.

Consider an infinite homogeneous medium containing n gamma ray emitters per cubic centimeter, each with a source strength of emission of one gamma ray per second. To calculate the total gamma ray flux that would be seen by a detector at a given point in this medium, refer to Fig. 50.19. The contribution to the total counting rate from a spherical shell of thickness dr at a distance r from the detector would be the number of emitters contained in this shell multiplied by the attenuation over the path length r to the detector,

$$d\Psi = 4\pi r^2 n dr \frac{e^{-K_a \rho_b r}}{4\pi r^2}, \dots \dots \dots (33)$$

and the total counting rate is just the integral

$$\Psi = n \int_0^\infty e^{-K_a \rho_b r} dr, \dots \dots \dots (34)$$

$$\Psi = n \frac{1}{K_a \rho_b}, \dots \dots \dots (35)$$

This simply says that the total counting rate is proportional to n/ρ_b , which can be expressed as the weight percent of the material that is radioactive. Consequently, the utility of expressing the radioactive contents as weight fractions is seen.

One of the fundamental difficulties in the interpretation of the gamma ray device measurements is inherent in its very concept. There are nonradioactive clays and there are "hot" dolomites. The use of spectral gamma ray devices can often point out an anomaly such as a "hot" dolomite or other formation with some unusual excess of U, or in other cases K or Th.

Both types of devices suffer to some small degree from the borehole environment. Because of mud in the borehole and varying hole diameters, the gamma rays emitted from the formation must pass through different amounts of gamma ray absorbers to reach the detector. Additional complications can arise because of mud additives such as barite or KCl. In the first case, the barium content of the mud becomes a very efficient absorber of low-energy gamma rays emanating from the formation. In the second case, the borehole fluid is also a source of radioactive potassium, which is contained in the KCl additive. Ref. 7 discusses a method for correcting for these effects.

Gamma-Gamma Density Devices

As noted in an earlier section, the transmission of gamma rays through matter can be related to the electron density if the predominant interaction is Compton scattering. Thus, a gamma ray transmission-type measurement through a formation can be used to determine its density and with some information on the material composition (lithology and pore fluids) the porosity can be determined.

The gamma ray source usually used in density devices is ^{137}Cs , which emits gamma rays at 662 keV, well below the limit for pair production. This isotope has a half life of about 30 years, which provides a usable, stable intensity during a reasonable period. Some devices use ^{60}Co , which emits two gamma rays at 1332 and 1173 keV.

The earliest devices consisted of the gamma ray source and a single detector, which initially was called a Geiger-Müller tube. However, to compensate for the frequent occurrence of intervening mudcake, modern devices incorporate two detectors (generally both NaI) in a housing that shields them from direct radiation from the source and is forced up against the formation with a hydraulically operated arm. This arm provides a force of application as well as a measurement of the diameter (along one axis) of the borehole.

The measurement principle derives from the fact that the counting rate of a detector will vary exponentially with the density of the formation. Consequently, the formation density can be determined simply from an observed counting rate. However, in the case of intervening mudcake of unknown density and thickness, there will be a disturbance of the counting rate. Fig. 50.20 shows the usual logging situation. To correct for this intervening mudcake, the apparent density of the long- and short-spacing devices can be derived. Laboratory measurements then are used to define the correction, $\Delta\rho$, that must be applied to the apparent density from the long-spacing detector to read the value of the formation density behind it.

In at least one device the shape of the gamma ray spectrum is measured and correlated with the photoelectric absorption parameters of the formation, which, in turn, can be linked with the lithology of the formation. The photoelectric factor, F_{pe} , is proportional to the photoelectric cross section per electron. Fig. 50.21 shows the utility of such a measured parameter for distinguishing between the three principal matrices.

Since the F_{pe} of mixtures does not combine volumetrically, a new parameter, U , which has the property of combining linearly, has been developed for interpretation purposes. The definition of U is the product of F_{pe} and electron density,

$$U = F_{pe} \rho_e, \dots \dots \dots (36)$$

and corresponds to the macroscopic photoelectric cross section. This follows from the definition of F_{pe} , which is the photoelectric cross section per electron, and ρ_e , which is proportional to the number of electrons per cubic centimeter. Thus, the value of U for any mixture can be computed by making a simple volumetric addition of the U associated with each of the pure components of the mixture. Table 50.3 lists some useful lithology parameters for a number of commonly encountered minerals. Fig. 50.22 shows the use of U and density in the determination of lithology once the effect of porosity has been eliminated.

Examination of Table 50.3 shows the enormous sensitivity of the parameter U or F_{pe} to elements with a large atomic number. In particular, note the values of F_{pe} for the several iron compounds and for barium. In the case of iron, this sensitivity can be exploited to make a determination of shale content of the formation if there is iron associated with the clay mineral. This is discussed in the section on interpretation. However, the sensitivity to barite makes the F_{pe} measurement difficult in heavily weighted barite muds. If there is a substantial thickness of barite mudcake between the tool skid and the formation or if there is invasion of BaSO_4 particles into the formation, the resultant photoelectric absorption can seriously disturb the measurement.

Neutron Porosity Devices

Historically, the neutron device was the first nuclear device to be used to obtain an estimate of formation porosity. The principle of operation is based on the fact that hydrogen, with its relatively large scattering cross section and small mass, is very efficient in the slowing of fast neutrons. Thus, a measurement of the flux of epithermal neutrons resulting from the interaction of high-energy source neutrons with a formation will be related to its hydrogen content. If the hydrogen (in the form of water or hydrocarbons) is contained within the pore space, then the measurement will yield porosity. The simplest version of the device consists of a source of fast neutrons such as Pu-Be or Am-Be with average source energies of several MeV and a detector of much lower-energy neutrons at some distance from the source. Two general categories will be considered on the basis of the types of neutrons detected—epithermal or thermal.

To be a little more quantitative about the response of neutron porosity devices, we can use the results of two-group diffusion theory,⁸ which show that the flux of

Fig. 50.22—Matrix identification chart from U and density once the effect of porosity has been eliminated.

epithermal neutrons, in an infinite medium containing a point source of fast neutrons, falls off exponentially with the distance from the source, L , with a characteristic length, L_s , which is determined by the constituents of the medium:

$$\Psi_{\text{epi}} \propto \frac{1}{D} \frac{e^{-L/L_s}}{L}, \quad \dots \dots \dots (37)$$

where D is the epithermal diffusion coefficient, which is related to the transport mean free path of neutrons. At a fixed spacing, counting rates should vary nearly exponentially with the slowing-down length of the formation. An indication of this type of behavior can be seen in Fig. 50.23, which shows, on the left, the counting rate of one of the early epithermal neutron devices as a function of porosity, and on the right as a function of slowing-down length. The matrix effect is much reduced in the

Fig. 50.23—Counting rates for a long-spacing epithermal detector in test formations of various porosities. On the left, the data are plotted as a function of the formation porosity with three data trends resulting that correspond to the three matrices of the test formations. On the right, the same data have been replotted as a function of the corresponding slowing-down length for each of the test formations.

Fig. 50.24—The ratio of near to far detector counting rates as a function of porosity for a thermal neutron porosity device.

Fig. 50.25—The calculated migration length, L_m , as a function of porosity for the three principal matrices: sandstone, limestone, and dolomite.

second presentation. It also shows how the counting rate in any other material, once its slowing-down length has been calculated, then can be estimated or, conversely, how the slowing-down length of the formation can be determined from a measurement of the epithermal flux. It was seen in Fig. 50.11 that the slowing-down length is strongly dependent on the amount of hydrogen present in the mixture for which it is calculated.

Fig. 50.11 also shows the slowing-down length as a function of porosity for three common matrix materials: limestone, dolomite, and sandstone. From this presentation, it can be seen that if the matrix is known, the appropriate true porosity can be determined. As an operational expedient it has been convenient to convert the epithermal counting rate into porosity directly, assuming a limestone matrix with a slight correction to be made for the other two matrices. The separation of the three curves in the previous figure suggests how such a correction is made.

One of the first really quantitative devices of this type used a single epithermal detector in a skid applied mechanically against the borehole wall. This sidewall epithermal neutron device had the advantage of minimizing borehole effects, although it is sensitive to the actual size of the borehole and can be disturbed by the presence of mud-cake between the pad surface and the borehole wall.

A more recent development is the dual-detector compensated neutron device. This type of device uses a pair of thermal detectors for increased counting rate to improve the statistical uncertainty of the derived porosity values at high porosity. The second detector, the nearer to the source, is used to provide compensation for borehole effects. Although thermal neutron detection is used, it can be shown⁸ that if the source-to-detector spacings are appropriately chosen, the ratio of the two counting rates should vary exponentially as the inverse of the slowing-down length just as in the case of the single epithermal detector. In practice, however, it is found that some additional corrections must be made to the measurements, which can deviate from expected values if the thermal capture properties of the borehole and formation are significantly different. These generally are provided by the service companies in the forms of charts or nomographs. More recently they have been provided as a part of computerized interpretation.

The migration length, discussed in an earlier section, provides a convenient way to characterize the response of the thermal neutron device. Fig. 50.24, taken from Edmundson,⁹ shows the ratio of the near to the far counting rate of such a device for three types of lithologies as a function of porosity. If the porosity values on the points of this plot are converted through the use of Fig. 50.25, which shows the migration length, L_m , as a function of porosity, then the counting rates for the three lithologies lie on a single line, as seen in Fig. 50.26. This demonstrates that the response characteristics of the neutron porosity tools are given by some function of the slowing-down length and diffusion length rather than porosity.

Although the API committee⁶ that set up the gamma ray calibration standards also took some steps to standardize neutron log responses, their recommendations for API units have not been implemented. The conventional approach to neutron log output is to calibrate the tool in limestone primary formations and to report all readings

in apparent limestone porosity. Conversion charts are then necessary to correct the apparent limestone porosity for the matrix in which the measurement actually was made. (As noted previously, some consideration should be given to using the slowing-down length and diffusion length as the units for reporting the log measurements.) These measurements would be converted to porosity by use of charts similar to Figs. 50.11 and 50.25, lying entirely in the realm of interpretation.

One of the biggest limitations of the thermal porosity device is the disturbance on the measurement that can be caused by shale, either from its iron or potassium content or associated trace elements with high thermal capture cross section. However, even without the additional disturbance of thermal absorbers, clays and shales present a problem for all neutron porosity interpretation because of the hydroxyls associated with the clay mineral structure. Fig. 50.27 illustrates this point by showing the variation of slowing-down length of a sand/illite and sand/kaolinite mixture as a function of porosity. In both cases the sand and shale volumes are in equal proportions. It is clear that if the presence of clay in addition to the sand is not taken into account, large errors in porosity can result. Also note that the apparent porosity of kaolinite is much larger than that of illite. The examples shown in the figures indicate that a 20-PU sand/illite mixture will appear to be about 25 PU, whereas the 20-PU sand/kaolinite mixture will have an apparent porosity of about 36 PU. This will be seen in a later section to be caused by the differing hydroxyl content of these two clay minerals.

It is also of note that the most recent neutron porosity device consists of a pair of thermal and a pair of epithermal detectors. This enables measuring an apparent porosity unaffected by thermal absorbers and simultaneously obtaining a measurement of the macroscopic thermal absorption coefficient, Σ , which additionally describes the formation.

Pulsed Neutron Logging Devices

Pulsed neutron logging devices respond to the macroscopic thermal absorption capture cross section. The macroscopic thermal absorption cross section depends on the chemical constituents of the matrix and pore fluids. Chlorine, which is nearly always a constituent of formation waters, has a large absorption cross section. Thus, a measurement of the absorption cross section can provide the means of identifying salt water and measuring formation fluid saturation.

To determine the macroscopic thermal cross section, the actual phenomenon being measured is the lifetime of thermal neutrons in an absorptive medium. In a manner analogous to radioactive decay, we can predict the time-dependent behavior of thermal neutrons. The reaction rate for thermal neutron absorption is given by the product of the macroscopic cross section Σ and the velocity of the neutron, v . So for a system of N_N neutrons the rate of thermal absorption is given by

$$dN_N = -\Sigma v dt, \quad \dots \dots \dots (38)$$

which when integrated yields

$$N_N = N_i e^{-\Sigma v t}, \quad \dots \dots \dots (39)$$

Fig. 50.26—The ratio data of Fig. 50.24 plotted as a function of the migration length, L_m , corresponding to the matrix and porosity of the test formation measurements.

Fig. 50.27—The calculated slowing-down length as a function of porosity for sand and sand/clay mixtures. For the two lower lines the matrix is composed of equal mixtures, by volume, of sand and kaolinite or illite.

Fig. 50.28—Schematic timing diagram of a pulsed neutron capture/gamma ray device.

which relates the number present at time t to an initial number N_i at time zero. The exponential decay constant is seen to depend inversely on the desired quantity Σ .

The practical realization of such a pulsed neutron logging device depends on a pulsed source of high-energy neutrons. Such a device was discussed previously. The basic mode of operation consists of pulsing the source of 14-MeV neutrons for a brief period. This forms a cloud of high-energy neutrons in the borehole and formation, which then becomes thermalized through multiple collisions. This process is illustrated in Fig. 50.28. Only at thermal energies does the absorption become important and the neutrons begin to disappear in accordance with Eq. 39. As each neutron is captured, whether it be by hydrogen or chlorine, gamma rays are emitted, and the decay of the gamma ray counting rate is the actual measurement that reflects the decay of the neutron population.

As seen from Eq. 39, the decay constant for a particular formation is given by $1/v\Sigma$. The value of the capture cross section Σ is listed in Table 50.4 for a number of pertinent cases. Included in the table is the decay time associated with the particular matrix, which was computed from the relationship

$$\tau_d = \frac{K}{\Sigma_{\text{abs}}}, \quad (40)$$

where K is 4550 μsec , because v for thermal neutrons is 0.22 $\text{cm}/\mu\text{sec}$ and Σ_{abs} , the thermal absorption cross section, is in capture units.

TABLE 50.4—CAPTURE CROSS SECTIONS AND DECAY TIMES

	Σ (c.u.)	τ_d (μsec)
Quartz	4.26	1086
Dolomite	4.7	968
Lime	7.07	643
20-PU lime	10.06	452
Water	22	206
Salt water (26% NaCl)	125	36

Since the derivation of the decay-time measurement is based on the simple model of a cloud of thermal neutrons being present and then decaying, it is of some interest to see just how long it is after the burst of 14-MeV neutrons that they become thermalized. To estimate this time we need only to refer to the section on neutron physics, where the average number of collisions for thermalization and the mean free path were discussed. The simplest estimate of the time required is to suppose that between each collision the average distance traveled is the mean free path ($1/\Sigma_t$). The time between one collision and the next, Δt , is then given approximately by

$$\Delta t \approx \frac{1}{\Sigma_t} \frac{1}{v}, \quad (41)$$

where Σ_t is the total cross section and v is given in terms of the energy E by Eq. 23. The $1/v$ factor can be replaced by using Eq. 23 in conjunction with the expression (Eq. 30) for the average number of collisions, \bar{n} , yielding

$$\frac{1}{v} \propto e^{\bar{n}\xi/2}, \quad (42)$$

where ξ is the average logarithmic energy decrement defined in Eq. 25.

The value of an average mean free path for formations of interest can be estimated from Fig. 50.10. From the above information, the total time, t_t (μsec), from emission to thermal energies is given by

$$t_t = \int \Delta t = \frac{1}{\Sigma} 3.6 \times 10^{-4} \int_0^{\bar{n}} e^{\bar{n}\xi/2} d\bar{n}. \quad (43)$$

Evaluation of this expression for 20%-porosity limestone gives an estimate of about 2.8 μsec and in water it is only 0.5 μsec , both of which are much smaller than the decay times shown in Table 50.4.

Numerous measurement schemes are used for controlling the period during which the 14-MeV neutrons are produced and the period during which the gamma rays are measured. Some devices use dual-detector systems in an attempt to correct for the small disturbance that can be introduced by the borehole size and salinity as well as to provide some measure of the porosity.

Inelastic and Capture Gamma Ray Spectrometry

The primary motivation for the development of induced gamma ray spectroscopy devices was the possibility of performing in-situ chemical analysis of the formation constituents. The tantalizing possibility of directly measuring the ratio of the number of carbon atoms to oxygen atoms and thus providing the first direct downhole measurement of the presence of hydrocarbons spurred the development of a number of technologically sophisticated devices. This is to be contrasted with a traditional approach that depends on the analysis of a core or side-wall sample.

Tools of this type are based on a type of chemical analysis that can be performed through the use of neutrons and gamma ray spectroscopy. Neutrons are used to excite the nuclei, which then emit gamma rays of precise

Fig. 50.29—Cross sections for the production of inelastic gamma rays by carbon and oxygen as a function of the incident neutron energy.

Fig. 50.30—Comparison spectra from a high-resolution solid-state detector (Ge) compared to the gamma ray spectrum detected with a more conventional NaI detector.

energies uniquely identifying the isotope in question. There are two neutron reactions that can produce such gamma ray emissions: inelastic scattering, which can occur with very-high-energy neutrons, and capture reactions with thermalized neutrons as exploited in pulsed neutron logging.

Few elements for well-logging applications have large inelastic cross sections, but fortunately carbon and oxygen do. Fig. 50.29 shows the cross sections for the production of gamma rays from inelastic scattering from carbon and oxygen. These inelastic induced gamma rays are observed not only by spectroscopic gamma ray detection but also in conjunction with timing. To avoid confusion with gamma rays produced from thermal capture, the inelastic gamma rays are detected during the burst of 14-MeV neutrons. At some later time, gamma rays arising from thermal absorption are detected, providing sensitivity to a large number of elements such as H, Fe, Cl, Si, Ca, S, etc. At least two different neutron pulsing and gamma ray detection sequences are currently in use. One method¹⁰ uses a fixed time of about 50 to 100 μ sec between neutron bursts, and another method,¹¹ which collects information on the capture gamma rays, uses a variable neutron-pulse interval that is controlled by the characteristic decay time of the thermalized neutrons.

Tool design differences can optimize the detection of the inelastic or capture gamma rays. Some designs incorporate the measurement of both through appropriate timing cycles. In addition to the measurement of the gamma ray yields of the various elements, the macroscopic cross section Σ can be determined from an analysis of the decay of the total gamma ray signal, which is also measured. The only practical limitation on the number of elements is determined by counting statistics and the inherent detector resolution.

An experimental tool that uses a high-resolution Ge detector has measured more than two dozen different elements in borehole logging. This type of detector must be operated at very low temperatures (-196°C), which introduces a number of technological problems for borehole measurements. However, the advantage that it brings is in the much improved resolution, which increases the number of distinct gamma rays that can be distinguished in the spectrum. Fig. 50.30 shows the dramatic improvement compared to a conventional NaI detector for the examination of a natural uranium sample. Two elements that are readily detectable with such a device are aluminum, which is very useful in the classification and quantification of in-situ clays, and vanadium, which can be correlated¹² with the API gravity of the associated oil.

Interpretation of Nuclear Logs

The following section discusses how the previously mentioned nuclear logging tools are used in interpretation. However, it should be stated at the outset that this is not intended to be a self-contained log interpretation course. A number of references¹³⁻¹⁷ of such works should be consulted for further information.

The approach taken here is more or less a stand-alone interpretation of each tool. An examination of all the combination measurements and the interpretation techniques used with each tool is beyond the scope of this chapter. Nonetheless, several of the more standard tool combination interpretation approaches are discussed. Fig. 50.31

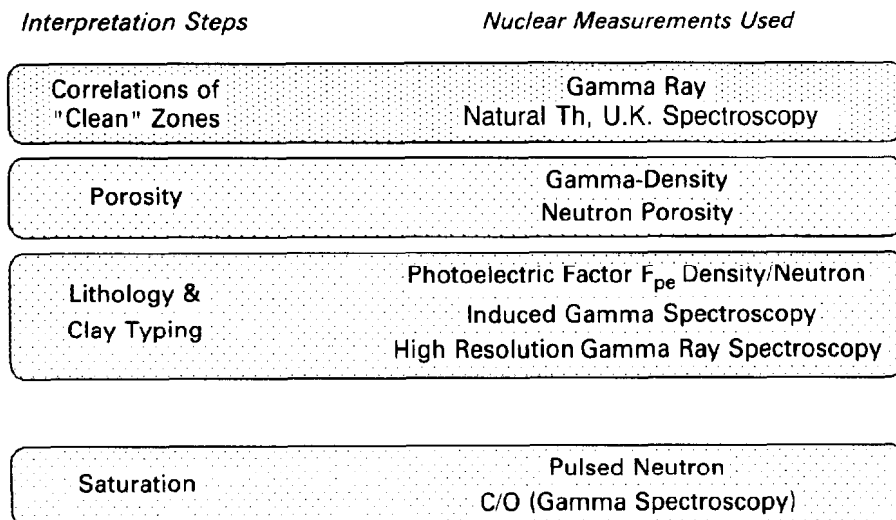

Fig. 50.31—Four interpretation tasks and the nuclear measurements associated with them.

indicates four of the steps in the interpretation process and the nuclear measurements used to obtain the desired results. The indicated list of measurement devices or techniques is in the order of the discussion that follows.

Interpretation of Gamma Ray Measurements

The gamma ray log traditionally has been used for correlating zones from well to well, crude lithology identification, and rough volume of shale estimation. With the current state of knowledge of clay composition and other more refined lithology determinations, it is clear that the surest use of the gamma ray is, indeed, for correlation.

For estimating the volume of shale, the approach is to scan the log for minimum and maximum gamma ray readings, γ_{\min} and γ_{\max} . The minimum reading then is assumed to be the clean point and the maximum reading is taken as the shale point. Then the gamma ray reading in API units at any other point in the well, γ_{\log} , is scaled accordingly:

$$V_{sh} \propto \frac{\gamma_{\log} - \gamma_{\min}}{\gamma_{\max} - \gamma_{\min}} \quad (44)$$

This ratio usually is referred to as the gamma ray index and can be scaled into percent shaliness according to charts¹³ depending on rock type. This method is sometimes appropriate, if in fact the maximum gamma ray reading corresponds to the same type of shale as the values that are being interpreted.

Numerous examples show the deficiencies of this method, and for this reason the spectral gamma ray tool was developed. Tools of this type measure, in fact, the relative concentration of three radioactive components of the total gamma ray signal. It is interesting to point out the relationship between the concentration of the three radioactive components and the total gamma ray signal in API units. It is given by

$$\gamma_{API} = A \times Th + B \times U + C \times K \quad (45)$$

When thorium and uranium are measured in ppm and potassium in weight percent, it is found that ratios of the coefficients (A:B:C) are 1:2:4; i.e., 1 wt% K contributes four times more to γ_{API} than 1 ppm of thorium. It is obvious from this that in a shaly sand, if a mineral rich in potassium (such as mica) is present, the total gamma ray signal will increase and give a false indication of percentage shale when, in fact, this additional radioactivity is caused by the mica.

There are two solid reasons for using a spectral gamma ray measurement over the standard gamma ray, which is really reliable only for correlation. The first is for the detection of radioactive anomalies, such as referred to previously, and the second is to make some estimation of the clay types by classifying them in terms of the relative contributions of the three radioactive components. For this second point the reader is referred to publications on spectral gamma ray interpretation.¹⁸⁻²⁰

Fig. 50.32 shows a log example from the North Sea in a micaceous sand. At 10,612 to 10,620 ft, a shale is indicated that has a total gamma ray signal of about 90 API units. With just the total gamma ray as an indicator it appears that the zone 10,568 to 10,522 ft contains about half the amount of shale estimated for the lower zone. However, the decomposition of the gamma ray signal shows quite clearly that the amounts of U, Th, and K in these two zones are quite different. In fact, the upper zone is a mixture of sand and mica, whereas the lower zone is, indeed, shale.

In the next example, Fig. 50.33, the gamma ray alone would indicate that below the lower boundary of the shale bed at 12,836 ft, there is a relatively clean sand. It can be seen, however, from the K trace that the high level of potassium in the shale zone persists several feet below 12,836. This excess potassium was found to be caused by feldspar, which has considerable impact on the grain density to be used in the interpretation of density logs.

The third example, Fig. 50.34, shows how a uranium-rich formation would be misinterpreted (in simple gamma ray interpretation) as being shale. The sudden increase

Fig. 50.32—A spectral gamma ray log from the North Sea in a micaceous sand.

Fig. 50.33—A spectral gamma ray log from Nigeria where a continuing trace of K is attributed to the presence of feldspar.

in uranium content alone signals that this is not a simple shale of the variety in the adjacent levels. Core analysis showed this zone, however, to be rich in organic material and U is often trapped in organic complexes.

Porosity Determination

Gamma-Gamma Density Devices. The basic output of the gamma-gamma density device, bulk density, is conceptually the simplest measured parameter to interpret in terms of porosity. The basic relation (Eq. 1) is

$$\rho_b = \phi \rho_f + (1 - \phi) \rho_{ma}$$

which volumetrically links the density of the pore fluid, ρ_f , and the rock matrix density, ρ_{ma} , to the bulk density, ρ_b .

However, there are a few difficulties to overcome to interpret the output of such a density device, especially the matter of electron density index, ρ_e . It was shown in an earlier discussion that the gamma-gamma density device is measuring the electron density index. Table 50.3 shows a comparison between bulk density and electron density index. It is in close correspondence for nearly all the compounds listed except for water and hydrocarbons. This is because the average value of Z/A is about $1/2$ for all elements except hydrogen. It is seen that because of

Fig. 50.34—A spectral gamma ray log showing a zone of anomalous U concentration.

this discrepancy for hydrogen, the bulk density and electron density index of water differ by about 11%.

To compensate for this fact, a simple transform of the electron density index is made so that in water-filled limestone the transformed or log density, ρ_{\log} , agrees with the bulk density. Fig. 50.35 shows this simple transform where the bulk density for 0-PU limestone and water are plotted against the electron density values. The equation of the straight line connecting these two points,

$$\rho_b = 1.0704\rho_e - 0.188, \quad (46)$$

corresponds to the published transform¹⁴ used by the logging companies. It is worthwhile to point out that this transformed density, ρ_{\log} , will also agree to within 0.004 g/cm³ for the other principal matrix materials listed in the table.

Returning to the interpretation problem, the solution of Eq. 1 for porosity yields

$$\phi = \frac{\rho_{ma} - \rho_b}{\rho_{ma} - \rho_f}, \quad (47)$$

so the problem rests on knowing the values to insert for fluid and matrix density. Before examining the means for determining these values, it is perhaps of some interest to know to what precision these two parameters must be known.

It is interesting to look at the uncertainty that can be tolerated on the value used for the matrix density, ρ_{ma} . From the previous equation we can write

$$\partial\phi = \left[\frac{\rho_b - \rho_{ma}}{(\rho_f - \rho_{ma})^2} - \frac{1}{\rho_f - \rho_{ma}} \right] \partial\rho_{ma} \quad (48)$$

Fig. 50.35—The transform between the measured electron density index, ρ_e , and bulk density, ρ_b .

If this is evaluated for the case of a sand of about 30% porosity we can use the values $\rho_b = 2.16$, $\rho_f = 1.00$, and $\rho_{ma} = 2.65$ and obtain

$$d\phi = 0.43d\rho_{ma} \quad (49)$$

Thus, for the uncertainty in ϕ to be less than 0.02, the uncertainty in ρ_{ma} must be less than 0.05 g/cm^3 . A more detailed analysis of the uncertainty in grain density that can be tolerated can be found in Ref. 21.

For values of fluid density it is necessary to know the type of fluid in the pores. The fluid density for hydrocarbon may range from 0.2 to 0.8. Salt-saturated water (NaCl) may be as high as 1.2 g/cm^3 , and with the presence of CaCl_2 , values even as great as 1.4 g/cm^3 may occur. However, the uncertainty that can be tolerated in ρ_f is much greater than that for ρ_{ma} . An error analysis of Eq. 47 for the values chosen above shows that $\partial\phi = 0.18\partial\rho_f$, which allows about double the margin of error.

The value for matrix density in simple cases can be taken from Table 50.3, which shows a rather narrow variation between 2.65 g/cm^3 for quartz and 2.96 g/cm^3 for anhydrite. Grain densities for shales are an entirely separate matter and will not be covered here. The obvious problem left is assigning a matrix density, which can only be done with a knowledge of the lithology. In essence, all density interpretation aimed at porosity determination revolves on this.

Before going on to the determination of lithology and thus an estimate of grain density, quality control of the density measurement should be discussed.

As mentioned earlier, the modern gamma-gamma density devices are compensated measuring devices. They use two detectors at different spacings from the gamma ray source to compensate for the possible intervening presence of mudcake or drilling fluid. Normally, in addition to the density curve the log will also show a trace of the compensation, generally referred to as the $\Delta\rho$ curve. This curve represents the correction made to the apparent density seen by the long-spacing detector (ρ_{ls}) based on the discrepancy between the long- and short-spacing measurements.

The counting rate from either detector can be converted to an apparent density after a series of laboratory calibrations.²² If there is not any intervening material between the tool surface and the formation being measured, then the two values will be equal. As the mudcake thickness increases, the two density values will diverge for some reasonable value of thickness (generally less than 1 in.). The quantity $\Delta\rho$ is determined by experimentation, as a function of the density differences, to be the amount to be added to the apparent long-spacing density, ρ_{ls} , to match the bulk density of the formation—i.e.,

$$\rho_b = \rho_{ls} + \Delta\rho \quad (50)$$

Although it commonly is thought that $\Delta\rho$ is a measure of the mudcake thickness, h_{mc} , it is, in fact, proportional to the product of mudcake thickness and the density contrast between the mudcake, ρ_{mc} , and the formation density—i.e.,

$$\Delta\rho \propto h_{mc}(\rho_b - \rho_{mc}) \quad (51)$$

Beyond some thickness (~ 1 in.), the compensation scheme will break down and the ρ_b value will be in doubt. However, this point cannot be identified simply by use of a cutoff value of $\Delta\rho$. A very small gap of water ($\rho_{mc} = 1$) in front of a low-porosity formation would yield a large value of $\Delta\rho$ and yet be perfectly compensated for, whereas a 1-in.-thick mudcake of medium density in front of a high-porosity zone may yield a small $\Delta\rho$ with some residual error in the compensation. Nonetheless, it is certain that the $\Delta\rho$ curve will be used as quality control on the bulk density with some fixed cutoff value despite this caution.

Neutron Porosity Devices. Modern neutron porosity devices are of two types, depending on the energy range of detection: thermal or epithermal. By convention, the log output usually is scaled in equivalent limestone porosity units. Under appropriate circumstances, this would correspond to the true porosity of a clean, water-filled limestone formation. In the following discussion it is assumed that the log reading already has been corrected for the various environmental effects. In addition to the environmental corrections that must be made before the porosity values are interpreted, there are three effects that must be considered in more detail.

Matrix Effect. As in density logging, it is necessary to know the rock matrix to make any practical use of the apparent limestone porosity value measured. Fig. 50.36 shows, for a thermal and an epithermal device, the matrix correction necessary to transform the measured units into the appropriate porosity units. It should be noted that these

Fig. 50.36—Matrix correction chart for two specific neutron porosity tools.

two charts are for two very specific tools (CNL* and SNP*). When such tools are involved, the appropriate chart for the corresponding tool should be used, since some of the so-called matrix effect is tool-design dependent. However, a large part of the matrix effect can be understood in terms of the two basic parameters used to describe the bulk parameters of the formation (i.e., the slowing-down length and the migration length).

First consider the case of epithermal detection. To demonstrate the construction of the matrix-effect correction curves, there are four steps to consider.

1. The first step is the link between the measurement (for this case we take the simple case of using the ratio of near- to far-detector counting rate) and porosity in the primary laboratory calibration standards. This is a freshwater-filled limestone with 8-in. borehole. Fig. 50.37 shows the behavior of the ratio, $F = N_{Nn}/N_{Nf}$, as a function of limestone porosity, ϕ_{ls} . From this plot a fit can be established to ascribe a functional relationship between the measured parameter F and the limestone porosity ϕ_{ls} ,

$$F = f(\phi_{ls}). \quad (52)$$

2. In the second step, the relationship between the measured parameter F and the slowing-down length, L_s , must be established for measurement in all three of the principal matrices. That this can be done easily is shown in Fig. 50.38, where measurements in quartz, dolomite, and limestone are shown for a range of porosities. From this plot a new fit can be found,

$$F = f(L_s), \quad (53)$$

*Mark of Schlumberger.

Fig. 50.37—Experimental values for the ratio of epithermal counting rates as a function of porosity in limestone calibration formations.

that allows the prediction of the measured ratio from the known slowing-down length of the formation.

3. The next step is to establish the connection between the slowing-down length, L_s , and porosity for limestone as shown in Fig. 50.39 and seen earlier in Fig. 50.11. This curve now represents the limestone “transform” of Eq. 52 and the porosity axis represents true porosity.

4. The slowing-down lengths of sandstone and dolomite now are calculated as a function of porosity and are shown also in Fig. 50.39. They fall on either side of the limestone response because of their different chemical compositions, which influence their slowing-down lengths.

Fig. 50.38—Data of Fig. 50.37 plotted as a function of the equivalent slowing-down length, L_s , of the corresponding formations.

Fig. 50.39—Estimation of the epithermal matrix effect from slowing-down length, L_s , as a function of porosity for sandstone and dolomite.

Fig. 50.40—A neutron/density cross plot for a thermal neutron porosity device. The lithology of a formation can be identified by plotting points representing ϕ_n (in limestone porosity units) and ρ_b . Point A may represent a 22-p.u. limestone or, less likely, a mixture of sandstone and dolomite.

The apparent limestone porosity for either formation can be found by selecting a porosity, 10-PU sandstone for example, and finding the corresponding slowing-down length (approximately 15.5 cm). The apparent limestone porosity then is obtained by finding the porosity associated with the limestone formation of the same L_s value. In this case it is 8.5 PU. The same case for dolomite indicates 14 PU instead of 10 PU.

A similar procedure can be used for a thermal neutron porosity device. As shown earlier, it has been found useful to cast the results in terms of the migration length L_m .⁹ Because the L_m contains some information concerning the macroscopic thermal absorption cross section, the results are qualitatively similar to the preceding but differ slightly in magnitude. This can be seen by performing the preceding exercise on the plots of L_m vs. porosity of Fig. 50.25.

Fig. 50.40 shows the neutron/density crossplot for a dual-detector thermal device. The matrix effect can be observed by comparing the equiporosity points on the individual lithology lines with the apparent limestone porosity scale on the abscissa. These discrepancies are the same as indicated in the portion of Fig. 50.36 indicated as "thermal." Ref. 23 discusses the effect of absorbers on the thermal tool response.

Gas Effect. Neutron porosity devices have been calibrated for liquid-filled porosity. However, the replacement of the liquid in the pores by gas will have a considerable impact on the slowing-down length of the formation and thus on the apparent porosity. In general terms, partial replacement of the water component of the mixture by a much lighter gas will increase the neutron slowing-down length and thus the apparent porosity will decrease. The actual apparent porosity decrease will be a function primarily of the true porosity, the water saturation, the gas density, and, to some extent, the lithology. In a situation such as this, replacement of fluid in the pores by a less-dense gas will decrease the bulk density of the formation. These two effects have been exploited in well logging by making the density and neutron porosity measurements in a single measurement pass. On the log presentation these two effects cause the density and neutron traces to separate, which can be recognized easily as being caused by the presence of gas, if the invasion is less than 6 in.

To quantify the traditional neutron-density gas separation indication and to illustrate the possibility of estimating gas saturation from an epithermal neutron measurement and a density measurement, consider Figs. 50.41 and 50.42. In both these figures the slowing-down length of a sand formation has been computed between zero and 40 PU at 2-PU increments. These values of slowing-down length have been plotted as a function of the corresponding bulk density of the formation for the five gas saturations indicated on the figures. In the case of Fig. 50.41, the gas density, ρ_g , has been taken to be 0.001 g/cm³, and in Fig. 50.42, the gas density has been taken to be about 0.25 g/cm³, which covers the entire range possible under normal reservoir conditions. In either case it is clear that, for the presence of gas at a fixed porosity, the slowing-down length is larger than that associated with the water-filled porosity. The interpretation of this larger value of L_s is an apparent decrease in porosity. In the case of the total gas saturation curve of

Fig. 50.41—A plot of slowing-down length, L_s , vs. bulk density, ρ_b , for sandstone formations with varying gas saturation. Invasion of borehole fluid is assumed to be negligible and the gas density is taken to be 0.001 g/cm³.

Fig. 50.42—Effect of gas saturation in sandstone for a gas density of 0.25 g/cm³.

Fig. 50.41, L_s values greater than ~ 28 cm would correspond to zero or negative apparent porosities on the log readings.

On the plots of L_s vs. ρ_b , a pair of points (L_s , ρ_b) will yield the saturation and porosity corresponding to the conditions of gas density specified. For both figures the assumption for the calculation is that the matrix is sandstone with no shale. The gas density difference for the two plots spans the range of expected gas densities. The saturation referred to on the figures is with reference to a gas/water mixture. For the lowest curve on both figures, the porosity is entirely filled with water.

Since the slowing-down length normally is not presented on a neutron porosity log, an example taken from the log of Fig. 50.43 can serve as a guide. From the gas zone clearly indicated on this figure we can use the following values for the illustration: ϕ_N , neutron porosity (sand) = 27 PU and ϕ_D , density porosity (sand) = 35 PU.

The lowermost curves on Figs. 50.41 and 50.42 serve to determine the correspondence between ϕ_N and the slowing-down length, L_s . It is indicated by the horizontal line to be about 11 cm for this example. The density porosity of 35 PU can be seen to correspond to a density of about 2.07 g/cm³, as indicated by the vertical line. The intersection of these two points at the coordinate (2.07, 11), shown in the figure, indicates about 25% gas saturation in the case of a gas density of 0.25 g/cm³ (Fig. 50.42), and a saturation of about 12.5% if the gas density is taken to be nearly zero. The porosity of the formation can be found by following the slope of the equiporosity lines from the example coordinate to the lower liquid-saturated line and is seen to indicate a value of about 33 PU for both cases.

With more information concerning the gas properties of a reservoir, this interpretation can be used instead to yield an indication of the invasion of the drilling fluid into the zone of investigation of the neutron and density devices.

Shale Effect. Generally, the presence of shale tends to increase the neutron porosity values. The reason for this lies in two effects: additional hydrogen resulting from the

Fig. 50.43—Log example of the neutron/density combination exhibiting the characteristic crossover behavior in a gas zone.

Fig. 50.44—Comparison of $(1/L_s)^3$ for sandstone, kaolinite, and illite as a function of porosity. The apparent porosity of pure illite is seen to be about 53 p.u. and for illite, 12 p.u.

Fig. 50.45—Variation of $(1/L_s)^3$ vs. porosity for sand and sand/kaolinite mixtures. A line at 30 p.u. indicates the effect of changing the matrix from sand to kaolinite, and another indicates the change in $(1/L_s)^3$ expected when the 30 p.u. is filled progressively with kaolinite.

Fig. 50.46—Correction for a thermal neutron porosity tool as a function of the formation, Σ .²⁴

hydroxyls in the clay minerals, and in the case of thermal porosity devices, the possibility of additional thermal neutron absorbers such as boron associated with the clay minerals.

Initially, consider the case of thermal absorbers and consider just two types of clay minerals, kaolinite and illite. For these two clays (and many others) we refer to the data compiled by Edmundson *et al.*⁹ The chemical formula for kaolinite is $\text{Al}_4\text{Si}_4\text{O}_{10}(\text{OH})_8$ and the formula for illite is $\text{K}_2\text{Si}_6\text{Al}_3\text{Fe}_3\text{O}_{20}(\text{OH})_4$.

The important point to note about these formulations is the differing amount of (OH). A rough calculation indicates that kaolinite has about one-third the hydrogen density of water and that illite, with a lesser amount of hydroxyls, has about one-tenth the hydrogen density of water. In the case of either of these "pure" clay minerals, a neutron porosity device will detect some large value of porosity, since the slowing-down length will be influenced greatly by the presence of the (OH) components.

That the slowing-down length is considerably affected can be seen in Fig. 50.44, which shows the value of L_s of sand, illite, and kaolinite from 0 to 100 PU. The ordinate in this figure is $(1/L_s)^3$, which has been chosen because it tends to vary linearly with the combination of two materials of differing values of L_s . Values for the two pure clay minerals are indicated at 0 PU. From the figure, the apparent porosity would be about 53 PU for pure kaolinite and about 12 PU for illite. This is consistent with the trend expected from the hydrogen density. For the slowing-down length, the choice of the replacement of three Fe atoms for three Al atoms is immaterial, but it will have an impact on the thermal neutron absorption because of capture by the iron.

By using a plot similar to Fig. 50.44, the expected response of an epithermal neutron porosity device to a mixture of kaolinite and sand can be predicted. Fig. 50.45 shows an example of this. In the case of a true 30 PU (that is, 30% of the volume is water-filled), the mixed-matrix line indicates the change of L_s with a change in the sand/kaolinite matrix. Following the indicated line, a matrix of 70% sand and 30% kaolinite would have an apparent porosity of about 41% compared to the actual value of 30%.

On the other hand, we can take the case of 30 PU, or more precisely the case of 70 vol% being sand, and ask what happens to the value of L_s as the porosity is filled with kaolinite. This process also is indicated by the porosity-infilling line in Fig. 50.45. It is clear that the endpoint of this line must lie on the line of the 30/70 kaolinite mixture. As indicated in this case, the minimum apparent porosity as deduced from the slowing-down length will be about 12 PU where, in fact, there will be no porosity available for fluids.

The impact on thermal neutron porosity devices is somewhat more difficult to predict and will depend in detail on the tool design and consequent response. A similar type of graphical construction using the migration length instead of the slowing-down length can be used to see that for the normal neutron absorbers, such as iron, in the clay minerals there is not a large effect. However, if boron is present in any substantial quantity, this will not be the case. To deal with this problem Arnold *et al.*²⁴ have determined experimentally a correction for the apparent porosity of a dual-detector thermal neutron porosity

device as a function of the macroscopic absorption cross section $\Delta\Sigma$ of the formation. It is shown in Fig. 50.46.

Despite the foregoing discussion, it must be recognized that neutron porosity devices do, in fact, respond to porosity, among other things. The dynamic range of the measurement at low porosity is excellent because of the sensitivity of the slowing-down length in this range. The problems of interpretation caused by the influence of shale are tractable when the neutron measurements are combined with other tools.

Lithology Determination

Neutron/Density Combination. One of the traditional methods of lithology interpretation is the neutron/density combination. The useful property of combining these two measurements can be seen in Fig. 50.40: the three principal lithologies form three different response lines. The grain density, ρ_{ma} , increases in an almost linear fashion from sand to dolomite, so that it is tempting to draw lines of equal grain density for intermediate points that do not lie on any of the three lines. This type of presentation is shown in Fig. 50.47. With this approach, the particular lithology mixture is not of great importance but a fair estimation of the appropriate grain density is obtained despite the fact that ρ_{ma} is not a characterizing parameter for neutron logs.

The combination of the neutron and density measurements in this fashion can solve only simple binary mineral combinations. To interpret the results unambiguously, the two minerals must be known. For example, one can imagine a result, marked as Point A on Fig. 50.40, arising from a formation consisting of a sand and dolomite mixture. In this case, with no additional knowledge, the interpretation of the indicated point, intermediate between dolomite and sandstone, would be limestone.

Photoelectric Factor. Discrepancies such as these can be resolved by the use of additional information. In particular, one such nuclear measurement is the photoelectric factor, F_{pe} . It is convenient for purposes of interpretation to use the quantity U (Eq. 36). It has the property of combining volumetrically for the case of several substances being present in the scattering region whose individual absorption characteristics can be computed. For a two-component system (fluid and matrix) of porosity ϕ this can be written as

$$U = U_f \phi + U_{ma}(1 - \phi). \quad (54)$$

F_{pe} for this mixture then can be determined from Eq. 36, where

$$\rho_e = (\rho_e)_f \phi + (\rho_e)_{ma}(1 - \phi). \quad (55)$$

The results of this type of computation are shown in the crossplot of Fig. 50.48, which shows how F_{pe} varies as a function of density for the three principal matrices: limestone, dolomite, and sandstone. The interesting thing about this presentation is the order in which the three lines fall; dolomite now is bracketed by limestone and sandstone. It is obvious that in the hypothetical case of the sandy dolomite, given previously, the ambiguity about the presence of limestone would be removed when inspecting the corresponding value of F_{pe} . In this case it would clearly indicate a sand/dolomite mixture.

Fig. 50.47—Extracting apparent grain density, ρ_{ma} , from the neutron/density cross plot.

One elementary use of the F_{pe} curve in conjunction with density is to make a simple two-mineral model. This is no more than formalization of the relationships seen in the preceding figure. This is done by solving the following set of equations for U and ρ , and using the fact that the volumes sum to unity:

$$U_{log} = U_1 V_1 + U_2 V_2 + U_f \phi,$$

$$\rho_{log} = \rho_1 V_1 + \rho_2 V_2 + \rho_f \phi, \quad (56)$$

and

$$1 = V_1 + V_2 + \phi.$$

Fig. 50.48—A cross plot of the photoelectric factor vs. density. Lines for the three principal matrices are indicated. The points represent the sampled log data.

Fig. 50.49—A log example showing the conversion of the excess F_{pe} in a shaly sand to the weight fraction of iron. In Track 1, the estimate from F_{pe} (Eq. 61) is compared to values obtained by core analysis.

The indicated parameters for the two suspected minerals can be inserted in this equation to solve for the appropriate porosity and lithology mix.

However, there is no reason to limit this type of analysis to two minerals. It can be expanded to many more with the addition of supplementary measurements such as Th, U, K, Al, Fe, and Si. The natural combination with the gamma ray spectral information has been shown useful for complex mineralogy in which two different three-mineral combinations can be treated.²⁵

Another interesting use of F_{pe} can be to get an estimation of shale in sand. The F_{pe} values measured in shales are related primarily to their iron content. For an example of this application, refer to Fig. 50.48. The data points shown on the crossplot are from some sand and shale sequences. The clean-sand points are evident by their placement with respect to the indicated sand line. The shale points are those scattered to higher values of F_{pe} . In this case the lithology measurement is responding to the photoelectric absorption resulting from the iron associated with the shale. In this particular case the shale is known to be a mixture of kaolinite and illite and the iron is associated with the illite.

To demonstrate the quantitative nature of the F_{pe} measurement, consider the following argument for the determination of the weight percent of a trace photoelectric absorber in an otherwise two-component system. If F_{pex} represents the photoelectric factor of the trace absorber and the associated volume fraction is V_x (which is considered to be much smaller than unity), the following approximate equation applies:

$$U \approx U_f \phi + U_{ma}(1 - \phi) + U_x V_x, \quad (57)$$

where $V_x \ll 1$ and

$$U_x = \rho_{ex} F_{pex}. \quad (58)$$

Note that the third term in this equation represents the product of the trace element absorption factor and its associated mass contained in 1 cm^3 :

$$U_x V_x = F_{pex} \rho_x V_x. \quad (59)$$

Thus, the weight per cubic centimeter of the absorber can be determined from the measured parameter (i.e., from the product of the measured ρ and F_{pe}) U from the following:

$$\rho_x V_x = \frac{U - U_f \phi - U_{ma}(1 - \phi)}{F_{pex}}. \quad (60)$$

The fraction by weight of the solid fraction, f_x , is then given by

$$f_x = \frac{U - U_f \phi - U_{ma}(1 - \phi)}{F_{pex} \rho_{ma}(1 - \phi)}. \quad (61)$$

An interesting application of this idea is shown for the log data of Fig. 50.48. The measured F_{pe} curve is shown in Track 2 of Fig. 50.49 along with the curve of the anticipated F_{pe} based on pure sandstone. The shading represents the "excess" photoelectric factor, which can be converted to percent weight of iron by use of the above argument. The resulting curve of the iron concentration is found in Track 1 of Fig. 50.49, along with a series of discrete measurements of the iron concentration made on the core samples. The good agreement demonstrates the validity of the supposition that, in this case, the F_{pe} measurement is responding primarily to the iron concentration in the shale and the volume of shale present. A similar procedure could be followed for any other suspected trace element of sufficient concentration and photoelectric absorption factor.

Induced-Gamma-Ray Spectroscopy. The induced gamma spectroscopy tools are very important for lithology determination in complex situations. In the case of induced capture gamma rays a large number of elements can be identified: hydrogen, silicon, calcium, iron, sulfur, and chlorine. Lithology identification can be made by comparing the yields of particular elements. For example, anhydrite is identified easily by the strong gamma ray yield from sulfur and calcium associated with this mineral.

**TABLE 50.5—ATOMIC DENSITIES IN UNITS OF
AVOGADRO'S NUMBER (6.023×10^{23})**

	Density (g/cm ³)	Oxygen (atoms/cm ³)	Carbon (atoms/cm ³)
Limestone	2.71	0.081	0.027
Dolomite	2.87	0.094	0.031
Quartz	2.65	0.088	—
Anhydrite	2.96	0.087	—
Oil	0.85	—	0.061
Water	1.0	0.056	—

Limestone can be distinguished from sandstone by comparing the silicon and calcium yields. Numerous references^{26,27} show examples of these types of procedures as well as interpretation schemes proposed by some service companies.

High-resolution spectroscopic devices will provide enormous advances in mineralogical identification. Such devices use solid-state gamma ray detectors instead of the conventional NaI detectors, which suffer from poor resolution. One of the most promising applications of such devices is the possibility of making aluminum activation measurements. Because aluminum is a common constituent of clay minerals, it is well adapted to quantitative clay content determination. As an example of the type of information that is obtainable from a high-resolution gamma ray spectroscopy device, refer to Fig. 50.50, which shows the gamma ray spectrum obtained after irradiation of the formation with a ²⁵²Cf source. Along with the gamma rays from the naturally occurring thorium, uranium, and potassium, the artificially produced radiation from manganese, sodium, aluminum, and vanadium is seen.

The gamma ray intensities from the aluminum and vanadium isotopes can be used to produce a log calibrated in weight percent of the two elements. In the case of the aluminum, the measurement is a continuous one made at about 400 ft/hr and is shown in Fig. 50.51 along with core measurements from the same well. To detect the vanadium, since it is present in rather small amounts, stationary readings were taken. These values are indicated along with error bars representing the uncertainty of the measurement caused by counting statistics. These two traces illustrate the type of detailed evaluations that can be made by logging devices, which previously could be made only with extensive core analysis.

Saturation Determination

Inelastic Gamma Ray Spectroscopy. Two nuclear tools are well adapted for the determination of saturation. The first is based on the determination of the ratio of carbon to oxygen atoms in the formation. The use of such a ratio is shown clearly in Table 50.5, where it is seen that there is a significant difference between the atomic C/O ratios of oil, water, and the common matrix minerals.

Fig. 50.52 shows how the atomic C/O ratio changes as a function of porosity and water saturation for the three principal matrices. From this figure it is clear that for clean formations of a given lithology the interpretation is relatively straightforward. An inherent difficulty in the measurement is immediately obvious. At low porosities the dynamic range of the C/O ratio as a function of water

Fig. 50.50—Gamma ray spectrum obtained with a high resolution Ge gamma ray spectrometer and Cf neutron source.

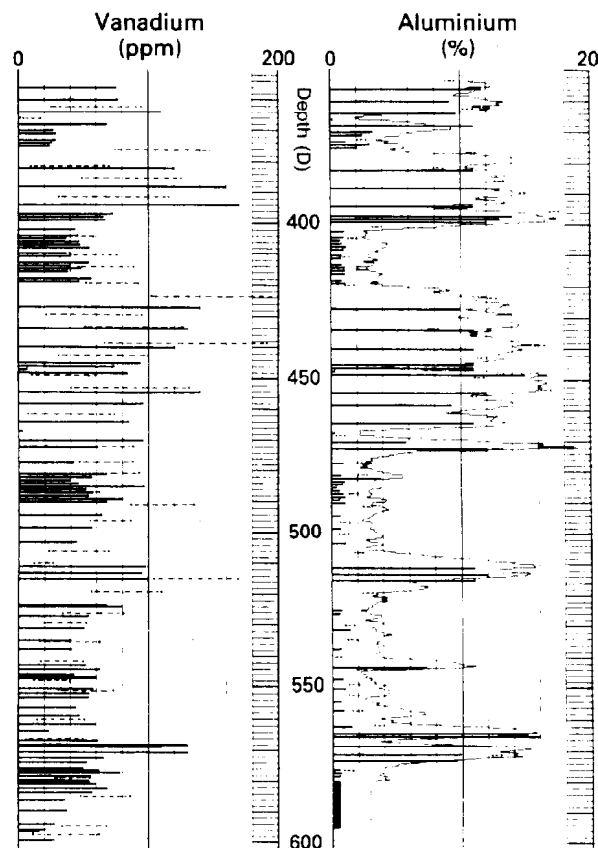

Fig. 50.51—Aluminum and vanadium logs of an oil-bearing shaly sand derived from a high-resolution gamma ray spectrometer. The solid bars represent the results of core analysis. The dashed bars indicate the log value of vanadium and its statistical uncertainty.

Fig. 50.52—Variation of C/O as a function of porosity and water saturation.

saturation shrinks to zero. Examples of interpretation of this ratio in more complex situations can be found in the references.^{28,29}

Pulsed Neutron Logging. The second type of nuclear device used for the determination of water saturation, particularly in cased wells, is the pulsed neutron device. This log responds primarily to the time taken for the thermal neutrons to be absorbed by the formation. The most common important thermal neutron absorber is chlorine, which is present in most formation waters. Hence, the response of the pulsed neutron tool resembles the usual openhole resistivity measurements.

The advantage, however, of the pulsed neutron technique is the ability to log in cased hole. It can distinguish between oil and salt water contained in the pores. If the porosity is known, gas/oil interfaces can be distinguished. Under ideal conditions of salinity, porosity, and lithology, the water saturation, S_w , can be computed.

In the simplest case of a single mineral, the measured value of Σ_{\log} can be thought of as consisting of two components, one from the matrix and the other from the formation fluid:

$$\Sigma_{\log} = (1 - \phi)\Sigma_{ma} + \phi\Sigma_f \quad (62)$$

Fig. 50.53—Solution of S_w with Σ .

In terms of water saturation, the fluid component is broken into water and hydrocarbon components:

$$\Sigma_{\log} = (1 - \phi)\Sigma_{ma} + \phi S_w \Sigma_w + \phi(1 - S_w)\Sigma_h \quad (63)$$

The graphical solution of this equation for S_w is shown in Fig. 50.53. To use this approach the values of Σ_w and Σ_h must be known.

The presence of shale, which may contain thermal absorbers such as boron, will seriously disturb this simple interpretation scheme, but a number of references³⁰ indicate methods for dealing with the problem. For saturation determination, the results of a single measurement run are questionable if the water salinity is less than 50,000 ppm and if the porosity is below 15%, particularly in shaly zones.

Perhaps the greatest successful application of this type of device is in the time-lapse technique. In this procedure the change in saturation between two runs in a producing reservoir can be determined simply from the difference of the two measured Σ values, the porosity, and the difference in Σ_w and Σ_h —i.e.,

$$S_{w1} - S_{w2} = \frac{\Sigma_1 - \Sigma_2}{\phi(\Sigma_w - \Sigma_h)} \quad (64)$$

Uncertainties in the quantity (such as Σ_{ma} , Σ_{cl} , and clay volume) disappear in this differential measurement technique.

Future Interpretation Models

New interpretation models will evolve from a more fundamental approach to the interpretation of complex lithologies in which relationships are formed between the geochemistry of the formation, as determined from core analysis, and log measurements.

The premise of this approach is that the total geochemical signature of a formation may yield valuable information on the minerals present, including clays, the grain size, and other indications of the environment of deposition and diagenetic alteration. This information may be related to the types and abundances of clay minerals present, to the electrical properties of the clays and, perhaps, even to the location of the clays. It seems reasonable, for example, that chemical data can not only distinguish kaolinite from illite, but also that the chemical properties of a detrital kaolinite will differ from those of a kaolinite grown slowly in pore spaces.

One of the primary tools for the penetration into this area of interpretation is the high-resolution spectroscopic tool, which was described previously. It will enable us to obtain a precise mineral identification at each location of interest. However, other devices, such as the induced gamma ray spectroscopy tool, the gamma-gamma density device with a direct measurement of lithology, and the combination thermal and epithermal neutron device, are being examined for their responses to particular minerals of interest, for incorporation into this interpretation scheme.

In addition to the possibility of obtaining grain-size estimates from this approach and thus an additional input to permeability transforms, one result will be the real possibility of the detection, quantification, and classification of the clay minerals from log measurements.³¹ One of the primary benefits of such an interpretation output will be a reservoir damage risk assessment. This will be based on the knowledge that has been acquired through unfortunate experience concerning potential damage to a reservoir that can occur when the clay mineral content is not considered in production planning. For example, acidization of a formation containing chlorite, an iron-rich clay mineral, can produce an iron oxide gel that fills pores, ruining a potentially valuable formation. Another example is that diagenetic pore-lining kaolinite particles will remain in place at low production rates. At higher rates, however, the particles may break loose, lodge in pore throats, and damage production.

Although geochemical interpretation is in its infancy, initial experience with clay type and grain-size prediction from core analysis data and log data has been very encouraging. Refinement of this type of interpretation model may lead to a new cycle of future tool development. One can imagine measuring specific geochemical parameters with an entire range of new tools rather than inferring them from perturbations on measurements designed for other purposes.

Nomenclature

A = atomic mass
 D = thermal diffusion coefficient
 E = energy
 E_{GR} = gamma ray energy
 E_i = initial energy
 E_k = kinetic energy
 E_N = neutron energy
 E_o = energy before scattering
 E_γ = energy of mono-energetic gamma rays
 f_s = fraction by weight of solid fraction
 F = measured parameter

F_{pe} = photoelectric absorption factor
 F_{pex} = photoelectric factor of trace absorber
 h = thickness
 h_{mc} = mudcake thickness
 K = conversion constant between τ_d and Σ_{abs}
 K_a = mass absorption coefficient
 L = distance from the source
 L_d = diffusion length
 L_m = migration length
 L_s = slowing-down length
 m = mass
 M = molecular weight
 n = number of scatterers per unit volume
 \bar{n} = average number of collisions
 N_A = Avogadro's number
 N_i = initial number of particles
 N_N = number of neutrons
 N_{Nf} = neutron counting rate at far detector
 N_{Nn} = neutron counting rate at near detector
 N_p = number of particles
 N_r = counts from a radiation detector
 P = probability
 P_x = probability of having x nuclei decay in time dt
 q = probability of nonoccurrence
 r = path length (radius) to the detector
 S_w = water saturation
 t = time
 $t_{1/2}$ = half-life
 U = product of F_{pe} and electron density
 U_f = fluid parameter
 U_{ma} = matrix parameter
 U_x = trace element parameter
 v = velocity
 V_{sh} = volume of shale
 V_x = associated volume fraction
 x = number of decays
 z = particles observed
 Z = atomic number
 α = emitter
 γ_{log} = gamma ray reading in API units at any point in the well
 γ_{max} = maximum gamma ray reading
 γ_{min} = minimum gamma ray reading
 δh = thickness of slab material
 λ = decay constant
 $\bar{\mu}$ = average value of Poisson distribution
 ξ = average logarithmic energy decrement
 ρ_b = bulk density
 ρ_e = electron density index
 ρ_f = fluid density
 ρ_g = gas density
 ρ_{log} = log density
 ρ_{ls} = apparent long-spacing density
 ρ_{ma} = solid matrix density
 ρ_{mc} = mudcake density
 σ = microscopic cross section or standard deviation
 σ_{Co} = Compton cross section

σ_{pe} = cross section for the photoelectric effect
 Σ = macroscopic thermal absorption cross section
 Σ_{abs} = thermal absorption cross section
 Σ_{Co} = macroscopic Compton cross section
 Σ_f = formation fluid cross section
 Σ_h = hydrocarbon cross section
 Σ_i = macroscopic cross section
 Σ_{log} = observed formation cross section
 Σ_{ma} = matrix cross section
 Σ_t = total cross section
 Σ_w = water cross section
 τ_d = decay time
 ϕ = porosity
 ϕ_D = density porosity
 ϕ_{ls} = limestone porosity
 ϕ_N = neutron porosity
 Ψ = radiation flux
 Ψ_i = intensity of radiation
 Ψ_{epi} = flux of epithermal neutrons

Chapter 51

Acoustic Logging

A. (Turk) Timur, Chevron Corp.

Introduction

Acoustic wave propagation methods have become an integral part of formation evaluation since the first downhole measurement of velocities was conducted in 1927.¹ These early measurements were conducted to obtain time/depth curves to use in interpreting seismic data.² In the 1930's, proposals were made to conduct velocity measurements in a fashion similar to electric logging, by using an acoustic transmitter and one or more receivers. First successful implementation of this technology was in the late 1940's and early 1950's.³⁻⁵ Commercial acoustic velocity logs were first introduced in 1954 by Seismograph Service Corp. in the U.S. and by United Geophysical in Canada.

Since then, technology involving borehole measurements of acoustic wave propagation properties has developed significantly and has become established as a major formation evaluation method. These acoustic wave propagation methods used in well logging can be broadly classified into two groups: transmission and reflection. Properties measured in each method and their applications in formation evaluation are listed in Table 51.1

Compressional wave velocities measured by acoustic logging were found to be related to porosity so closely that the acoustic log became a standard porosity tool, which it still is in many areas. The second most common use of borehole acoustic measurements is in evaluating cement jobs by measurements inside casing.

This chapter describes the use of acoustic wave propagation properties in formation evaluation after a brief description of elasticity, acoustic wave propagation properties in rocks, and methods of recording these in the borehole.

Elasticity

Introduction

The theory of elasticity investigates relationships between external forces applied to a body and resulting

changes in its size and shape.⁶ In this theory, it is assumed that displacements are small and the body returns to its original condition after the forces are removed. Applied forces and the resulting deformations are described by stresses and strains.

Stress is the force, F , per unit area, A , applied; strain, ϵ , is deformation per unit length, L , or volume, V , as illustrated in Fig. 51.1.

Within the elastic limit, as shown in Fig. 51.2, stresses are found to be proportional to strains (Hooke's law). The ratio of stress to strain is a different constant for different loading conditions. These proportionality constants are defined as elastic moduli, which are fundamental properties of a material.

Young's Modulus, E . This is the ratio of tensile or compressive stress (F_L/A) to the resultant strain ($\epsilon_L = \Delta L/L$):

$$E = \frac{F_L/A}{\Delta L/L}$$

Shear (or Torsion) Modulus, G . The ratio of shearing stress (F_s/A) to the shearing strain $\epsilon_s = (\Delta L/L)$ is

$$G = \frac{F_s/A}{\epsilon_s}$$

Bulk Modulus, K . Bulk modulus describes the change of V under hydrostatic pressure, p :

$$K = \frac{p}{\Delta V/V}$$

where K is also the reciprocal of compressibility, c .

TABLE 51.1—ACOUSTIC WAVE PROPAGATION METHODS

Property	Application
Transmission	seismic and geological interpretation
Compressional- and shear-wave velocities	porosity lithology hydrocarbon content geopressure detection mechanical properties of rocks
Compressional- and shear-wave attenuations	cement bond quality location of fractures rock consolidation permeability indication
Reflection	location of vugs and fractures
Transit time and amplitude of reflected waves	orientation of fractures and bed boundaries channeling and microannulus casing quality

Poisson's Ratio, μ . This is a measure of the geometric change of shape under uniaxial stress. It is expressed as the ratio of the fractional change in diameter, d , (transverse strain, ϵ_T) to the fractional change in length (longitudinal strain, ϵ_L):

$$\mu = \frac{\Delta d/d}{\Delta L/L}$$

Relationships Among Elastic Parameters. These four elastic parameters are not independent; any one parameter can be expressed in terms of two others:

$$E = 2(1 + \mu)G$$

$$K = E/3(1 - 2\mu)$$

Acoustic Waves

Acoustic waves propagate mechanical energy. For instance, if an elastic material is subjected to an instantaneous force at one end, it is compressed (Fig. 51.3).

**Fig. 51.1—Longitudinal, transverse, and shear deformations.**

This disturbance is then transmitted along the material by a series of compressions and rarefactions. The disturbance travels at a constant velocity that is a fundamental property of the material. The elastic moduli and the density determine the velocity of propagation for each material.

Two types of mechanical wave propagation will be described qualitatively. Detailed discussions of acoustic wave propagation are given in Refs. 7 through 11.

Compressional Waves. Compressional waves are those in which the mechanical disturbance is transmitted by a particle motion parallel to the direction of wave propagation (Fig. 51.3). They are also called longitudinal, pressure, primary, or P-waves. Particles of the material oscillate around this rest position in simple harmonic motion. As they move from equilibrium, they push or pull their neighbors, thereby transmitting the disturbance through the material. The velocity of this compressional wave motion, v_p , is a constant for a given material:

$$v_p = \frac{1}{\rho} (K + \frac{4}{3}G)^{1/2}, \dots \dots \dots (1)$$

where ρ is the density.

Shear Waves. Shear waves, also called transverse, torsional, or S-waves, are those where particle motion is perpendicular to the direction of wave propagation (Fig. 51.4).

Particles in the material again move about their rest position with simple harmonic motion. For this motion to be transmitted, however, each particle must have a force of attraction to its neighbor. Whereas compressional waves can be propagated simply by elastic collision of one molecule with the next, attractive forces must exist between adjacent molecules to transmit shear waves. Since these forces are very small in gases and liquids, fluids do not transmit shear waves.

The velocity of shear waves, v_s , is also a constant for a given material:

$$v_s = \left(\frac{G}{\rho} \right)^{1/2} \dots \dots \dots (2)$$

**Fig. 51.2—Stress/strain diagram for an elastic material.**

Fig. 51.3—Compressional wave.

Characteristics of Acoustic Waves

Acoustic waves have many characteristics similar to light waves. They undergo interference, diffraction, reflection, and refraction. At a boundary separating materials of two different velocities, they are mode converted, reflected, and refracted according to Snell's law.

For either compressional or shear waves, velocities are related to frequency, f , by

$$v = \lambda f,$$

where λ is the wave length.

Motion of either compressional or shear waves in an extended medium is characterized by an infinite number of particles, each vibrating in simple harmonic motion. A simple description of this wave propagation is given by a plane wave solution of the wave equation:

$$u = A \cos(2\pi ft - 2\pi \frac{s}{\lambda}),$$

where u is the particle motion at a given point, s , away from the source and at any given time, t . At any given time, $t=0$, the displacement along the wave varies as $\cos(2\pi s/\lambda)$; hence, the u is equal to signal amplitude A , where s is equal to even multiples of wavelength—i.e., $s=0, \lambda, 2\lambda$. Motion of each particle, on the other hand, is described by a simple harmonic motion given by

$$u = A \cos(2\pi ft).$$

An additional feature of acoustic waves to be considered is attenuation. As one moves away from the source, the intensity of sound decreases. This decrease of acoustic waves results from (1) geometric spread of energy, reflection, refraction, and scattering, and (2) absorption, whereby mechanical energy is converted into heat.

The decrease in intensity because of absorption is given by

$$I = I_0 e^{-2\alpha s},$$

where I_0 is the acoustic intensity at the source, I is intensity at a distance, s , from the source, and α is the coefficient of absorption.

The acoustic intensity is proportional to the square of the amplitude; therefore, the amplitude, A , of a wave at a

Fig. 51.4—Shear wave.

distance, s , from the source is

$$A = A_0 e^{-\alpha s},$$

where A_0 is the amplitude at the source.

A schematic diagram of an experimental apparatus is given in Fig. 51.5 to illustrate the measurement of acoustic properties. Two piezoelectric elements are attached to the specimen as shown. A pulser provides the electric pulse to the transmitting piezoelectric element and also triggers the oscilloscope trace. The transmitter vibrates according to the change of voltage with time, generating a mechanical pulse in the specimen. As it travels through the specimen, the mechanical pulse is attenuated. The receiving piezoelectric element converts this attenuated pulse into an electric pulse that is displayed on the oscilloscope screen.

The travel time of the mechanical pulse through the specimen is read on the horizontal scale of the oscilloscope, and the velocity is calculated from

$$v = \frac{L}{t}.$$

By using a set of either P-wave or S-wave transducers, both velocities, v_p and v_s , can be measured as described. These velocities, assuming an infinite, isotropic, homogeneous, and elastic medium, are related to elastic moduli by

$$v_p^2 \rho = P = K + \frac{4}{3} G, \quad \dots \dots \dots (3)$$

$$v_s^2 \rho = G, \quad \dots \dots \dots (4)$$

Fig. 51.5—Experimental apparatus for measurement of velocity and attenuation.

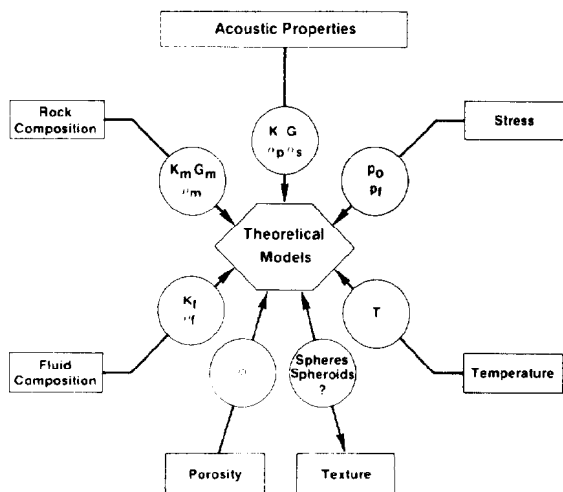

Fig. 51.6—Factors affecting acoustic properties of rocks.

and

$$\mu = \frac{0.5(v_p/v_s)^2 - 1}{(v_p/v_s)^2 - 1}, \dots \dots \dots (5)$$

where P , K , and G are P-wave, bulk, and shear moduli, respectively, μ is Poisson's ratio, and ρ is density.

As mentioned earlier, these same elastic constants can be obtained directly by measuring lateral and longitudinal strains as functions of stress. Elastic constants measured in this manner are referred to as static elastic constants in contrast to dynamic elastic constants measured through the use of acoustic wave propagation techniques.

One method for measurement of attenuation requires specimens of two different lengths from the same material. Assuming that the voltage amplitude of the received signal from the specimen of length L_1 is A_1 and from the specimen of length L_2 is A_2 , and that voltage amplitudes are proportional to the amplitudes of mechanical pulses, the two amplitudes can be expressed as

$$A_1 = A_0 e^{-\alpha L_1}$$

and

$$A_2 = A_0 e^{-\alpha L_2}$$

Hence, the coefficient of absorption, nepers/cm, is obtained from

$$\alpha = \frac{1}{L_2 - L_1} \ln \frac{A_1}{A_2}.$$

Or, in more common units, attenuation is given in decibels per unit length, defined as

$$\alpha = \frac{20}{L_2 - L_1} \log \frac{A_1}{A_2}.$$

Other parameters defining attenuation are the quality factor, Q , and the logarithmic decrement, δ . Coefficients of compressional and shear wave attenuation (α_p , α_s) are related to the respective quality factors (Q_p , Q_s) and the logarithmic decrements (δ_p , δ_s) by

$$\frac{1}{Q} = \frac{\alpha v}{\pi f} = \frac{\delta}{\pi}, \dots \dots \dots (6)$$

where v is velocity and f is frequency.

Acoustic Wave Propagation in Rocks

Introduction

Acoustic wave propagation properties of rocks are known to depend on porosity, rock matrix composition, stress (overburden and pore fluid pressures), temperature, fluid composition, and texture (structural framework of grains and pore spaces), as illustrated in Fig. 51.6.¹² A unified approach involving measurements of compressional and shear-wave velocities, analyses of rock composition, and use of theoretical models to interpret these data was described in Refs. 13 through 16.

Acoustic Properties

Acoustic wave propagation properties were described in the preceding section for homogeneous, elastic media. Applications of these relationships to rocks, however, are complicated by the presence of pores and cracks, and fluids contained in them. A simplified, theoretical development is described in the Appendix to illustrate some of these complications by incorporating rock-frame, pore-fluid, and rock-grain compressibilities into the velocity equations.

As indicated earlier, acoustic wave properties in rocks are functions of numerous independent variables. Therefore, evaluation of various theories of acoustic wave propagation requires laboratory experiments conducted on rock samples under controlled pressure, temperature, and saturation conditions.

Various experimental methods have been developed for measuring acoustic wave propagation properties of rock samples. Detailed description of one of the laboratory systems is given by Timur.¹⁷ It is designed to conduct sequential measurements of properties of both the compressional and the shear waves on rock samples subjected to simulated subsurface conditions. A typical experimental setup is shown in Fig. 51.7, where a rock sample is assembled between two transducers in a sample holder. This assembly is placed in a pressure vessel and subjected to varying overburden and pore fluid pressures and temperatures. A minicomputer digitally records the compressional and shear-wave pulses transmitted through the rock samples, as well as sample temperature, overburden and pore fluid pressures, and sample length changes.

Fig. 51.7—A typical sample ($d = 8.9$ cm, $L = 5.1$ cm) assembled for acoustic measurements.

A typical set of compressional and shear-wave velocity data obtained with this apparatus is shown in Fig. 51.8. The rate of change of porosity in this sample with varying overburden and pore fluid pressures is shown in Fig. 51.9. These data were obtained from concurrent measurements of changes in the sample pore and bulk volumes during acoustic measurements.

Fig. 51.10 illustrates typical compressional and shear-wave attenuation data, obtained from the amplitude spectra of transmitted pulses.

Porosity

Porosity dependence of v_p in rocks has been intensively investigated.¹⁸⁻²³ This forms the basis for estimating porosities from in-situ measurements with an acoustic velocity log.

Results of early laboratory measurement of compressional-wave velocities determined on water-saturated sandstones are plotted vs. porosities in Fig. 51.11.²⁴ The porosity/velocity relationship is within the indicated statistics as long as the lithology remains relatively constant.

Fig. 51.8—Pressure dependence of compressional- and shear-wave velocities in a Navajo sandstone.

Porosity dependence of v_s has also been investigated to some extent.²⁵⁻²⁸ A change in shear-wave travel times ($1/v_s$) per unit change in porosity (ϕ) is found to be almost twice the corresponding change in $1/v_p$.

Rock Composition

Rock composition affects the velocities in significant ways, as illustrated in Fig. 51.12.²⁹ Laboratory data plotted in this figure are for cores saturated with brine and subjected to an overburden pressure of 3,000 psi. The two principal minerals in the rock were quartz, in the form of tripolite, and calcite. They were mixed in relative proportions ranging from approximately 50% calcite/50% quartz to 80% calcite/20% quartz. The samples with lower porosity had a continuous calcite matrix, whereas the samples with a higher porosity had a continuous quartz matrix.

Effects of rock composition usually are taken into account by establishing velocity/porosity relationships for each group of rocks of similar composition through correlations of both the laboratory and the field data. This is illustrated in Fig. 51.12 by two separate groupings, one for calcite matrix and the other for quartz.

Rock composition plays a significant role in acoustic wave propagation properties. A procedure for comprehensive analyses needed for this purpose was described by Jones *et al.*¹³ First, they conducted a combination of measurements of X-ray diffraction, elemental analysis, clay analysis, and grain density measurements. Each of these then was assigned an experimental error, and linear programming was used to establish the rock mineral composition, as shown in Table 51.2.

Fig. 51.9—Pressure dependence of porosity of Navajo sandstone.

Fig. 51.10—Pressure dependence of compressional and shear attenuation in a Berea sandstone saturated with brine.

Stress

Pressure dependence of velocities of compressional and shear waves also has been the subject of numerous studies. Velocities of elastic waves traveling in a porous medium are known to be functions of both the external (overburden) pressure, p_o , and the internal (pore fluid) pressure, p_f . Some of the experimental results indicating dependence of compressional-wave velocity on confining pressure are given in Fig. 51.13 for various rock

samples including dolomite, limestone, and sandstone and for a sandpack.²⁹ In general, velocities increase with increasing p_o and decrease with increasing p_f .

From a theoretical analysis of elastic wave propagation in sphere packs, Brandt³⁰ predicted velocities to be functions of $(p_o - np_f)$, where n is a number between 0 and 1. Experimental data of Hicks and Berry³¹ and Wyllie *et al.*¹⁹ indicated n to be close to unity, whereas data obtained by Banthia *et al.*³² indicated values of n to

TABLE 51.2—ROCK COMPOSITION

Sample	Navajo sandstone
Petrography	medium-porosity, well-sorted quartzite
Grain density	2.60
Grain porosity	19.4
X-ray, wt%	
Quartz	93.0
Calcite	1
Dolomite	—
Clay	1.7
Feldspar	0.7
Pyrite	—
Anhydrite	0.4
NAA and AAS, wt%	
Si	42.60
Al	1.20
Ti	0.79
Fe	0.20
Mg	0.02
Ca	0.20
Na	0.00
K	0.16
O	54.00
Phyllo-silicate	6.00
Computed volume, %	
Quartz	68.37
Calcite	—
Dolomite	—
Clay	4.73
Feldspar	0.57
Pyrite	—
Anhydrite	—
Silica	6.93
Siderite	—

be significantly less than 1. To investigate this discrepancy, Gardner *et al.*³³ conducted experiments taking into account the past pressure history of samples. They found that p_o and p_f are equally effective in changing velocities—i.e., $n=1$, provided that the differential pressure ($p_d = p_o - p_f$) follows a pressure cycle previously imposed on the sample (Fig. 51.14).

Temperature

The effect of temperature on elastic wave velocities is considered to be of second order and usually is neglected in seismic exploration and acoustic log interpretations. To study this effect, early laboratory experiments³⁴⁻³⁸ were conducted by measuring velocity as a function of overburden pressure at constant values of temperature instead of as a function of temperature at constant pressure. Also, the effects of pore fluid pressure were not considered. Later, the effects of temperature on the velocities were investigated through laboratory measurements on rock samples subjected to simulated subsurface pressure conditions¹⁷ (Fig. 51.15). On the average, the compressional wave velocities were found to decrease by 1.7% and the shear-wave velocities by 0.9% for 100°C increase in temperature.

Below freezing temperatures, however, the effect of temperature on elastic wave velocities become much more significant. An increase of 50% or more in compressional wave velocities is observed upon freezing the pore fluid in some rock samples.³⁹ Below freezing, compressional wave velocity in water-saturated rocks was found to increase with decreasing temperature, whereas it was nearly independent of temperature in dry

rocks. The shapes of the velocity vs. temperature curves were functions of rock composition, pore structure, and the pore fluids. Some of the velocity vs. porosity data at subfreezing temperature is illustrated in Fig. 51.16.³⁹⁻⁴³

Fluid Composition

An understanding of the effects of fluid composition on elastic wave properties has become much more significant with the increasing interest in detection of hydrocarbons with seismic measurements. As a result, these effects have been the subject of many studies, both theoretical and experimental, in the recent literature. The

first important theoretical contribution was made by Gassmann,⁴⁴ who described the relationships between pore fluid, rock skeleton (or frame), and the rock grains by starting with first principles of the theory of elasticity. Later, Biot^{45,46} developed a more comprehensive theory of elastic wave propagation in a fluid-saturated, isotropic and microhomogeneous porous solid over a wide frequency range. Biot's theory, which reduces to that of Gassmann at low frequencies, incorporates the effects of fluid composition through the density and compressibility of the saturant fluid (see Appendix).

Geertsma⁴⁷ investigated the applications of Biot's theory to the interpretation of acoustic logs and estimated expected range of velocity dispersion by comparing velocities at zero and infinitely high frequencies. Since the estimated velocity dispersion was found to be generally less than 3%, the low frequency approximation of Biot's theory and, hence, Gassmann's theory is useful for most applications. Brown and Korringa⁴⁸ further generalized Gassmann's theory and succeeded in removing the requirement of macrohomogeneity.

The experimental data of King,⁴⁹ shown in Fig. 51.17 for brine-, kerosene-, and air-saturated (dry) Boise sandstone ($\phi=25\%$), illustrated the predicted behavior; compressional-wave velocity is greater in brine-saturated rocks than in comparable gas-saturated rocks, with the reverse true for shear-wave velocity.
